VOLUME 1

1 CHAPTER • 1 General: The Physical Examination Of The Dog And Cat

Stephen J. Ettinger*

2 The physical examination begins long before the veterinarian ever touches the animal. The traditional teachings of *look, smell,* and *listen* are as important as ever. Excellent veterinarians avoid making diagnostic decisions driven by laboratory-derived data that bypass the physical examination, because correlation of all data is relevant to the determination of an appropriate diagnosis. This chapter is dedicated to the concept that veterinarians must bring together data from the history, physical examination, and diagnostic tests to care for an animal in the context of its life—including the life the owner envisions for the pet.

When possible, the animal's temperature and weight should be recorded before the veterinarian enters the examination room. This provides the nursing staff the chance to communicate with the animal's caretaker, gather pertinent information, note changes in weight, and identify the owner's concerns or requests.

This also is a good time for the staff to record any drugs currently administered, the prophylactic agents used (e.g., for heartworms and fleas), the animal's vaccination status, and its reproductive status (i.e., spayed, neutered, or last heat cycle).

The process should be as expeditious as possible, and every effort should be made to provide the client with an on-time, efficient examination. Reading material (magazines of interest to a wide variety of clients *and* their children) should be available if there is a likelihood of the pet's caretaker having to wait. Pet owners should be given an indication as to the doctor's schedule and the length of any delay. Providing the client with this information can offset frustration, anger, or anxiety. If the hospital has new client brochures about its methods and services, this is a good time to deliver these and to allow the client to browse through the material.

1.1 OBSERVING THE PET AND MEETING THE CARETAKER: THE HISTORY

Every veterinarian approaches a pet in his or her own way. With time, it becomes second nature. It is important to develop proper animal handling skills. Furthermore, clients observe a great deal during this process and may determine long before any recommendations are made just how trusting they will be. *Gentle care, compassion, concern,* and *attention* cannot be emphasized enough.

The process begins as the veterinarian enters the area where the owner and pet are waiting. A friendly greeting and a small but appropriate amount of banter are usually appreciated. An occasional client makes it clear that the veterinarian should get down to business immediately, and in such situations, it is wise to do so. People appreciate being greeted and particularly like being acknowledged. Asking owners about something specific to them assures that the veterinarian knows who they are. If the case is a referral, noting the distance traveled or offering a kind word about the trip acknowledges the client in an important way. It is not a technique easily taught, and it is not difficult to see whether the veterinarian “gets it” quickly and learns to communicate or simply turns away from such contact.

The importance of letting each client know that the veterinarian cares about him or her and the pet cannot be overemphasized. This must be done in a genuine way, reflected in dialog, attention, body language, and actions, and not in a lip service way, such as having “We care” or some other logo stamped on hospital leashes or stationery. Every successful veterinarian can relate tales about brilliant doctors whom clients dislike! The smartest veterinarian will never have the opportunity to demonstrate his or her skills if concern and caring are not expressed. In fact, clients are likely to be antagonistic toward veterinarians who fail to express compassion. Complaints are likely to be made much more frequently about an arrogant veterinarian than about one who is poorly trained or medically

inadequate but friendly and compassionate. In a study comparing orthopedic surgeons, physicians with a disproportionately higher number of malpractice claims could be readily separated from those with fewer claims by evaluation of their examination room attitude. Not surprisingly, those with significant problems could consistently be identified.

A skilled veterinarian or physician understands that no part of the entire examination is as important as carefully listening to the client, therefore adequate time must be allowed for this in an environment that enhances the process. Examination rooms should be comfortable and inviting. Privacy for clients is necessary, because the situation may be a difficult one for them. Decisions that may seem routine and perhaps even minor to the veterinarian may not be perceived this way by the owner.

If there has been a delay, it is paramount that the doctor acknowledge this upon entering the room. The veterinarian should show clients the courtesy of recognizing that they have been waiting. Unnecessary interruptions should be minimized, and every hospital should have a policy in this regard. In a large critical care office, delays and interruptions do occur, but these must be limited. Phone calls should be restricted to those that are professionally relevant or urgent. When such calls interrupt me with new clients, I explain that I need to speak with other owners about their hospitalized pet, yet I still make it clear that I am focusing on their pet's problems.

It is important to get the *owners'* version of the history and not one that has been “dictated” to them. For example, when questioned, the owners may acknowledge that a friend or family member told them about the supposed problem. Further questioning may determine that the owners have not noted any clinical signs that warrant such a concern.

There is no single technique for the examination process. Because this chapter is intended to explain my method of examination, I will delineate the regimen I follow, a process learned over decades of experience. When possible, I try to immediately make eye and physical contact with the pet. Even before beginning the process of taking a history, I try to welcome the pet. First, I make a brief attempt at greeting the animal by extending the back of my hand to its face. For this, cats and smaller dogs can be placed on the examination room table. Usually, with medium to large dogs, I kneel down on the examination room floor to greet the animal (I use a gardener's pad for my old, weakened, debilitated knees). Of course, some dogs and cats (those in cages, particularly) let me know beforehand that they are not ready for such a greeting. Then, I bypass the greeting and make a light comment to the owners about the pet not wishing me well (after all, I say, “Who likes going to the doctor?”). This begins a conversation with the owners that acknowledges the possibility of the pet being fearful and allows the owners to let me know how they feel about the process.

Clients are likely to want to tell the veterinarian what they know, think, or understand about the pet's problems. Regardless of how clearly and confidently clients relate their interpretation of the animal's difficulties, it is essential for the examiner to “go back to square one” and self-interpret the pet's problem. Nevertheless, the client's opinion should not be ignored, because this diminishes the trust being developed during this important part of the examination. I like to give clients a few minutes to express themselves, regardless of the relevance, because what they have to say is likely to be important to the ultimate outcome of the process. For example, clients may refuse to acknowledge how sick the pet is, or they may be worried about “cancer” or may focus on something that may not be pertinent. Clients' comments provide valuable insight into their concern and desire to care for the pet. There are different levels of owner commitment, and pets thus receive varied levels of medical attention.

Clients may offer information obtained from friends, breeders, or sources such as the Internet and may wish to have the veterinarian go over this material. A reasonable technique the veterinarian can use that precludes taking time away from the office call is to acknowledge the request and inform the caretaker that the material will be reviewed once the examination and early decision-making processes have been completed.

An owner's expectations may seem to convey that, “OK, you are the doctor, so you tell me what is wrong.” A different tack then becomes necessary, and the approach changes from “Tell me what you have observed” to “It appears that your dog (or cat) has been losing weight; tell me, has this been a recent occurrence?” This may be all that is necessary to get the owners to begin talking about their pet.

Not every owner-veterinarian experience is informative. Valuable information is noted in the record. If the client refuses to provide a history or begins to attack another veterinarian, these comments should be noted in the record. The record provides not only a future legal defense but also a guide to further owner communication. Clients who have been dissatisfied with the results of prior care reasonably object when the same medications are prescribed for their pet. It suggests that the current veterinarian has not been listening. Inquiring in a unobtrusive manner about the owners' needs and desires helps define their wishes and permits the veterinarian to provide options from which the owners can choose.

Specifics about drugs currently being administered should be reviewed. The drug's name, dosage, and frequency of administration are significant. The veterinarian should also ask about prior drugs that may have been prescribed, including over-the-counter (OTC) products, prescriptions from other veterinarians, and holistic products. This is the time to inquire about the foods the animal is currently fed, prior diets provided, canned or kibbled formulations, supplements added, and treats given. The specifics of oral, topical, and injectable prophylactic products administered at home should be identified.

Information should be gathered regarding out of area travel and areas where the pet (or other pets in the family) previously may have lived. Clients should be questioned about the welfare of other pets currently living in the household. The vaccination history is needed for each pet in the household, particularly when laboratory tests for infectious diseases affected by prior exposure or vaccines are under consideration.

The history and the owner's story are equally important. These convey to the examiner the owner's perceptions, needs, and desires during this initial period of acquaintance or contact. I find that this can be the most useful time of the examination process. I can touch the pet, gently stroke it, feel the quality of the haircoat and skin, determine the hydration status, and generally get a good idea of the animal's physical well-being (e.g., debilitated or well conditioned, obese or thin, and so on) (Figures 1-1 and 1-2). This is also a convenient time to gently examine the pet without the animal being fearful, because a pet often seems more aware of its owner's voice than of the veterinarian going over its body. This also allows me to determine the animal's behavior and gives the client a feeling of assurance that I am getting to know or am reacquainting myself with the pet. Pets generally seem less fearful while I am at their eye level and when I refer to them by name. The physical examination begins while the history is still being taken.

It is not always possible to begin the examination process during this period, and I do not make a distinct effort to perform every examination this way. If the dog or cat is sitting anxiously (i.e., protectively or in a frightened manner) in the client's lap, I avoid this contact and dwell on the pet and the owner's story. Pets relax during this period and are less fearful of me as time goes by. A truly frightened or fractious animal presents a different situation, which may require use of a muzzle or, even better, an examination away from the owner in an environment that no longer requires the pet to feel it is protecting the owner. It is important to remember that owners should not be allowed to hold their pets during any examination process that entails a likelihood of injury to anyone in contact with a frightened or injured pet.

* The author wishes to acknowledge the assistance of Dr. Etienne Côté, Dr. Edward Feldman, Dr. Michael Schaer, and Ms. Linda Mills, who have reviewed this manuscript and made many favorable and helpful comments.

1.2 INITIATING THE PHYSICAL EXAMINATION

The physical examination commences when the veterinarian enters the examination room. The clinician should look at the general appearance of the pet, note odors, and observe irregularities. A severely sick or crisis presentation requires a different approach from that used for a dog or cat with a mild or chronic problem. Clients must also be observed and evaluated. They are prone to be particularly anxious in severe or acute life-threatening situations, and the veterinarian should assess the owner's state when first approaching the pet. Intense questioning may be inappropriate if the owner feels that the pet needs immediate medical attention.

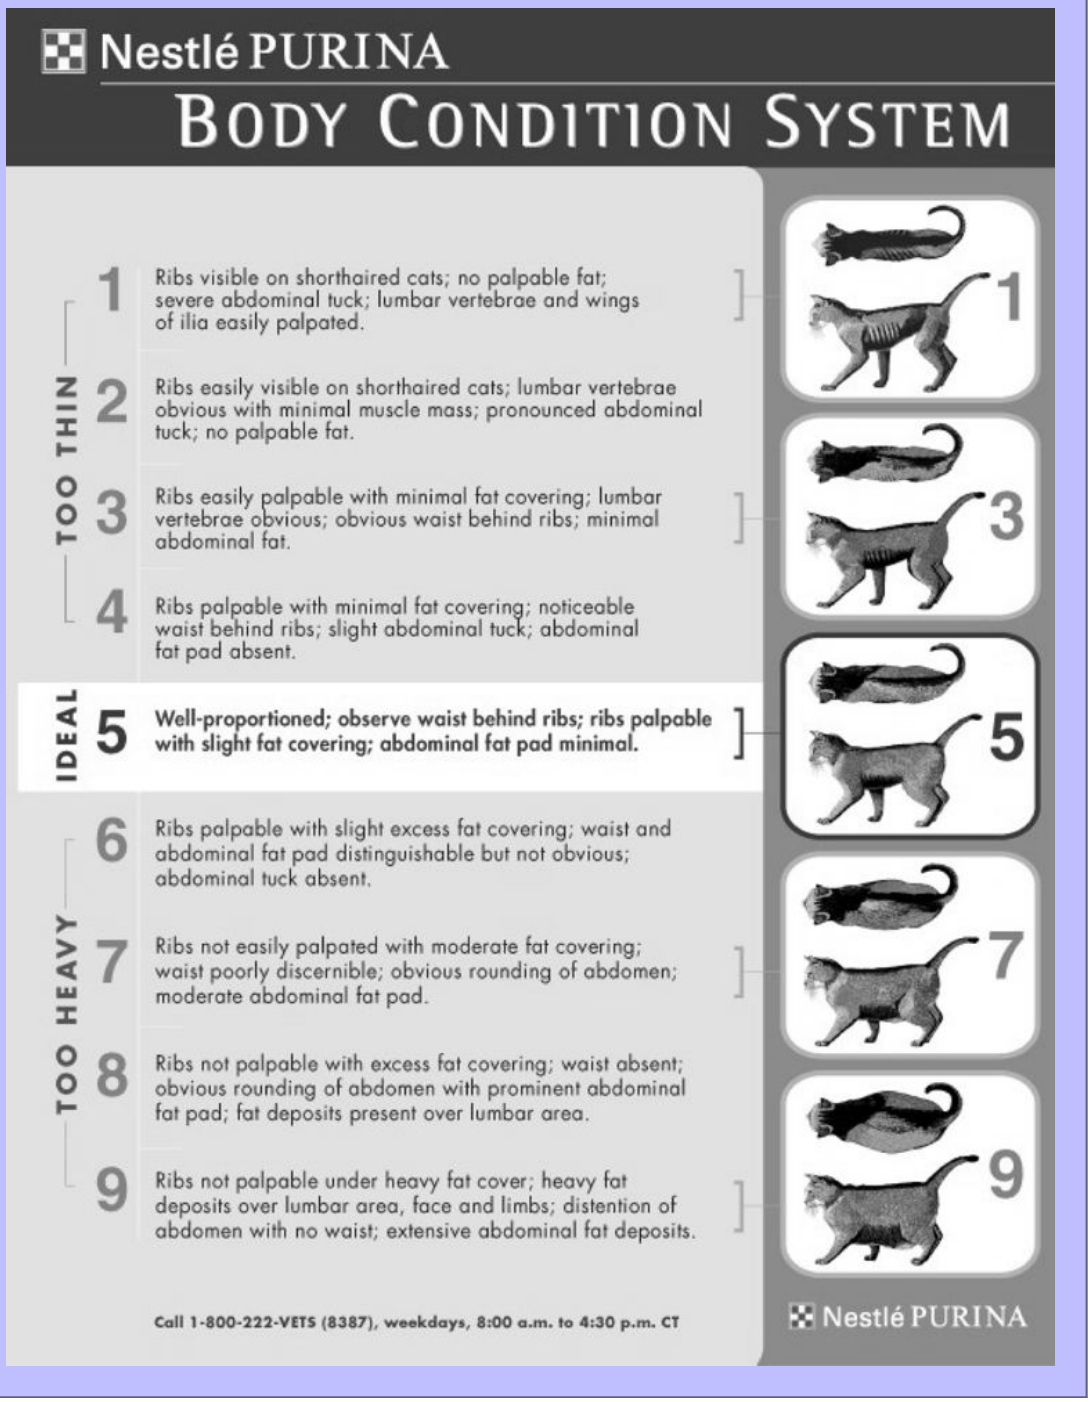
5

Figure 1-2 Body condition chart for the cat. (Used by permission from Nestle Purina Petcare.)



5

The veterinarian should listen for abnormal breathing sounds or grunting. The animal's body size and posture also should be observed: a plantigrade stance could suggest a neuropathy; head hanging in cats may indicate hypokalemia; fat pets may be overfed, hypothyroid, or inactive; thin pets may be hyperthyroid or cachectic. It is true that owners may point out these irregularities, but they may misinterpret such changes or may simply not be cognizant of their significance. In a desire to “wish well” for the pet, the owner also may fail to provide information for fear of its significance. The veterinarian has the responsibility to seek out this information.

Examples of signs and symptoms the veterinarian may observe upon entering the examination area are presented in this textbook under the section “Clinical Manifestations of Disease.” The chapters in this section are not “complete,” because the variety of maladies and the manifestations of disease are infinite. Suffice it to say that the examination process must not be so quick or superficial that an obvious underlying problem is overlooked.

If the animal is ambulatory and has a history of lameness, neurologic deficit, or weakness, it is essential that the veterinarian watch the animal move. This may be done before or after the hands-on physical examination process. At some point during this initial phase of the examination, the veterinarian must observe the pet's gait. This may require having the pet walk on a surface with traction, preferably with the owner as the handler. Lameness, signs of neurologic deficits, or irregularity in gait and appearance is noted. The physical examination is continued, and the clinician attempts to mechanically evaluate any specific lameness or suggestion of a localized abnormality (e.g., patella luxation, stifle cruciate drawer sign, elbow pain or mass).

A review of previous examination notes for prior irregularities can aid the clinical assessment. For example, comparing the size of a mass with previous findings is something clients appreciate, particularly if the records clearly identify prior size, appearance, and location. Measurement of lesions with calipers or a ruler is good for review and trend purposes.

Neurologic changes, such as diminished conscious proprioception, diminished muscle tone, limb dragging, or unusual pain during compression of the muscles or lumbosacral compression, are noted and may require further investigation to point to a diagnosis. Something can be said for performing at this time the “stand back” examination, which allows the veterinarian to observe breathing patterns or abdominal changes.

Every seasoned veterinarian has developed his or her own method of performing the physical examination, derived from a wealth of experience. For example, animals are frightened by a large figure looming overhead and are less anxious when approached at eye level. Therefore, as mentioned before, I prefer to kneel on the examination room floor to perform the physical examination (except for cats and small dogs). I find I am better able to perform auscultation completely and thoroughly in this way, and I also am able to palpate more thoroughly while having a good presence with the pet. Particularly with the neophyte examiner, there is something to be said for having most animals in the same position each time for the examination.

After the initial greeting, I prefer to stroke the pet to gain a more generalized knowledge of the overall body status. The body composition score is assessed (see Figures 1-1 and 1-2), as is hydration status, weight change, physical appearance, and the condition of the haircoat. Masses (size, shape, and appearance) are noted. I then examine the entire torso by touch, attempting to define the patient's status. Findings may include abdominal enlargement (fluid, fat, distention, pain), discomfort, and skin or musculoskeletal abnormalities (masses, changes in the haircoat, open wounds, fleas, dirt, ticks, or other abnormalities). Looking for bumps, lumps, or irregularities, I am able to distinguish lymph node changes, pain or swelling in the joints or limbs, physical deformities, and the nature of the femoral pulse. I evaluate the pulse, including its rate, quality, and character (see Chapter 56), and listen for any irregularities while auscultating the heart.

Swelling in the form of edema or fluid collections are correlated with other changes. Edema is identified as being generalized, localized to one limb or region, or associated with abdominal fluid and is noted to be pitting, cold, warm, or oozing in nature.

Specific lameness associated with trauma is identified and may provide an obvious cause; however, the veterinarian should not make that assumption without giving reasonable consideration to other possible causes (e.g., a pathologic fracture in a dog with osteosarcoma). I like to run both hands down the animal's body to check for asymmetry in body form.

Skin and coat changes must be evaluated in light of the animal's living arrangements, as established in conversation with the caretaker. Indoor pets should not have foreign body material in the coat; fleas, flea dirt, ticks, and other ectoparasites should not be present. Hair loss or thinning is a clue to clinical disease and should be noted. Hair loss should be assessed as unilateral or bilateral, and its full significance should be identified in the records. Coat changes must also be correlated with other body changes that may indicate a systemic illness, such as Cushing's disease. Areas of skin change should be evaluated and comments made with respect to the potential benefit of skin or hair culture, skin scraping, skin biopsy or allergy testing. Pets that live outdoors are more likely to have ectoparasites, weather-related haircoat changes, or bite wounds. As with the indoor pet, these conditions must be correlated with the clinical signs and recommendations made accordingly. Coats with a strong odor of perfume or smoke may indicate to the examiner possible problems with regard to allergic lung disease, highly reactive lungs, or an animal that has been in or around a fire.

My preference is to progress the physical examination from the head toward the tail. First, hydration status and mucous membrane color and moisture should be identified. Pain on dorsiflexion or ventroflexion or lateral movement of the head and neck is significant and may be noted when the head is first moved. The head first should be examined superficially for any changes or problems, such as hair loss or swelling. Areas of discomfort or irregularity are observed. The appearance of the mucous membranes (e.g., pallor gives reason to suspect anemia, hypoperfusion, or hypoxemia), oral cavity, pharynx, and teeth are recorded. Signs of drooling, discharge, or malodor from the oral region should be apparent at this time. It is important for the veterinarian to speak to the owner about the condition of the pet's teeth and gums; it also is important for the owner to see, if possible, any unexpected finding in the oral cavity.

A brief cranial nerve examination can be included during this portion of the examination process. The way the pet holds its jaw closed, the functions both of sensation and of motor ability of the maxillary muscles, and the appearance of the eyes may be relevant. Monitoring for superficial and deep changes within the eyeballs and the periorbital region extends this process. Ophthalmic sensitivity, squinting, or photophobia is recorded. Any discharge is noted and described as to color, composition, and volume and whether the discharge is unilateral or bilateral. Tear production is recorded (Schirmer tear testing), as is nasolacrimal duct patency (e.g., dry, cracked nasal tissue). If nystagmus, strabismus, or other deviations of one or both eyeballs are noted, the veterinarian continues the examination while looking for signs of conjunctival color changes or inflammation. Pupillary size and integrity are noted, as is the pupillary light response, both direct and consensual. Sensation in the eyelids and the surrounding tissue is observed.

The appearance of the skull, the muscles of mastication, and the muscles around the head are noted. Clients frequently suggest that a mass has developed in the occipital region associated with weight loss as the temporal muscles atrophy (occipital bone). Sinking of the eyes into the skull is a sign of periorbital fat loss and may relate to myositis, weight loss, cachexia, or another ophthalmic process. Pain, swelling, or heat in any region is observed. More detailed examination of the eyeballs, including direct and/or indirect ophthalmoscopy, may be completed at

this time; or, if there are suggestions of change, the examiner first may complete the rest of the physical and then perform this part of the eye examination.

Airflow through the nostrils can be quickly assessed using a stethoscope and contralateral compression of the nares or by allowing the pet to breathe onto a metal surface (e.g., a counter top in the examination room).

Examination of the ears, pinnae, and ear canals is expected by the client and is an important part of every veterinary physical examination. This is particularly relevant in the new puppy or kitten examination as a check for ear mites, infection, or odor. An owner may report that a pet has difficulty eating or chewing, but the problem may in fact be caused by pain from one or both ear canals. Discharge, unusual odor, or discoloration of the canal tissue may be noted. Owners are more likely to notice abnormal conditions of the pinnae (e.g., aural hematoma), but even without such information, the pinnae must be examined. Superficial examination of the ear canal can usually be accomplished in the examination room without difficulty, allowing the veterinarian to discuss chronic ear disease with the owners while showing them the abnormality.

The integrity of the jaw bite must be determined, as well as the loss of teeth, or the presence of extra teeth. The color of the mucous membranes, capillary refill time, ulcers, color of the tongue, discolorations, and neurologic integrity are identified. The teeth are examined for calculus, caries, fractures, displacement, or discoloration. Abnormalities are recorded and mentioned to the owner. Signs of dental wear due to fence biting or rock chewing should be noted, as well as any resulting sensitivity. Gingival hyperplasia, masses, gingivitis, or ulcers may correlate with clinical signs. In first-time puppy or kitten examinations, evaluation for cleft palate or other congenital defects is required. With an uncooperative or fractious animal, examination of the oral cavity can be a daunting procedure. When the pet resists such an examination, removal to a treatment area away from the owner often allows further examination without difficulty.

Evaluation of the pharyngeal region is limited during the physical examination to external palpation. In some dogs, depressing the caudal tongue with the index finger allows visualization of the tonsils and oropharynx. However, this is not always the case, and if an indication of an abnormality exists in the pharyngeal or laryngeal region, a more thorough examination under sedation should be encouraged. The tongue should be elevated (using dorsally directed pressure with the thumb between the rami of the mandibles) to assess the sublingual region, such as for linear foreign bodies in cats. The laryngeal region should be checked for sensitivity, pain, or masses or institution of the gag reflex. Detection of visible or palpable deformities and monitoring of the laryngeal apparatus may yet be possible without sedation.

Moving to the ventral cervical region, the veterinarian evaluates for masses, tracheal sensitivity, and enlargement of the lymph nodes or thyroid gland. At the thoracic inlet, the clinician examines for lymph node enlargement, crepitus (subcutaneous air leakage), or other masses. Asymmetry of the thorax (scapula, muscles, rib cage, masses, or fat accumulation) should be correlated with signs, as should kyphosis or sternal deformities. Breathing difficulty can be associated with changes in the appearance of the rib cage. Fluid accumulation in the thoracic cavity, significant pleural or pulmonary disease, and some muscle disturbances cause the rib cage to feel or appear abnormal. Congenital thoracic deformities may cause respiratory signs. Peritoneal-pericardial diaphragmatic hernia (PPDH) may be associated with deformities of the xiphoid region of the sternum, such that the examiner can insert a finger into the thoracic cavity and sometimes actually touch the heart.

My preference is to complete the entire physical examination before auscultating lung and heart sounds. These portions of the physical examination are described in Chapters 54 and 55. When palpating the thorax, the examiner should notice the point of maximal intensity (PMI) of the heart. Normally this is over the left fourth to sixth intercostal space at the level of the costochondral junction. Deviations imply cardiac or thoracic cavity diseases. Similarly, palpation of a cardiac thrill is indicative of an extremely loud heart murmur (greater than grade 4/6).

Cardiac thrills are usually found at the PMI but may be displaced; they should be identified and correlated with the heart sounds and clinical signs.

Progressing caudally to the abdomen, the examiner first should note whether the abdominal wall is pumping rapidly, a possible sign of anxiety, tachypnea, or dyspnea. Tachypnea and dyspnea are observed; they are not recognized through auscultation.

The general appearance of the abdomen is the first thing the clinician should assess. Distended, tucked up, muscular and firm, painful, tense, and soft and doughy are all terms used to describe the abdomen. Abdominal pain should be characterized as coming from the abdomen or from musculoskeletal dysfunction (e.g., disk disease) or just from plain annoyance with being examined. Not all pets are happy to be in the veterinarian's office, and some display their displeasure this way; it should not be mistaken for a pathologic process.

Examination of the abdomen, as with all other parts of the body, should be performed systematically. Examining the outside of the abdomen and spinal column first and then moving deeper with systematic palpation allows the clinician to review body systems in an organized manner.

During either the initial portion of the abdominal examination or at this time, the veterinarian has the opportunity to examine the mammary glands and surrounding tissue. Large lumps in the mammary tissue are usually easily recognized; however smaller, nondiscrete lesions may require more intensive evaluation and palpation. Carefully moving the finger tips up or down the chain on both sides permits the examiner to note discrepancies in the tissue. Likewise, enlargement of the sublumbar lymph nodes may be noted. In the male, changes in and around the prepuce are identified. Preputial discharge may not be readily seen unless the pet is placed in lateral recumbency. Extruding the penis to appreciate changes in the mucosa or sheath of the penis helps explain abnormal findings or a history of licking. In the male cat, evaluation of the penis and its surrounding area is important, particularly in cases of suspected feline urinary tract disease. Neutered tomcats have small to no spines present on the penis, in contrast to intact tomcats.

Palpation of the abdomen is an individually determined technique. I like to examine animals both from behind and from the side. When examining the abdomen from behind, I am able to palpate for bilateral changes, to assess the kidneys more accurately, and to identify midabdominal masses. Lateral palpation provides a clearer indication of hepatomegaly, splenomegaly, bladder stones, or an enlarged bladder. Occasionally it is helpful to pick up the pet and allow it to stand on the hind legs so that the abdominal viscera falls caudally, permitting a more comprehensive examination.

Distention of the abdominal cavity requires differentiation. In general, there are four major causes of abdominal enlargement: fluid or fat accumulation, muscle laxity, and abdominal organ enlargement. The examination begins with gentle ballottement to determine whether the cause is obesity, pregnancy, fluid accumulation, one or more masses, internal obstruction, muscle weakness, or simply poor muscle condition. Correlating the findings of this examination with the weight and temperature allows the veterinarian to consider abnormal results.

It is generally easier to perform a complete abdominal palpation examination on the cat and many smaller dogs than it is on larger dogs. In cats, it is frequently possible to palpate the intestines, spleen, kidneys, and bladder carefully. In larger animals this may not be possible, but there is still much that can be appreciated, such as enlargement of abdominal organs, masses, and fluid collections. In cats, palpation of an enlarged spleen often is a sign suggesting mast cell disease, lymphoma, or another neoplastic process. In dogs, a large, irregular splenic margin strongly suggests hemangiosarcoma, although other causes of splenomegaly must be considered (see Chapters 184 and 276). Differentiation from other abdominal masses may be done initially through the physical examination and later by radiographic and/or ultrasonographic monitoring.

Pain upon palpation of the abdomen is a significant sign. Pain requires distinction between referred spinal pain, abdominal pain, generalized pain, and discomfort. The acute abdomen needs correlation with laboratory tests and clinical signs. Pain should be localized, if possible, as cranial, midabdominal, caudal, or generalized. Palpation for masses and the detection of enlarged viscera comprise an art that is not replaced by more sophisticated, expensive, and complicated tests. Pain in the abdomen is a clear indicator for further testing, including radiography, ultrasonography, and laboratory analyses. It also must be correlated with the clinical history. Malaise, failure to move or change position, fever, and nausea may be explained by abdominal pain, whereas a fractious cat, ears back and pupils dilated, that has a tense abdomen may simply be displeased with being examined.

Distention of the belly must be correlated with clinical signs (e.g., hair loss, polyuria/polydipsia, paper-thin, scaly skin), fluid collection, pregnancy, neurologic changes, and disease, most notably liver and splenic neoplasia. Urinary bladder distention should be palpable and defined. The kidneys often can be palpated bilaterally if enlarged in the dog and are usually palpable normally in the cat. In most dogs and cats, the left kidney normally can be palpated under all circumstances except when the animal is obese. The right kidney of the dog usually can be palpated only when it is enlarged or displaced. The presence of a large or painful prostate should be noted and correlated with clinical signs. Symmetric enlargement of the fat pads and muscles of the lumbar region (love handles) are commonly seen in an older pet, particularly if it is gaining weight.

Palpation of the abdomen is best completed with the dog or cat standing and with the examiner's fingers kept close together. If the thumb is allowed to rest on the spinal tissue and extreme pressure is exerted, the examiner may misinterpret pain as abdominal rather than spinal (induced by the thumb pressure).

The examination of the caudal abdomen is completed by rectal palpation, which is performed in older male dogs or when signs suggest lower bowel dysfunction, possible lower urinary tract problems, or hind end disorders of an orthopedic or neurologic nature. Prostatic abnormalities are likely to be palpated per rectum in all but the largest male dogs. Correct palpation of the prostate is done with the index finger of one hand and simultaneous cupping with the other hand (via dorsocaudal pressure on the caudal abdomen to elevate the prostate gland toward the palpating finger). This is especially useful for larger dogs and/or shorter index fingers. A normal rectal examination identifies a symmetric, bilobed, nonpainful, rubbery-textured prostate gland with a median raphe that clearly separates the two lobes. The peripheral tissue should evoke no pain or irregularity along the canal wall or the bony pelvic structure surrounding the gland.

Upon entering the rectum, the examiner palpates the anal sacs at the 4 and 8 o'clock positions to determine whether they are enlarged and if they can be readily expressed. The ease with which these glands can be expressed and the type of fluid released aids the evaluation for anal sac disease. Many clients worry considerably about “full” anal sacs, and it is important to identify problems if they exist. It also is necessary to establish adequate dietary measures in dogs with problems so that the anal sacs can be expressed regularly when the animal has a bowel movement. Serious anal sac disease does occur in the feline species, albeit uncommonly. The rectal tissue should be neither rough nor painful.

While examining the rectal region and tissue, the clinician should check the animal for evidence of constipation, obstipation, or generally dry, hard stools. Such problems lead to difficulty defecating. The perianal region should be examined for masses and, particularly when straining to defecate occurs, for perineal hernia, either unilateral or bilateral. Perineal hernias are detected by lateral deflection of the index finger immediately after entering the rectum (i.e., no farther than the first or second joint of the inserted finger). If the examiner probes too deeply past that point, this important lesion will be missed. Rectal prolapse must be differentiated from ileal-colic intussusception. Prolapse is associated with the inability to pass a blunt instrument only to the level of the pelvic inlet. During this portion of the examination, the tail is checked for skin lesions and for pain on motion. Animals experiencing tail pain, and

occasionally urinary and/or anal sphincter problems, should be examined with injury to the tail region in mind. Tails that have been caught in doors or pulled aggressively (more common in the cat) may develop neurologic problems involving the urinary bladder, anal sphincter, and/or the ability to move the tail.

The testicles and scrotum should be examined in the intact male for pain, skin lesions, and variability in the size and shape of one or both testicles. The presence of one or no testicles in the intact male is an important diagnostic clue. Retention or neoplasia of one or both testicles may correlate with the presenting clinical signs. In the puppy examination, the presence or absence of testicles may indicate a congenital defect and must be identified to the pet owner because the purchase agreement may need to be reviewed. It is important to note the presence of an inguinal (flanker) testis because showing and breeding would be inappropriate, and the pet may be infertile.

In females, examination of the vulvar region is important in determining the presence of discharges, the state of estrus, or the presence of skin conditions that may be responsible for licking or irritability of the hind region. Asking questions that relate to the timing of the last or latest heat cycle may elicit insightful information relevant to pseudopregnancy or pyometra in the intact bitch. Vaginal swabs taken to evaluate the state of the vaginal mucosa are a quick, easy way to determine the presence of pus or red cells in the canal and the current hormonal status of the bitch.

Prior to examining the limbs, particularly in cases of lameness, the examining veterinarian must evaluate the mobility and flexibility of the head and neck. Particularly in larger breeds of dogs, cervical conditions cause neck guarding and failure to thrive, with nondescript signs of pain, lameness, and malaise. Intermittent or recurrent problems may not be immediately obvious on the physical examination. Dogs that are difficult to examine or animals with acutely painful conditions may be better evaluated under conscious sedation.

Rear leg pain, weakness, and wobbliness may be signs of a neurologic disorder, such as cervical disease, thoracolumbar disease, and/or lumbosacral disease. The physical examination should include compression of the tissues along the spinal canal and the lumbosacral region. Sensitivity alone may be inadequate grounds for making a diagnosis and may only point to one of several conditions that must be considered in the differential diagnosis. Neurologic changes, including postural tone, conscious proprioception, or muscle atrophy, assist the process of evaluating disease states.

8

9

Evaluation and examination of the limbs, including the pulses, lymph nodes, joints, foot pads, and interdigital regions, can reveal important clues to the presence of internal medical problems. Joint disease, often silent or less than immediately obvious, is easily overlooked unless specific attention is paid to joint swelling or discomfort. It is important to observe symptomatic cats out of the carrier, on the floor in a safe, escape-proof room. Swelling, heat, and pain in one or more joints can explain many signs, including lameness, malaise, and fever. Swelling of the peripheral subcutaneous tissues provides reason for further evaluation. Claudication or painful or non-weight-bearing lameness directs the examiner to the affected limb. Thorough examination of the limbs for differentiation of warmth, pulses, or swellings may yield a direct clue to the cause of lameness.

Deep palpation of the bony tissue provides information relevant to both medical and orthopedic problems. Taking into account the age and health of the animal is relevant, because some diseases are specific to young, growing dogs (panosteitis), whereas others would be expected in older, overweight dogs (cruciate rupture, osteoarthritis, bone cancer). Although a general evaluation of the joints is required whenever lameness is present, it is always performed with the realization that only with the animal under conscious sedation or general anesthesia can it be determined with certainty whether a joint problem exists. Cats are usually easier to palpate than dogs, but larger breeds of dogs are often difficult to examine without sedation. With that as a given, it is often advantageous to discuss with the client the benefits of radiology and a joint tap under sedation so that a more complete examination can be done. Palpation of the hips and evaluation for coxofemoral disease must be distinguished from examination for

lumbosacral problems and stifle disorders. The opportunity to evaluate these findings in greater detail may be left to a sedated state accomplished at another time. When radiographs of a limb are to be taken, the examiner should remember the benefit of radiographing both limbs to evaluate the significance of the changes noted. Other orthopedic problems, including patellar disease, may be more easily identified without sedation.

No lameness examination is complete without evaluation of the pads and interdigital regions. It is of paramount importance to examine these tissues carefully for infiltrating problems, particularly where foreign bodies are a possibility, and to distinguish interdigital cysts, digital tumors, and pad burns.

1.3 COMPLETING THE PHYSICAL EXAMINATION

Every hospital has its own set of paperwork. Smaller veterinary clinics may not require much in the way of paperwork, but this is the time to complete a well-written medical record. The traditional “SOAP” method provides the entire hospital and others with a record of the physical examination and history findings and of the plan for moving forward with the pet's care.

No physical examination is complete until the results are listed in the examination report and an assessment is made of the findings. This is the time for the veterinarian to identify in the records his or her recommendations for proceeding with the case. It is here that the client or caregiver can once again participate in the caregiving process. The veterinarian needs to summarize the findings, note the pertinent points, and identify how the case should proceed. Noting the findings alone without recommending a course of action does not complete the process. The owner must be informed of the possible courses of action and the estimated cost of such work. It is recommended that the veterinarian also note in the record, in addition to the subjective and objective findings, the likely rule-outs and tentative clinical assessment. A definitive diagnosis need not be made at this time, but identifying the rule-outs helps to portray a thought process in progress. If the prognosis is potentially poor or guarded, the examining veterinarian should discuss this with the owner at this point. Clients who fail to “hear” bad news may be very surprised to see that the veterinarian had written such news in the record one or more times in the course of record keeping. From a medical-legal point of view, keeping the client informed and up-to-date is very necessary. From the outset, discussing serious findings with the client ensures better practitioner-client communication.

2 CHAPTER • 2 Hyperthermia and Fever of Unknown Origin

James B. Miller

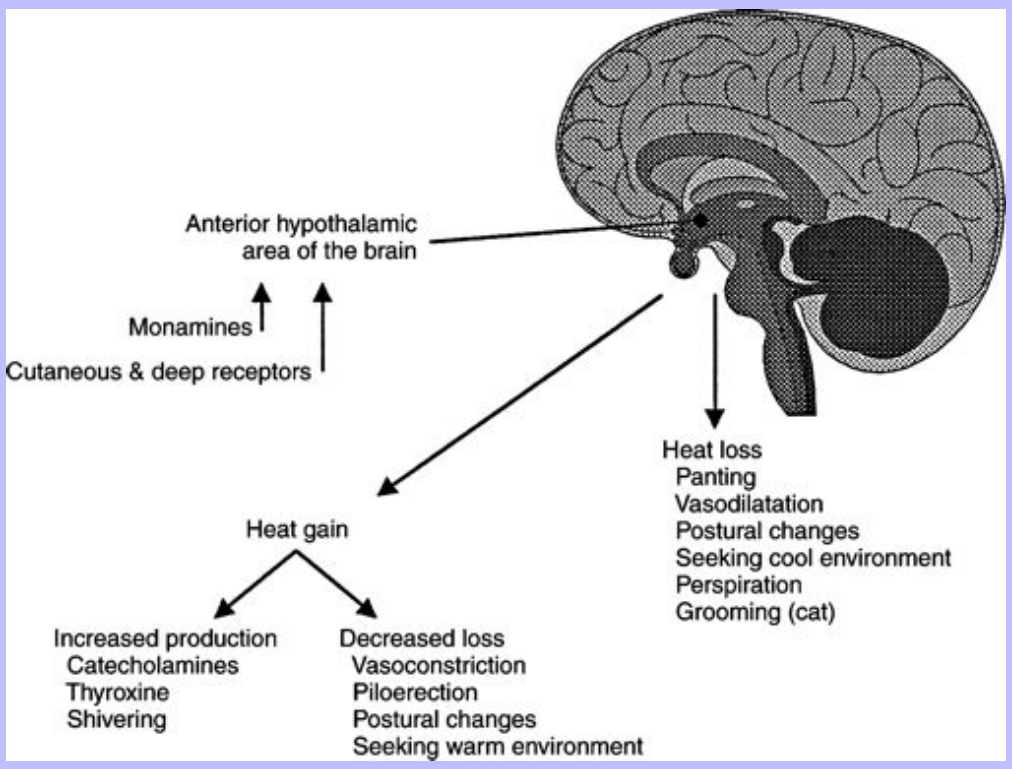
Obtaining a body temperature is part of every physical examination. Too frequently the veterinarian associates any elevation in body temperature with true fever. The assumption is then made that an infectious agent causes the "fever," even if no obvious cause exists. If the animal's fever resolves after giving antibiotics, the assumption is made that it was a bacterial infection. A normal body temperature is often assumed to mean the absence of disease. This approach to hyperthermia, fevers of unknown origin, and normothermia can be misleading and lead to improper diagnosis or therapy (or the lack of therapy).

2.1 THERMOREGULATION

The thermoregulatory center for the body is located in the central nervous system (CNS) in the region of the anterior hypothalamus (AH). Changes in ambient and core body temperatures are sensed by the peripheral and central thermoreceptors, and the information is conveyed to the AH via the nervous system. Thermoreceptors sensing that the body is below or above its normal temperature (normal "set point") will stimulate the AH to cause the body to increase heat production and reduce heat loss through conservation if the body is too cold or dissipate heat if the body is too warm (Figure 2-1). Through these mechanisms, dogs and cats can maintain a narrow core body temperature range in a wide variety of environmental conditions.

10

Figure 2-1 Schematic representation of normal thermal regulation.



2.2 HYPERTHERMIA

Hyperthermia is the term used to describe any elevation in core body temperature above accepted normal for that species. Hyperthermia is a result of the loss of equilibrium in the heat balance equation such that heat is produced or stored in the body at a rate in excess of heat lost through radiation, convection, or evaporation. The term *fever* is reserved for those hyperthermic animals where the set point in the AH has been "reset" to a higher temperature. In hyperthermic states other than fever, the hyperthermia is not a result of the body attempting to raise its temperature but is due to the physiologic, pathologic, or pharmacologic intervention where heat gain exceeds heat loss. Box 2-1 outlines the various forms of hyperthermia.

2.2.1 True Fever

2.2.1.1 Exogenous Pyrogens

True fever may be initiated by a variety of substances, including infectious agents or their products, immune complexes, tissue inflammation or necrosis, and several pharmacologic agents including many antibiotics. Collectively, these substances are called *exogenous pyrogens*. Their ability to directly affect the thermoregulatory center is probably minimal, and their action is to cause the release of endogenous pyrogens by the host. Box 2-2 lists some of the more important known exogenous pyrogens.

2.2.1.2 Endogenous Pyrogens

In response to stimuli by an exogenous pyrogen, proteins (cytokines) released from cells of the immune system trigger the febrile response. Macrophages are the primary immune cell involved, although T and B lymphocytes and other leukocytes may play significant roles. The proteins produced are called *endogenous pyrogens* or *fever-producing cytokines*. Although interleukin-1 (IL-1) is considered the most important cytokine, at least 11 cytokines capable of initiating a febrile response have been identified (Table 2-1). Some neoplastic cells are also capable of producing cytokines that lead to a febrile response. The cytokines travel via the blood stream to the AH, where they bind to the vascular endothelial cells within the AH and stimulate release of prostaglandins (PGs), primarily prostaglandin E_2 (PGE_2) and possibly prostaglandin $E_{2\alpha}$ ($PGE_{2\alpha}$). The set point is raised, and the core body temperature rises through increased heat production and conservation (Figure 2-2).

2.2.2 Inadequate Heat Dissipation

2.2.2.1 Heat Stroke

Heat stroke is a common form of inadequate heat dissipation. Exposure to high ambient temperatures may increase heat load at a faster rate than the body can dissipate the heat. This is especially true in larger breeds of dogs and brachycephalic breeds. Heat stroke may occur rapidly in the dog, especially in closed environments with poor ventilation (e.g., inside a car with windows closed), even on moderately hot days. Environmental temperatures inside a closed car exposed to the direct sun may exceed 120°F (48°C) in less than 20 minutes, even when the outside temperature is only 75°F (24°C). Death may occur in less than an hour, especially in the breed types mentioned. Heat stroke will not respond to antipyretics used in true fever. The animal must be treated with total body cooling immediately if a fatal outcome is to be avoided. Water baths and rinses using cool (but not cold) water best accomplish total body cooling. If the water is too cold, a tendency exists for peripheral vasoconstriction, which will inhibit heat loss and slow the cooling process. Cool water, gastric lavage, or enemas have also been suggested. Cooling should be discontinued when body temperature approaches normal to avoid potential hypothermia. In addition to total body cooling, treatment for vascular collapse and shock should be instituted with severe hyperthermia (greater than 107°F [41.6°C]) or when clinical judgement warrants its use. Intravenous crystalloid solutions given at shock doses and glucocorticoids are indicated in an attempt to prevent permanent organ damage and disseminated intravascular coagulopathy (DIC).

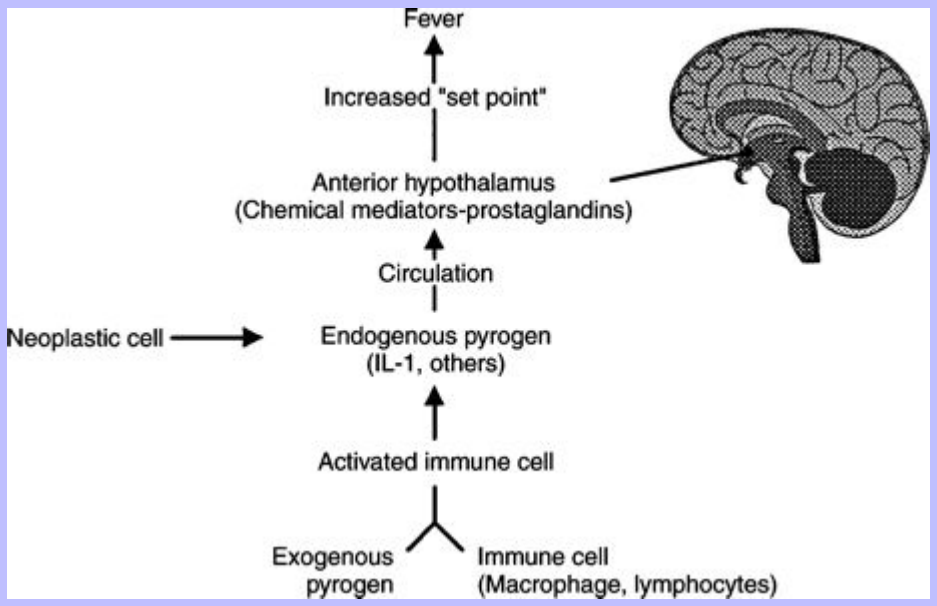
2.2.2.2 Hyperpyrexic Syndrome

Hyperpyrexic syndrome is associated with moderate-to-severe exercise in hot and humid climates. This syndrome may be more common in hunting dogs or dogs that “jog” with their owners. In humid environments, a tendency exists toward a zero thermal gradient for dry heat loss leading to a net heat gain. In addition, severe exercise may cause the cardiovascular system to supply skeletal muscles with adequate blood flow while compromising peripheral heat loss by not allowing proper vasodilation in the skin. Many hunting dogs and dogs that run with their owners will continue to work or run until they become weak, begin to stagger, and then collapse. In suspected cases, owners should obtain a rectal thermometer. If increased, in the future the clinician should evaluate the dogs' rectal temperature at the first sign of weakness or not wanting to continue. Owners should be instructed that rectal temperatures above 106°F (41°C) require immediate total body cooling, and temperatures above 107°F (41.6°C) are an immediate threat to permanent organ damage or death.

2.2.3 Exercise Hyperthermia

The body temperature will slowly rise with sustained exercise because of increased heat production associated with muscular activity. Even when extreme heat and humidity are not factors, dogs will occasionally reach temperatures that would require total body cooling. This is especially true in dogs not accustomed to exercise, overweight, or those with respiratory disease. Puppies seen for vaccinations have often been excited and active during the trip. Activity and probable release of catecholamines results in the increased body temperatures obtained on physical examination. These dogs will display features suggestive of attempting to dissipate excess body heat and are neither febrile nor ill.

Figure 2-2 Schematic representation of the pathophysiology of fever.



Eclampsia results in extreme muscular activity that can lead to significant heat production resulting in severe hyperthermia. Total body cooling should be initiated in conjunction with specific eclampsia therapy if the dog or cat is hyperthermic. Be cautious of lowering body temperature too quickly and of decreases to subnormal levels.

Seizure disorders as the result of organic, metabolic, or idiopathic causes are encountered frequently. Hyperthermia associated with severe muscular activity can be a feature, especially if the seizures are prolonged or occur in clusters. The initial concern of the clinician should be to stop the seizures; however, when significant hyperthermia is present, total body cooling is recommended.

2.2.4 Pathologic and Pharmacologic Hyperthermia

These types of hyperthermia encompass several disorders that lead to impairment of the heat balance equation. Lesions in the hypothalamus may obliterate the thermoregulatory center leading to impaired response to both hot and cold environments. Malignant hyperthermia has been reported in the dog and cat. It leads to a pharmacologic myopathy that is initiated by pharmacologic agents, including inhalation anesthetics (especially Halothane) and muscle relaxants such as succinylcholine. Extreme muscle rigidity results with the production of excess body heat. Removal of the offending causative agent and total body cooling may prevent death. Hypermetabolic disorders may lead to hyperthermic states. Endocrine disorders such as hyperthyroidism and pheochromocytoma can lead to an increased metabolic rate, vasoconstriction, or both, resulting in excess heat production and decreased ability to dissipate heat. These conditions rarely lead to severe hyperthermia requiring total body cooling.

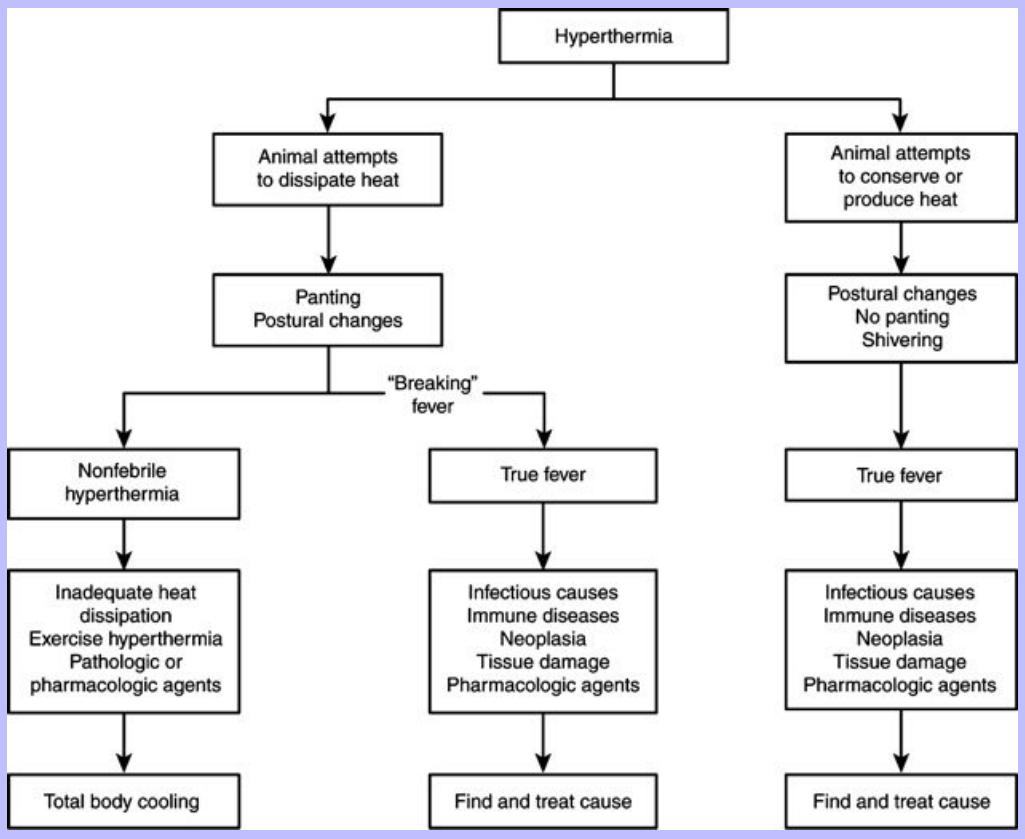
2.2.5 Clinical Approach to the Hyperthermic Patient

When a dog or cat has an increased body temperature, an effort should be made to approach the problem in a logical manner to avoid erroneous conclusions (Figure 2-3). A complete history and physical examination should be performed unless the problem is of extreme nature (temperature greater than 106°F [41°C]) and the animal is obviously attempting to dissipate heat (panting, postural changes) or comatose. In such cases, immediate total body cooling and supportive care should be initiated. In other cases, specific questions concerning previous injuries or infections, exposure to other animals, disease in other household pets, previous geographic environment, and previous or current drug therapy may be beneficial. Through this type of questioning and a complete physical examination, the clinician can frequently decide if the increased body temperature is true fever. Temperatures less than 106°F (41°C), unless prolonged, are usually not life threatening, and caution should be taken on using antipyretics before a proper clinical evaluation.

2.2.6 Fever of Unknown Origin

Fever of unknown origin (FUO) is defined in human medicine as a fever that has lasted 3 weeks and has a cause that has not been determined through laboratory evaluation and radiographs. In veterinary medicine, most clinicians consider any animal that does not have any historical or physical finding that would cause a FUO. Although research involving a large number of patients with FUO has been completed in humans, little veterinary information suggests the most common causes of FUO in dogs or cats. The information given in this chapter is based primarily on clinical experience. Most dogs and cats with FUO probably have an infection or suffer from products of those agents. The prevalence of the causative infectious agent varies depending on the area where the clinician practices and the previous travel history of the pet. Although bacterial infections are probably the most common cause of FUO in the dog, in some geographic locations, systemic fungal diseases or rickettsial infections might be more common. Endocarditis, pyelonephritis, prostatitis, closed pyometra, pyothorax, and other deep abscesses should be considered in a dog with FUO. In the cat, viral diseases such as feline leukemia virus (FeLV), feline infectious peritonitis (FIP) virus, and feline immunodeficiency virus (FIV) are common infectious causes of FUO and may exceed bacterial infections as the leading cause. The next most common cause of FUO in the dog and cat is immune-mediated disease. Most immune-mediated diseases occur in young adult dogs. Immune complexes are a potent stimulator for the release of fever producing cytokines and frequently lead to temperatures of 105°F (40.5°C) or 106°F (41°C). Neoplasia is not as common as immune-mediated disease in causing fevers but should always be considered, especially in the older animal. Another, often overlooked cause of fever, is tissue trauma. Trauma often causes mild fever (103°F to 104°F [39.6°C to 40°C]) 1 or 2 days postsurgery when there has been significant muscle involvement. Most of these animals do not have infections and probably should not be treated with antibiotics without additional evidence of infection.

Figure 2-3 Algorithm for treatment of hyperthermia.



Evaluating for infectious disease, immune-mediated disease, neoplasia, and causes of tissue trauma will usually lead to a final diagnosis, even when no obvious cause for the fever exists.

2.2.7 Nonspecific Therapy for Fever

Mild-to-moderate elevations in body temperature are rarely fatal and may be beneficial to the body. Hyperthermia may inhibit viral replication, increase leukocyte function, and decrease the uptake of iron by microbes, the latter being necessary for growth and replication of many microbes. If a fever exceeds 107° F, a significant risk of permanent organ damage and the initiation of DIC exist. The benefits of nonspecific therapy versus its potential negative effects should be considered before initiating such therapy.

Nonspecific therapy for true fever usually involves the use of inhibitors of prostaglandin synthesis. The compounds most commonly used are the salicylates (acetylsalicylic acid and sodium salicylate) and dipyrone. These products inhibit the chemical mediators of fever production and allow the normal thermoregulation. They do not block the production of endogenous pyrogens. These products are relatively safe, although acetylsalicylic acid is potentially toxic to cats and lower dose and frequency of administration relative to the dog is recommended. Dipyrone may lead to bone marrow suppression, especially when given over a prolonged period, and should be given only for a short period.

Phenothiazines can be effective in alleviating true fever and appear to act on the thermoregulatory center and cause peripheral vasodilation. The sedative qualities and potential for hypotension caused by the phenothiazines should be considered before use in the febrile patient.

14

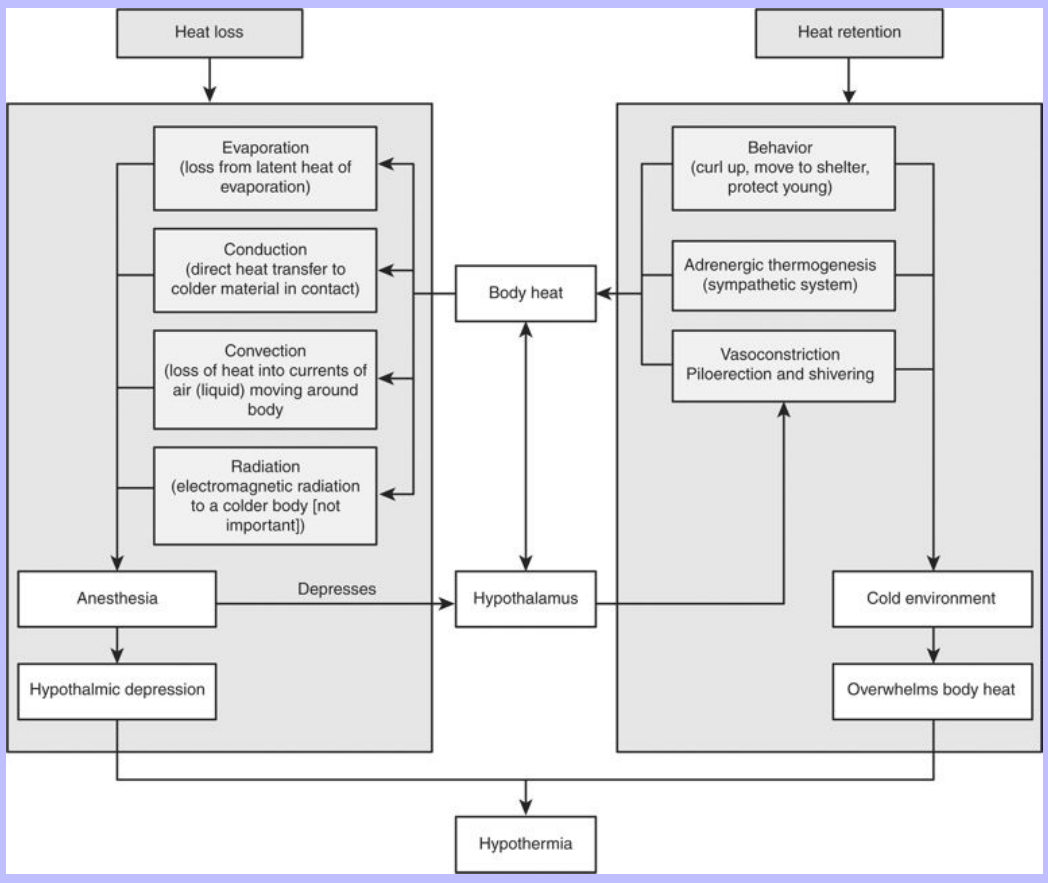
3 CHAPTER • 3 Hypothermia

Polly M. Taylor

3.1 MAINTENANCE OF NORMAL BODY TEMPERATURE

Mammalian body temperature is maintained closely around a constant set point at which cellular function is optimal. A number of complex mechanisms exist to maintain body temperature within tight control. The anterior hypothalamus maintains overall control of body temperature. It responds to local increases or decreases in temperature and also to neural input from warm and cold receptors in the skin, the abdominal viscera, and the spinal cord.

Figure 3-1 How heat is lost from the body.



To maintain constant temperature, heat generated by muscular activity and metabolism is matched to heat loss. Temperature is regulated largely by control of heat lost from the body surface via the classic routes of heat exchange: conduction, convection, evaporation, and radiation (Figure 3-1). Heat is also lost from the respiratory tract through evaporation and in urine and feces. If the body becomes too cold, heat is retained in the body core

14 15

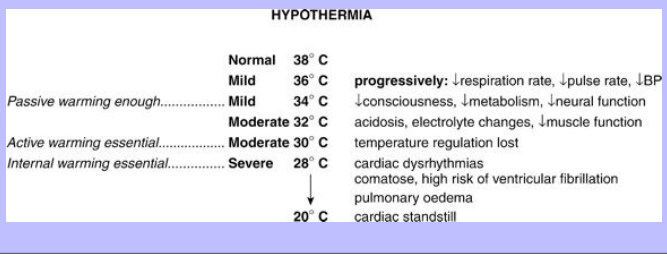
through peripheral vasoconstriction, which prevents warm blood reaching the body surface. Piloerection insulates the skin by trapping a layer of stationary air. Some additional heat is generated through muscle activity, such as shivering and voluntary movement. Chemical thermogenesis (adrenergic) may also play a part. Behavioral responses to cold are important in preventing heat loss; for example, moving into shelter and warmth, curling up, and dams protecting the young. Heat is lost by reversal of these processes, such that vasodilation of superficial blood vessels allows warm central blood to reach the skin. Panting increases evaporation from the respiratory tract. In some species, sweating is stimulated to provide the most effective heat loss through evaporation. Dogs and cats do not sweat from the skin, and loss via the respiratory tract through panting is the most significant form of active heat loss.

3.2 DEVELOPMENT OF HYPOTHERMIA

Hypothermia develops when either the methods of heat production and conservation are overwhelmed by a cold environment or when the mechanisms of heat retention are impaired. Smaller animals, in which the ratio between body surface area and volume are high, are more likely to develop hypothermia. Old, sick, or otherwise debilitated animals are also more likely to become hypothermic as heat generation and temperature control may be impaired. Neonates, with underdeveloped temperature-regulating mechanisms, are particularly susceptible. Hypothermia leads to a progressive failure of body function, ultimately leading to cardiac standstill and death. In man, a core body temperature of 35°C or below is regarded as hypothermia. Although animal temperatures are slightly higher than human temperatures, the definitions of degrees of hypothermia applied in human medicine serve well in other species as a guide to the expected degree of malfunction (Figure 3-2). Initially, as core body temperature falls below 36°C, respiratory rate, pulse rate, and arterial blood pressure fall. As temperature decreases below 34°C, muscular control and neural function begin to fail, consciousness is depressed, and metabolism is slowed. Acidosis and electrolyte imbalance may occur. Below 30°C, cardiac dysrhythmias are likely and temperature regulatory mechanisms fail even in the absence of any drugs. Hence, animals with a body temperature below 30°C are unlikely to regain normal temperature without treatment. Progressive metabolic and respiratory failure takes place when body temperature is below 28°C, with a high risk of ventricular fibrillation; cardiac standstill occurs at around 20°C.

Normal cats and, particularly, dogs withstand a cold environment very well. For instance, dogs immersed in water at 20°C can maintain heat regulation for 5 hours with less than a 1°C fall in body temperature. Hypothermia is most commonly seen when normal control mechanisms are disrupted by sedation and anesthesia, which impair hypothalamic function and behavioral responses. Many anesthetics and sedatives cause some degree of peripheral vasodilation, which itself allows more heat loss. As a consequence, most small animal patients are likely to lose body heat during anesthesia. Exposure to a cold environment or near drowning is a much less common cause of hypothermia in animals. In these circumstances the normal heat retention mechanisms are simply overwhelmed by the environmental conditions. The consequences of cold-exposure hypothermia and the treatment are essentially the same as in anesthesia-induced hypothermia. However, hypothermia is likely to be more severe after cold exposure but has the advantage of being uncomplicated by effects of surgery or drugs.

Figure 3-2 The effects of hypothermia (algorithm).



Anesthetic-associated heat loss and the resultant decrease in body temperature slows drug metabolism and leads to prolonged recovery from anesthesia. If severe, it is possible that cardiac function may be affected sufficiently to cause death. More commonly, postoperative hypothermia causes morbidity or death through the consequences of a slow recovery. A long period of unconsciousness increases the likelihood of unresolved, obstructed airway and prolonged hypoxia. Shivering will worsen this effect through increased oxygen and energy demands. Lack of movement while still under the influence of vasodilating anesthetics and sedatives leads to a vicious circle of further heat loss and reduced drug metabolism prolonging recovery and further increasing the chance of airway obstruction and hypoxia.

3.2.1 Prevention and Treatment

It is a great deal easier to prevent heat loss during anesthesia than to try to restore the temperature of a cold, anaesthetized patient at the end of a long surgical procedure. Effort should be made right from the start of anesthesia to maintain body temperature between 36°to 38°C. Much can be done by passive methods, largely insulation, although active methods using external heat are usually required where body cavities are exposed.

3.2.1.1 Passive Warming

Most heat is lost through conduction to colder surfaces in contact with the animal, such as the operating table, and through evaporation of body fluids and liquids used for surgical preparation. The animal should be insulated from colder surfaces and from the surrounding air, and it should be kept as dry as possible. A warm operating theatre may reduce heat loss into the surroundings, but working in an environment at body temperature is unpleasant; some heat loss by conduction into air circuits flowing around the animal will still occur unless it is insulated. Insulation between the operating table and the animal is easy to achieve with foam padding and other positioning aids. It is also easy to insulate the whole animal by wrapping any exposed parts with bubble wrapping or aluminium foil. A compromise between the ultimate asepsis and the best heat retention must be made by clipping the minimal amount of hair and wetting the smallest area compatible with the proposed surgery. At all costs, excess scrub water must be dried up; the animal should not lie in a pool of scrub liquid during surgery.

15

16

It is impossible to prevent evaporation from the exposed surgical site. Intestinal surgery is the worst in this regard because large surface areas of serous membrane may be exposed. Regular flushing with warm (38° to 40°C) saline helps to reduce the amount of evaporation of body fluid and may help to prevent heat loss. Heat is also lost through the respiratory tract. Use of low-flow rebreathing circuits that retain both heat and moisture are advantageous in this respect. Heat and moisture exchangers placed between the endotracheal tube and the breathing circuit help to retain moisture and hence heat, as evaporation is reduced. These exchangers increase dead space and may be inappropriate for the very small patients that most need the heat retention.

3.2.1.2 Active Warming

Active methods to prevent heat loss are usually required during surgery of the body cavities. These include heated pads, infrared lights, heated gels, and hot-air circulators. Circulating water-heated pads are the safest because they do not become too hot; electrically heated pads may overheat, resulting in burns to the unconscious patient who cannot move off the heat source. Gel pads that are catalysed into an exothermic reaction when changing state to a stiff form are useful in very small patients. The heat generated is not excessive, lasts for 1 to 2 hours, and the stiffened gel bag can be used to position the animal. They are “regenerated” after use by placing in boiling water until the gel state returns. By far the most effective of the

active-heating systems are the hot-air blankets, in which hot air is blown into a perforated blanket that is placed about the animal under the surgical drapes. A very wet animal will initially be cooled as the result of evaporation, but in all other circumstances this method has proved extremely effective.

Treatment of hypothermia depends on its severity and cause. After anesthesia, active warming is required as homeostatic mechanisms are impaired. Where the environment has caused hypothermia, normal heat-generating mechanisms will be more effective, and passive methods such as insulation with warm, dry blankets may be sufficient (see Figure 3-2). Very severe hypothermia (core temperature <30°C) requires internal active warming with intravenous fluids at 40°C and gastric, colonic, or peritoneal lavage with fluids at 40° to 42°C. This is to prevent further core cooling, which occurs when surface warming causes vasodilation, thereby allowing cold, peripheral blood to circulate into the body core.

4 CHAPTER • 4 Pain Identification

Peter W. Hellyer

"Is this patient likely to be in pain, and if so, what is the best way to prevent and manage that pain?" This is an essential question that veterinarians should be asking themselves on a routine basis. When using this approach, the veterinarian has embraced a philosophy of providing the best care possible for the patient—this is practicing good medicine. The importance of measuring pain in patients is exemplified by what has been occurring in human medicine. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) mandated in the year 2000 that human hospitals in the United States must measure pain in their patients and take steps to manage that pain. It is a sad commentary that the human medical community did not recognize that patient comfort is part of good medicine and all important to the patient, necessitating JCAHO to mandate that pain be considered the fifth vital sign (in addition to temperature, pulse, blood pressure, and respiration). In fact, the human medical community has known about the issues of unrelieved pain for almost 30 years, since the landmark study by Marks and Sacher (1973) exposed the practice of withholding effective analgesia from terminally ill patients. In establishing pain as the fifth vital sign, JCAHO acknowledged that treating pain results in quicker clinical recoveries, shorter hospital stays, fewer readmissions, and improved quality of life, leading to increased productivity. Thus pain relief should be considered part of good medicine. In veterinary medicine, pain may be considered as a vital sign, in addition to temperature, pulse rate, and respiratory rate. Pain is similar to other patient parameters in that it is more readily apparent once the clinician looks for it. Unlike the other vital signs, pain is difficult to measure and quantify. The tools to measure pain in veterinary patients will undoubtedly change as more clinical and research information becomes available. This chapter provides a brief summary of the current tools available to evaluate pain in dogs and cats.

4.1 IDEAL PAIN SCALES

Over the past decade, pain scales have been developed and used as part of research studies designed to evaluate specific therapeutic modalities in the treatment of acute or chronic pain in dogs and cats. Nevertheless, the science of accurately measuring pain in animals in general, and dogs and cats in particular, is still in the early stages of development. Because animals cannot tell clinicians that they are in pain, no "gold standard" exists to assess pain in animals. The situation in human medicine provides a useful comparison.

Identifying pain in neonates and young children has been extensively studied over the last 20 years. The results of those efforts have been a proliferation of scales that are used to assess pain in children of different developmental ages and in different settings. Refinement of the scales used in children continues to create tools that are sensitive and specific for pain. The same process needs to occur in veterinary medicine, with the additional challenge of creating scales that are species specific. Criteria for an ideal pain scale are presented in Box 4-1. Because ideal pain scales do not exist for every species and every medical condition, how should the information in Box 4-1 be used? When evaluating a patient for pain, it is essential to be aware of the normal behavior for that species, age, and individual. Deviations from normal behavior suggest pain, anxiety, or some combination of stressors that are inducing a state of distress. If a pain scale was developed to evaluate acute postoperative pain after orthopedic surgery, the scale may be of little help in assessing abdominal pain. Accordingly, pain scales should be used as a guide to identify behavioral changes from normal and as a way to track response to therapy. Pain scales should not be used to deny analgesia based on an arbitrary number.

4.1.1 Box • 4-1 Characteristics of an Ideal Pain Scale

Patient characteristics:

1. Species specific
2. Breed specific (there may be differences in genetic sensitivities to pain)
3. Environmental and rearing specific (e.g., individual animal versus group rearing, home versus clinic)
4. Developmental/age specific (e.g., neonates versus pediatrics versus adult versus geriatric)
5. Gender specific (the role of gender on pain perception is still unclear)
6. Cause of pain specific (e.g., pathology-induced pain, procedural pain, surgical pain)
7. Body region specific (e.g., facial pain, ocular pain, abdominal pain)
8. Character of pain state specific (i.e., acute, subacute, chronic, localized, diffuse)
9. Pain intensity specific (spectrum from none to severe)
10. Recognize individual variations

Pain scale indices and criteria should be:

1. Clearly defined
2. Consistently useable by different individuals
3. Have clearly understood strengths and weaknesses
4. Be able to differentiate differences in the intensity and degree of pain
5. Be straightforward and practical to use
6. Be validated according to carefully considered standards
7. Be a useful tool to guide clinical decision making

4.1.2 Current State of Assessing Pain

Assessing pain in animals on either end of a spectrum from *no pain* to *severe pain* is relatively straightforward, provided the veterinarian and staff are aware of normal behavior for that species and individual. Realistically, many of the most challenging cases involve patients that have varying degrees of pain somewhere between the extremes of *none* and *severe*. Trying to determine the degree of pain and the ability of that animal to cope with its pain can be difficult. In a survey of Canadian veterinarians, Dohoo and Dohoo (1996) found that one of the main factors that determined if veterinarians routinely administered analgesic drugs postoperatively was the veterinarians' perception of the degree of pain felt by animals. The fact that 51.5% of those veterinarians surveyed never used analgesics highlights the clinical importance of being able to recognize pain in the species under a veterinarian's care. Even amongst veterinary personnel committed to treating pain, it can be frustrating at times trying to decide if the benefits (i.e., decreased pain intensity) of the analgesic protocol selected outweigh the side effects (e.g., sedation, nausea). Compounding the decision-making quandary is the fact that many veterinarians and their staff never received any formal training in the recognition of pain. As more studies focus

on species-specific pain behaviors, the ability to recognize and treat pain in animals will improve; however, the assessment of pain in animals will remain a subjective and inaccurate undertaking for the near future. This brings up an interesting question: Is it appropriate to assume that if a procedure is painful in people it will also be painful in an animal? An ever-growing body of scientific literature describes new knowledge and understanding of the anatomy, physiology, and pharmacology of nociception (i.e., pain). The vast majority of those studies are carried out in animals with the information often extrapolated to people, leading to the development of new drugs and techniques and ultimately to clinical trials. From people, clinicians are able to evaluate the efficacy of these new techniques and drugs and often improve the way that pain is treated. In other words, clinicians can ask human patients if the treatment has improved their level of pain. However, if veterinarians apply this pain information gathered from humans to animals, they risk being accused of anthropomorphism. Recognizing that marked differences exist in species pain tolerance, in demonstration of overt signs of pain, and in responses to therapeutic interventions, it nevertheless defies logic and ethics for the scientific community to use animals to understand pain in people while simultaneously denying that pain exists or is important in animals. Thus it is appropriate at this time to assume that if a condition causes pain in people, it will also cause some degree of pain in animals. For animals, pain may be more or less than that experienced by a person; therefore it is incumbent on the veterinarian to determine how well the patient is coping with the pain.

The evaluation methods described in this chapter have been extrapolated from human medicine (i.e., visual analogue scale) or designed to assess acute postoperative pain in dogs. These methods can be adapted to cats and other species provided the veterinarian recognizes that pain behaviors are likely to be different between species. Importantly, all of the methods described are subjective and prone to the error of either underestimating or overestimating the degree of pain. All of the pain scales used in animals rely on the recognition or interpretation (or both) of some behavior. The most useful scales determine the presence or absence of specific behaviors while minimizing the interpretation of those behaviors. Even if the amount of pain is correctly estimated, determining how well the individual animal is coping with the pain may be difficult. In addition, all of the current pain scales are subject to interobserver variability to one degree or another. Finally, it should be recognized that all of these methods are used to assess the effects of physical pain and that none have been designed to evaluate mental or psychologic dimensions of pain that an animal may be experiencing.

4.1.3 Physiologic Assessment of Acute Pain

Physiologic data (e.g., changes in heart rate, respiratory rate, arterial blood pressure, pupil dilation) are useful in assessing responses to a noxious (painful) stimulus in a lightly anesthetized animal. Physiologic responses also occur in conscious patients as a result of acute pain or other stressors but not with the same degree of reliability as in anesthetized patients. Central nervous system (CNS) and cardiopulmonary reflexes control cardiovascular and respiratory function to maintain a state of homeostasis; therefore reflex control mechanisms may dampen the physiologic responses to pain. In addition, physiologic parameters are not specific enough to differentiate pain from other stressors such as anxiety, fear, or physiologic responses to metabolic conditions (e.g., anemia). The reader should note that some pain scales use physiologic data and some do not. In the author's opinion, physiologic parameters are useful in assessing responses to noxious stimuli in patients under general anesthesia or for transient periods in conscious patients. The longer a conscious patient experiences pain, the less useful are physiologic parameters in assessing the degree of pain. When physiologic responses are used to assess pain, it is important to be aware of their limitations and to assess the selected parameter in light of baseline physiologic data. As such, changes in heart rate, respiratory rate, and other physiologic responses may be more useful in assessing the patient than any absolute value for each criterion.

4.1.4 Behavioral Assessment of Acute Pain

Evaluation of pain in animals relies on observation of animal behavior and interpretation of what the behaviors mean by an observer. Pain may be indicated by abnormal behavior that may appear as either an increase or a decrease in activity. In general, pain behaviors are easier to recognize in dogs as compared with cats. For example, dogs in pain may appear restless, agitated, or even delirious. This is particularly true during recovery from anesthesia after surgery. At the other end of the spectrum, dogs may be lethargic, withdrawn, dull, or obtunded. These dogs may not pay attention to environmental stimuli. The normal sleep-wake cycle may be disrupted, such that less sleep than normal is obtained. Normal activity such as grooming or eating may decrease or stop. Dogs may bite, lick, chew, or shake painful areas. Painful dogs may adopt abnormal body postures in an attempt to relieve or cope with pain in a given area. For example, dogs with abdominal pain (e.g., pancreatitis) may assume a posture with a rigid torso and arched back. Dogs with abdominal or thoracic pain may be reluctant to lie down in spite of obvious exhaustion. Although dogs do not have the same degree of motor control over their facial muscles as do primates, changes in facial expression can be used in some dogs to detect pain. The dog may hold its ears back or in a down position. The eyes may be wide open with dilated pupils, or partially closed with a dull appearance. Many dogs will display a “fixed stare” into space, apparently oblivious to their surroundings. Some dogs may display a type of grimace uncharacteristic of the dog when not painful. Disuse or guarding of a painful area is a fairly reliable indicator of pain. The dog's gait may be abnormal, or the dog may appear much more rigid than normal. Vocalization may indicate pain in the dog, however it is an insensitive and nonspecific indicator of pain. Vocalization may occur as a whimper, whine, yelp, groan, grunt, yowl, or any combination. Interactive behaviors are frequently changed in the painful animal. Dogs may become more aggressive and resist handling or palpation. In contrast, they may become more timid than usual and seek increased contact with caregivers. Behavioral changes indicative of pain may be too subtle or take too long to recognize under routine clinical situations. Similarly, sporadic observation of animal behavior may not reveal signs of pain. Except in the most severe circumstances, the signs of pain may be “masked” by behavior that is stereotypic of the species being observed. For instance, dogs may wag their tail and greet an observer at the cage door in spite of being in pain. Cats may simply hide in the back of their cage and demonstrate no behaviors that would suggest to a casual observer that they are in pain. Cats may continue to purr even when painful. Behavioral changes indicating pain may not be what we expect. A cat sitting quietly in the back of the cage after surgery may be in pain; however, pain would not be recognized if the caregiver expects to see more active signs of pain such as pacing, agitation, or vocalizing. Unfamiliarity with normal behaviors typical of a particular species or breed makes recognition of pain-induced behaviors difficult or impossible.

4.1.5 Types of Scoring Systems for Acute Pain

4.1.5.1 Preemptive Scoring System

The preemptive scoring system is a subjective scoring system based on the amount of pain an individual believes the animal will experience after a given procedure. Preemptive scoring systems assign a degree of pain (none, mild, moderate, severe) based on the procedure performed and the amount of tissue trauma involved. In essence, preemptive scoring systems follow the philosophy that if a procedure is likely to cause pain in a human, then it is likely to cause a similar degree of pain in animals. In general, the greater the amount of tissue trauma induced by a procedure the greater the assigned level of pain. Preemptive scoring systems are useful in planning perioperative analgesic strategies. Procedures inducing moderate to severe pain often require the use of multiple analgesic drugs and techniques to adequately manage pain. Preemptive scoring systems are not useful in actually determining the degree of pain felt by an individual patient or in

assessing response to therapy. Therefore it is important to keep in mind that individual patients may experience more or less pain than predicted by the preemptive pain scale.

4.1.5.2

Visual Analog Scale

The visual analog scale (VAS) is typically a straight, horizontal line, 100 mm in length, bracketed with descriptors of pain intensity (e.g., no pain, worst pain possible) on either end of the line (Figure 4-1). The VAS is a semiobjective scoring system. The human patient draws a vertical line across the line in a position that best represents his or her degree of pain. The patient may be asked to assess pain at the current time or the worst pain that occurred since the last assessment. The VAS has been used extensively in people and is generally considered to be a useful tool to assess pain and the response to therapy. The scale avoids the use of imprecise descriptive terms and provides many points from which to choose. In people, bracketing the VAS with phrases such as “no relief of pain” and “complete relief of pain” may provide more clinically useful information because patients do not all start with the same degree of pain. The use of the VAS may result in greater variability of pain scores than a simple descriptive scale. The VAS may erroneously appear as a more sensitive scale compared with other scales resulting in overinterpretation or excessive confidence in the results. The advantages of the VAS are primarily ease of use and that it provides a general sense of whether pain is getting worse or improving. A disadvantage of a standard VAS used to rate pain intensity is that pain is a multidimensional experience, and pain intensity is only one aspect of that experience. Disadvantages of the VAS in veterinary medicine occur primarily because the scale relies on an observer to identify and interpret pain behaviors. Thus observer bias may play a key role in assessing pain, leading to the possibility of over-or underdiagnosing pain. Variability of visual acuity among observers may affect the accuracy of the VAS. Interobserver variability, when more than one observer evaluates an animal, affects the accuracy of the VAS. The sensitivity of the VAS has not been determined in animals; therefore changes in VAS score should be interpreted in light of overall patient appearance. If a VAS is to be used, it is important to have all individuals within the practice that will be assessing pain receive training on the use of the scale. It should not be assumed that an untrained individual would provide a similar assessment of animal pain as would someone with more training and familiarity with the species being observed.

4.1.5.2.1

Box • 4-2 Simple Descriptive Scale

- No pain
- Mild pain
- Moderate pain
- Severe pain

4.1.5.3 Simple Descriptive Scale

The simple descriptive scale (SDS) is a semiobjective scoring system that usually consists of four or five categories or descriptions of pain intensity (Box 4-2). Each description is assigned a number, which becomes the patient's pain score. This differs from the preemptive scoring system, in that the SDS assigns a score based on observation of the animal and not the nature of the procedure performed. Advantages of the SDS are that it is simple to use and the results are not affected by visual acuity (no drawing of a line required). Disadvantages of the SDS are that it is not a sensitive scale to assess pain (it consists of only four or five categories); therefore it may overestimate or underestimate the degree of pain and the efficacy of analgesic therapy. As with other assessment tools, observer bias may play a key role in determining pain score.

4.1.5.4 Numerical Rating Scale

The numerical rating scale (NRS) is a semiobjective scoring system that consists of multiple categories in which to evaluate the patient, with descriptive definitions of pain for each category. The NRS generally uses categories that are assigned whole numbers, and the importance of each category is not weighted. The NRS prompts the observer to evaluate certain aspects of the patient that might otherwise go unnoticed (e.g., appearance of the eyes, interactive behaviors, physio-logic parameters). Advantages of the NRS include a more thorough patient evaluation than what is prompted by the VAS or SDS, an easy method to tabulate the score, and numerous categories on which to base an assessment of patient comfort.

Disadvantages of the NRS include lack of accuracy and little improvement over the SDS. Categories are generally scored by whole numbers, suggesting that equal differences exist between categories when in fact that may not be true. Numeric rating scales have been used extensively in the evaluation of postoperative pain in dogs and cats. In spite of numerous categories, painful animals may go undiagnosed. For example, a dog with severe abdominal pain may not receive a high enough number to be considered painful when using a scale designed to assess surgical pain. In the postsurgical patient, NRS may be too insensitive to detect differences in some animals that receive analgesics and those that go untreated. Thus NRS may only be able to identify those animals with extreme pain that overtly demonstrate pain behaviors and would have been identified otherwise.

4.1.5.5 Behavioral and Physiologic Responses Scale

The University of Melbourne Pain Scale (UMPS) is a scale based on specific behavioral and physiologic responses. The UMPS includes multiple descriptors in six categories of parameters or behaviors related to pain. Advantages of the UMPS may include increased accuracy over the Preemptive Scoring System, VAS, SDS, or NRS and an ability to weigh the importance of certain behaviors or parameters. The evaluation of multiple factors increases the sensitivity and specificity of the UMPS. Most importantly the UMPS relies on behavioral observations and evaluates changes in behavior or demeanor, thereby limiting interpretation and observer bias. Disadvantages of the UMPS are limited validation to date; the specific types of patients and procedures in which the UMPS would be expected to be accurate have not been elucidated. As such, the UMPS may not be sensitive enough to detect small changes in pain behaviors, particularly if patient evaluations are performed only periodically. The UMPS was designed to evaluate dogs after surgery, therefore the accuracy of the scale for other uses or for use in cats has not been established. The UMPS requires some knowledge of the demeanor (mental status) of the dog before anesthesia and surgery. Although the veterinary staff usually knows this, the dog's actual mental status when truly comfortable at home will probably not be known. In other words, the mental status of the dog after surgery will be compared with an already altered

mental status that exists simply because the dog is in a veterinary hospital and away from familiar surroundings.

4.1.5.6 Behavioral Response Scale

The Glasgow Composite Pain Tool is a scale based on specific behavioral signs believed to represent pain in the dog. The behaviors included in the scale were derived from a questionnaire of veterinarians. The expressions used to describe pain behaviors were reduced to specific words and expressions using a variety of statistical methods. The advantages of this scale include limited interpretation and bias by the observer providing increased accuracy over the Preemptive Scoring System, VAS, SDS, and NRS. An observer is asked to identify whether or not a behavior is present, rather than to interpret what various behaviors mean. Most importantly, the terms used to describe individual behaviors are specifically defined, thereby decreasing uncertainty in using the scale. Physiologic data are not included, making the scale easier to use than the UMPS and perhaps more accurate. Nevertheless, an evaluation of physiologic parameters can be added when evaluating any patient. Disadvantages of the scale are limited validation in actual animal studies and a lack of a numeric scoring system that would allow for comparison of scores over time.

4.1.5.7 Modified Pain Scale

A modified pain scale used by the Anesthesia Section at Colorado State University is presented in Figure 4-2. This is a composite scale derived from the UMPS and the Glasgow Composite Pain Tool and was developed as part of a study evaluating pain after ovariohysterectomy and castration in dogs (unpublished data). In accordance with the Glasgow Composite Pain Tool, behaviors are identified as either *present* or *absent*. Physiologic data are not included, with the exception of dilated pupils; although changes in heart rate, respiratory rate, and arterial blood pressure can be added. Salivation and vomiting are included as indicators of nausea and as occasional signs of pain. Regardless of the cause, frequent vomiting undoubtedly increases the discomfort of the patient. The modified scale provides a record to track the frequency of behaviors indicative of pain. The frequency of pain behaviors should be low or decreasing with effective analgesic therapy. If a numeric score is desired, behaviors can be assigned the number located in parenthesis. Advantages of this scale are ease of use and minimal interpretation required. Importantly, this scale uses the specific descriptors from the Glasgow scale for individual behaviors. Specific definitions of descriptors decrease interobserver variability and interpretation. Disadvantages of this scale include lack of validation by clinical studies comparing it to other scales and the use of an arbitrary numeric scale when a specific score is required. Another disadvantage is that modifications made in the scale for use in cats have not been validated to date.

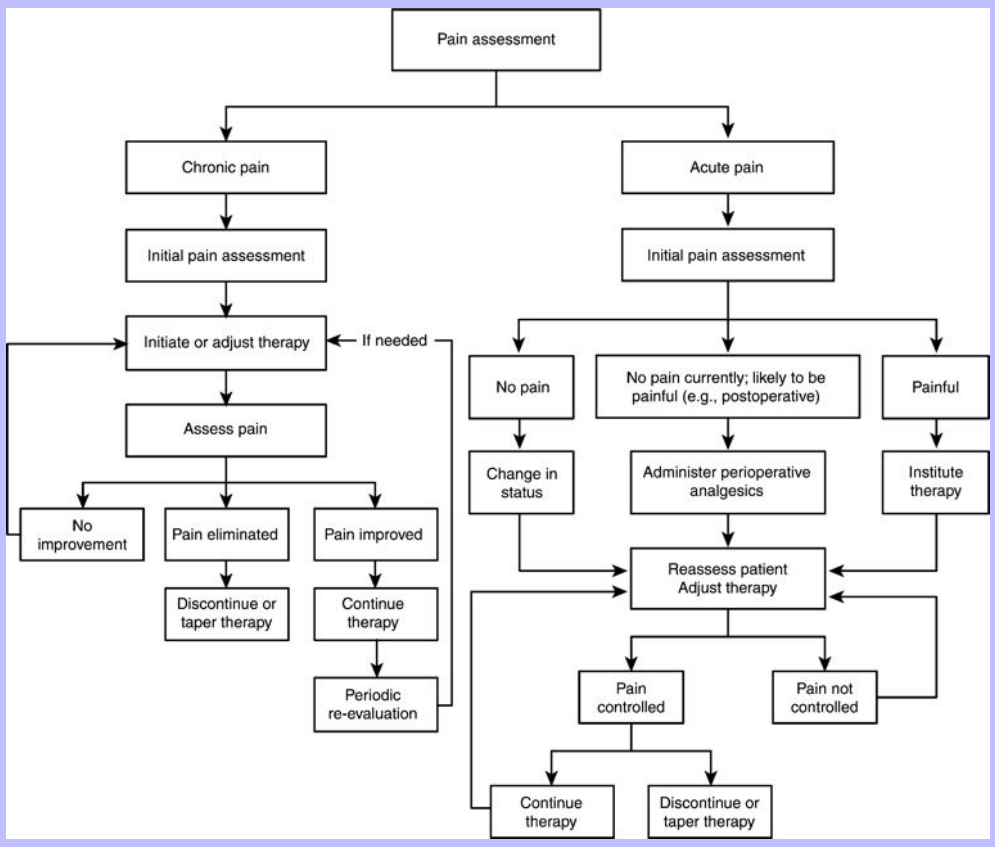
Figure 4-3 Algorithm for the assessment of acute and chronic pain.



4.1.5.8

Assessment of Chronic Pain

A number of pathologic states, such as osteoarthritis, cancer, and dental disease may cause chronic pain. The clinical signs of pain will depend on the underlying cause and may range from subtle to obvious. Chronically painful animals may experience acute flare-ups of pain that prompt an owner to seek veterinary assistance. For example, a dog with osteoarthritis may experience an episode of acute pain after excessive strenuous activity. In general, the clinical signs of chronic pain tend to be subtle and may be difficult to recognize during a brief examination in the veterinary clinic. Clinical signs suggestive of pain include decreases in activity, reluctance to get up or play, changes in sleeping patterns, changes in appetite, changes in social interactions and grooming habits, and other behavioral changes (e.g., aggression). Obviously, these clinical signs are also suggestive of numerous other medical conditions. Careful history taking, a thorough physical examination, appropriate laboratory tests, and the occasional response to analgesic therapy are used to diagnose the role that pain is playing in the patient's symptomology. A key aspect of treating the veterinary patient with chronic pain is the absolute requirement to have a close working relationship with the patient's caregiver. As noted in Figure 4-3, periodic reevaluations and possible adjustments in therapy are critical components in managing the chronically painful patient. As noted previously, species-specific pain scales need to be developed that are

sensitive and specific for the type of chronic pain experienced. In the meantime, simply having the caregiver keep a log of daily behaviors may provide useful insight into the efficacy of therapy.

5 CHAPTER • 5 Pain Management

Steven C. Budsberg

The sensation of pain, whether actual or anticipated, triggers a myriad of responses within the body. Pain is a complex experience involving not only the transduction of noxious stimuli from the periphery to the central nervous system (CNS) but also the processing of the stimuli by the higher centers in the CNS. Recent advances have been made in understanding the molecular mechanisms of pain yielding new, important information that is now being incorporated into clinical pain management at all levels. This molecular information coupled with the increasing data supporting the importance of pain modulation on normal systemic physiologic functions has led to increased use of analgesics. Yet despite all the new information, it is humbling to realize how little is known about pain; thus the ability of clinicians to intervene effectively and correctly in this treatment area is still in its infancy.

This chapter will focus on prompting proper use of analgesics in dogs and cats. It must be realized that despite an increased awareness of pain management, many animals are not currently receiving analgesics or are receiving inadequate amounts. The goal of this chapter is to guide the reader through a systematic approach to considering analgesic use in patients. However, the reader must remember that the current discussion is very limited. At least two recent publications have provided excellent compilations on pain and its management (see References). To that end, the present discussion heavily cites these two publications.

First, clinicians must acknowledge that their patients are in pain. In small animal practice, the diagnosis of pain is either observational or presumptive. Several studies have examined the attitudes of veterinarians, physicians, and associated health care providers about pain recognition and management. At best, results of these studies reveal significant knowledge deficits in all groups. These deficiencies contribute to the inconsistent recognition and treatment of pain. In the vast majority of cases the error is undermedication of patients. The paradigm that should be used is to assume the animal is in pain until proven otherwise. Thus the question is not whether analgesia is appropriate but rather what therapy can be instituted to maximize pain relief while minimizing potential side effects and costs. Two common false assumptions about managing pain are that (1) one drug at one dose will work for all patients, and (2) pain management is an “all or none” occurrence. First, each patient may require different drugs, doses, or even a combination of therapies to maximize pain relief. Secondly, a clinician should work toward the goal of pain reduction and subsequent improved patient comfort. Pain management should be individualized to the patient based on the mechanism of pain induction in that patient. Considerations with each patient must include whether the pain is acute or chronic, the type of pain, and the perceived intensity of the pain.

To begin to logically formulate a pain management plan, clinicians need to briefly review the peripheral and central mechanisms of pain. Peripheral sensitization is defined as enhanced sensitivity of nociceptive nerve endings. Nociceptive pain is evoked by activation of peripheral nociceptors. These sensory receptors are often classified by their size and degree of myelination and according to their responses to mechanical, thermal, and chemical stimuli. During inflammation, a high proportion of somatic and visceral peripheral nociceptors can be sensitized by various mediators, including bradykinin, prostaglandin (PG), various leukotrienes, serotonin, histamine, and perhaps free radicals. Tissue injury causes alterations in sodium-and calcium-mediated channels causing the C and A-δ fibers to send action potentials to the CNS. If the injury is persistent, additional recruitment of A-β fibers and silent nociceptors occurs along with alterations in ion activity. The action potentials are propagated to the CNS. Central sensitization is defined as enhanced sensitivity of nociceptive spinal dorsal horn neurons to sensory stimulation. Central sensitization is triggered by impulses in nociceptive C fibers. The neural mechanisms that underlie central sensitization are still being explored. Central sensitization is also evoked by several mediators in the dorsal horn of the spinal cord, including PG, nitric oxide (NO), glutamate and other excitatory amino acids, and substance P. Ascending pathways transmit pain to the brain. In the brain, complex modulation and processing occur at several sites. Finally, a short

discussion of the concept of neuronal plasticity is needed before moving on to treatment. *Neuronal plasticity* refers to changes that occur in the established nervous system. More simply stated, it is the alteration of physiologic response based on previous stimuli. Pain perception by an individual for an identical stimuli may vary each time the stimuli is present. Injury, inflammation, and different diseases can cause neuronal plasticity. A subsequent increase in pain perception takes place by means of either increased excitatory or decreased inhibitory mechanisms. At a molecular level, pain hypersensitivity is the consequence of early posttranslational changes, including phosphorylation of membrane-bound proteins and later transcriptional dependent changes in genes at multiple levels along the nociceptive pathway. Neuronal plasticity can result in short-term changes that last minutes or hours, or it can result in permanent long-term changes.

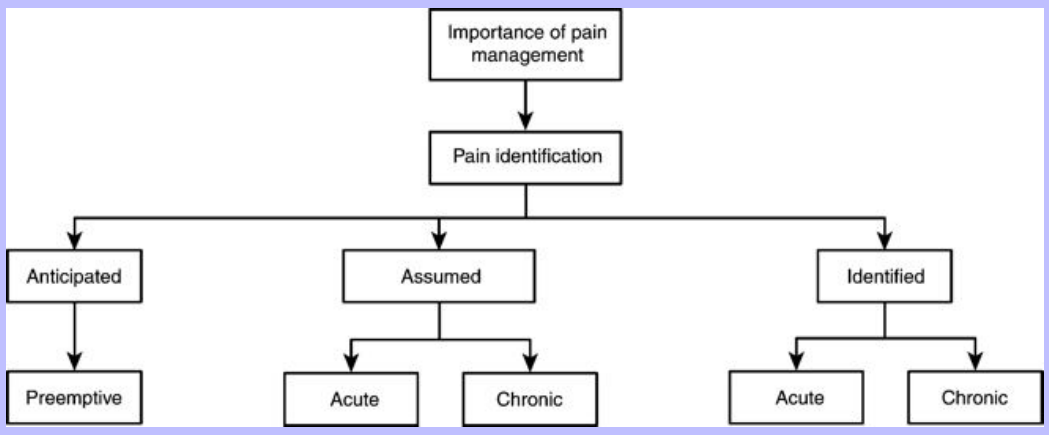
The management of pain involves a myriad of events (Figure 5-1). Although the complexity of the process can seem overwhelming, it does offer several sites for potential intervention. The first concept to consider is the timing of analgesic initiation. Intuitively one should treat pain as soon as it occurs. The three basic periods to consider in pain management are (1) acute, (2) chronic, and (3) preemptive. Although the first two time periods are self-explanatory, the concept of preemptive analgesia is somewhat new but has already become a staple to the management of pain, especially perioperative pain. In essence, an injury causes central sensitization that leads to a prolonged and amplified hypersensitivity state in the patient. By giving drugs as a "preemptive analgesic," one attempts to prevent the induction of the aforementioned central sensitization, thus preempting the hypersensitivity state after the injury (which is usually surgically induced).

Anatomically, the sites of pain modulation are peripheral and central (both spinal and supraspinal). Attenuation at these sites can be done either by local infusion or systemic administration. As an example, nerve blocks (peripherally or epidurally) using lidocaine block sodium channel propagation of action potentials during painful stimuli. Another underused local administration is direct infusion into joints after arthrotomy. The instillation of local anesthetic agents have been shown to dramatically decrease surgically induced pain. Agents used in local infusions include local anesthetics, opioids, and nonsteroidal antiinflammatory drugs (NSAIDs). Systemic administration can alter both peripheral and central nociception. Interestingly, systemic NSAIDs act peripherally and spinally, whereas opioids can act peripherally, spinally, and supraspinally. Therefore clinicians must be familiar with the drugs to maximize their mechanistic effect and to administer the appropriate drugs according to their pharmacokinetic profiles. Finally, great benefit comes from combining drugs that act on different mechanisms of nociceptive modulation to enhance additive and synergistic effects; this is known as a *multimodal* or *balanced treatment* approach. Multimodal therapy is becoming more commonplace, and its use will continue to increase in small animal analgesia therapy.

22

23

Figure 5-1 Algorithm for pain management.



The following is an overview of the major analgesic drugs that should be considered for use in the management of acute and chronic pain. Morphine and other pure μ-receptor agonists including fentanyl are often the first choice for severe pain (almost always acute pain) because their analgesic efficacy is very high. These drugs act at each target site (peripheral, spinal, and supraspinal). They show a sigmoidal dose and effect relationship that allows their dose to be adapted to the intensity of the acute pain perceived. The analgesic effects of opioids are related to their plasma concentration. Opioid drugs diffuse through the blood-brain barrier in proportion to their lipophilicity and the concentration gradient. Hepatic metabolism of opioids may produce pharmacologically active metabolites (morphine 6-glucuronide [M6G] is 20 to 40 times more potent than morphine). The phenylpiperidine analgesics, including fentanyl, are potent μ-receptor agonists with moderate to high lipid solubility. They diffuse rapidly through lipid membranes. The major pharmacodynamic differences between these drugs are potency and rate of equilibration between plasma and effect site. The next group of opioids to consider is the mixed agonist-antagonist agents. All opioids with mixed agonist-antagonist activity including butorphanol have limited flexibility in dosing in comparison with pure agonists, and they show ceiling effects for analgesia. Finally, partial agonist opioids (e.g., buprenorphine) exist. These compounds show high affinity for the μ-receptor but with low intrinsic activity. These drugs have a dose-response curve that exhibits a ceiling effect at less than the maximal effect produced by a full agonist. Therefore buprenorphine does not provide better analgesia than morphine but it may produce fewer side effects. However these side effects are often overemphasized and have been incorrectly used, more often than not, to justify avoiding the opioids in practice.

NSAIDs are another group of drugs that are rapidly becoming common as use for pain management. These agents are now available in both oral and parenteral formulations. Their analgesic effects result primarily from the inhibition of the cyclooxygenase (COX) isoenzymes (including COX-1, COX-2, and specific gene variants) that synthesize proinflammatory prostanoids. For this discussion, the primary prostanoid is prostaglandin E_2 (PGE_2) in the traumatized and inflamed areas. PGE_2 alters peripheral sensitization by binding to G protein–coupled receptors that increase levels of cyclic adenosine monophosphate (cAMP) within nociceptors, thereby increasing the threshold of activation of the nociceptors. Centrally, PGE_2 likely increases the excitability of dorsal root ganglion (DRG) cell bodies by reducing membrane depolarization needed to initiate action potentials and increase repetitive spiking. This is done by phosphorylation of the channel protein by cAMP-dependent proton kinase. The expression of COX-2 enzyme in the spinal neurons is believed to contribute to neuronal plasticity and central sensitization. NSAIDs are used today for the treatment of postoperative pain, with or without supplemental opioid agents. NSAIDs are useful for achieving multimodal or balanced analgesia given the multiplicity of mechanisms involved in pain. Clinically it must be remembered that NSAIDs are enzyme inhibitors, and their onset of effect is slower than that of opioids. Thus to be clinically relevant it has been recommended that clinicians administer NSAIDs before surgery to enhance their pain-relieving and opioid-sparing effects in the immediate postoperative period.

The α_2-agonists (medetomindine, xylazine) are also commonly used in clinical practice for both sedation and analgesia. These drugs act both peripherally and centrally by activation of α_2-receptor subtypes. The large variations in receptor structure, location, and specificity within and between species are important factors for the clinician to consider and may alter dose and expected effect within a particular patient. This group of drugs does have the potential for significant cardiovascular and respiratory side effects. They are, however, widely used very successfully in small animal practice.

The use of N-methyl-D-aspartate (NMDA)–receptor antagonists (most commonly ketamine) in pain management has begun to rapidly increase in small animal practice. Studies suggest that the spinal dorsal horn NMDA–receptor has an important role in mechanisms underlying central sensitization. NMDA–receptor antagonists lessen the hyperactivity of dorsal horn neurons after prolonged activation of primary afferent neurons and inhibit nociceptive behavior induced by peripheral tissue or nerve injury. Ketamine is a noncompetitive NMDA–receptor antagonist. Analgesia obtained with

ketamine occurs at serum concentrations one tenth to one fifth of an anesthetic dose, with a highly significant correlation between pain relief and serum concentrations of ketamine.

Finally, one should strongly consider local anesthetics in the management of pain. Local anesthetics reversibly block transmission of nerve fibers. Blockade of the sodium channels in the cell membranes causes an inhibition of the generation and conduction of the nerve impulses. The size and the presence of myelination drastically alter different nerve fiber susceptibility to local anesthetic blockade. Examples of local pain management include local tissue infiltrations, direct nerve blocks, or intraarticular administrations. The reader should remember that local blocks are easily combined with systemic analgesics to provide economic and effective mutimodal therapy.

Some key points should be remembered in reference to the management of pain. First, with pain management one must think in terms of mechanism-based, rather than symptomatic, treatment of pain. The clinician must focus on the reason the animal is in pain, not just on the fact that the animal is showing pain or discomfort (or the intensity of that reaction). To do this, one must understand the different types of inciting stimuli, neuronal pathways involved, and most importantly the systemic consequences of pain to the patient. These pathophysiologic considerations should lead the clinician to more multimodal therapy with improved clinical success without considerable increased costs. Finally, from a practical point of view the veterinarian needs to educate clients and staff about the importance of pain management. The use of analgesics should not be an option given to owners, it should be an integral part of each patient's therapy. Clinicians should establish protocols for assessing pain and what drugs to use when pain is encountered or anticipated. This is no different than the different anesthesia protocols each clinic has today. In addition, clinicians should routinely assess and record pain and provide a scoring system chart on each cage that is easy to use and read. This will begin to sensitize the staff to the course of pain in a particular disease or surgical procedure. The bottom line is that as one appreciates the negative side effects of pain and becomes more willing to treat it, everyone benefits—the patient, the client, and the clinician.

6 CHAPTER • 6 Syncope

Sandra L. Minors

Sudden, transient and unpredictable loss of consciousness has both intrigued and frustrated physicians throughout the ages. Hippocrates is credited with having made the first description of syncope; the medical term for *fainting* is derived from the Greek term *syncoptein* (to cut short). Despite being one of the oldest recorded medical problems, syncope remains an alarming symptom. This is largely because the causes of syncope are diverse, ranging from benign to life threatening. As aptly stated by one observer, “The only difference between syncope and sudden death is you awake from one.”

The definition of syncope is a sudden and brief loss of consciousness with a loss of postural tone, from which recovery is spontaneous. The pathophysiology of all forms of syncope consists of a sudden decrease in or brief cessation of cerebral blood flow and nutrient delivery to the parts of the brain subserving consciousness (i.e., the brain stem reticular activating system, and both cerebral hemispheres) (Figure 6-1). The brain has very limited storage of high-energy phosphates for oxidative phosphorylation and requires continuous delivery of both oxygen and glucose for normal function. Studies in humans have shown that after 5 to 15 seconds of cerebral anoxia, loss of consciousness, pallor, and muscle relaxation occur. More prolonged cerebral ischemia (>15 seconds) is associated with generalized tonic spasms and incontinence. Loss of vascular resistance and decreased cardiac output are responsible for the vast majority of syncopal events as a result of transient systemic hypotension. Episodic weakness or presyncope represent less severe grades of syncope without loss of consciousness, whereas more prolonged hypotension results in shock.

6.1 LOSS OF VASCULAR RESISTANCE

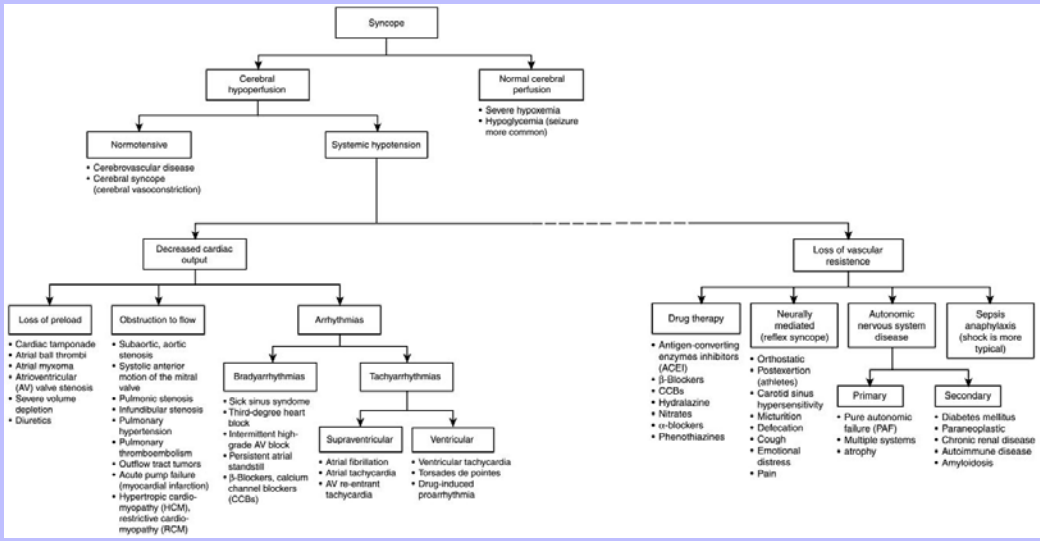
Changes in posture and physical exercise are among many activities that challenge cerebral perfusion. Baroreceptors located in the arterial and cardiopulmonary regions evolved to closely regulate blood pressure. Information from the baroreceptors is relayed to the central nervous system (CNS), where neuronal cell groups regulate reflex cardiovascular activity through changes in sympathetic nervous system (SNS) and parasympathetic nervous system (PNS) outflow. Failure of these homeostatic mechanisms can result in hypotension and syncope. This type of syncope is referred to as *neurally mediated syncope* (NMS), reflex, vasovagal, or neurocardiogenic syncope. This is the most common cause of syncope in humans and is the most likely cause in healthy patients.

NMS is characterized by arterial vasodilation (SNS withdrawal) in the setting of relative or absolute bradycardia (PNS stimulation). Correction of the bradycardia does not necessarily alleviate symptoms of syncope because of the concurrent vasodepressor response. Neurally mediated syncope typically has specific triggers, such as strong emotion, pain, or strong vagal stimulation (e.g., cough, micturition, defecation, swallowing). Patients may experience prodromal signs of autonomic stimulation that include pallor, nausea, mydriasis, hyperventilation, and bradycardia. Complete recovery from NMS tends to be slower than with other causes of syncope. These episodes are believed to represent a hypersensitive autonomic system that overresponds to various stressors in predisposed individuals. The exact cause of NMS has not been elucidated and is likely heterogenous. The risk of sudden death is thought to be very low in NMS. Markedly prolonged periods of asystole may rarely lead to sudden death.

NMS can be classified as postural (associated with the upright position), central (occurring in response to strong emotional stimulation or epileptic discharges), and situational (after specific stimulation of sensory or visceral afferents). In dogs, central and situational NMS is recognized. Examples include syncope induced by hyperexcitability or hyperventilation (or both), vomiting, excessive pulling on a lead, exertion, and cough. Long

periods of ventricular asystole (>8 seconds) have been documented to precede cough-induced syncope. Boxers seem predisposed to NMS. Vigorous exercise, excitement, or both typically precede collapse, which is characterized by the classic pallor, absolute or relative bradycardia, and gradual recovery. In pugs, syncope associated with stimulation of afferent fibers from the laryngeal or nasal mucosa, leading to decreased blood pressure, cardiac standstill, and apnea has been demonstrated.

Figure 6-1 Pathophysiology and differential diagnosis for syncope. *A-V,* Atrioventricular; *RV,* right ventricular; *HCM,* hypertrophic cardiomyopathy; *RCM,* restrictive cardiomyopathy; *CCB,* calcium channel blocker; *ACEI,* angiotensin converting enzyme inhibitor.



NMS represents only one aspect of a broad, heterogenous group of disturbances of the autonomic nervous system (ANS). In contrast to intermittent periods of hypotension seen in reflex syncope, other patients can develop failure of the ANS to function under normal circumstances. In contrast to patients with reflex syncope, patients suffering from ANS failure syndromes have many other complaints relating to ANS disturbances in other organ systems (e.g., disruptions in bladder and gastrointestinal function). Autonomic failure secondary to a wide variety of disorders, including diffuse systemic illnesses, such as renal failure, cancer, and diabetes mellitus may produce varying degrees of disruption in autonomic function, leading to hypotension and syncope.

6.2 REDUCED CARDIAC OUTPUT

In the evaluation of syncope, the presence of structural heart disease (such as cardiomyopathy, congenital and valvular heart disease) has emerged as the most important factor for predicting the risk of death and the likelihood of arrhythmias. Underlying heart disease, irrespective of the cause of syncope, is the factor associated with an increased risk of death.

Malignant causes are more likely if syncope is exertional. Exertional syncope is a common manifestation of all types of heart disease in which cardiac output is fixed and does not rise normally (or falls) with exercise. Systemic vascular resistance normally decreases with exercise because of arteriolar dilatation. This decline in peripheral

vascular resistance normally is compensated for by an increase in cardiac output, thus maintaining arterial pressure and cerebral perfusion. In conditions that cause severe obstruction to flow, cardiac output may not increase, leading to hypotension and syncope. Exertion may also lead to neurally mediated syncope in patients with severe aortic or subaortic stenosis. Heightened SNS stimulation and high intraventricular pressures associated with exercise are thought to stimulate ventricular mechanoreceptors that normally respond to stretch. The resultant afferent neural traffic to the brain stem is thought to mimic conditions of hypertension, leading to a paradoxic sympathetic withdrawal and vagal simulation despite systemic hypotension. Abnormal vascular responses to exercise as a result of altered baroreceptor function have been shown to cause syncope in human patients with hypertrophic cardiomyopathy. Patients who demonstrated vascular instability were also at markedly increased risk of sudden cardiac death.

In patients with CHF, the combination of a low cardiac output, volume depletion caused by diuretic use, and vasodilator therapy likely all play a role in syncope. The propensity for arrhythmias is exacerbated in CHF. In addition, patients with overt pulmonary congestion may be prone to exertional collapse because of hypoxia-induced pulmonary vasoconstriction leading to pulmonary artery hypertension. Many animals with congestive symptoms that collapse will not experience syncope once their heart failure is controlled.

Arrhythmic causes for syncope include tachyarrhythmias and bradyarrhythmias. Tachyarrhythmias lead to collapse as the result of the abrupt reduction in cardiac output related to the marked reduction in diastolic filling. Supraventricular tachyarrhythmias in young dogs without structural heart disease should raise one's suspicion of atrioventricular (A-V) reentrant tachycardias caused by accessory pathways. In the presence of substantial heart disease and concomitant atrial enlargement, atrial tachycardias and atrial fibrillation (sustained or paroxysmal) are common. Supraventricular arrhythmias are less likely to lead to sudden death than ventricular tachyarrhythmias.

Life-threatening ventricular tachyarrhythmias occur most commonly in patients with advanced heart disease of any cause. Boxer and Doberman cardiomyopathies are considered particularly high risk for sudden death, which may be the first manifestation of malignant ventricular arrhythmias in these breeds. Advanced mitral valve disease can result in ventricular arrhythmias and sudden cardiac death. Because exercise can exacerbate subendocardial myocardial ischemia, ventricular tachyarrhythmias may be provoked by exertion in all types of severe heart disease. Exertional sudden death is common in severe subaortic stenosis.

Bradyarrhythmias can lead to very subtle symptoms, such as occasional stumbling, to very dramatic symptoms, such as multiple transient collapses on a daily basis. Seizure activity caused by cerebral hypoperfusion (termed *convulsive syncope*) is most likely to occur in the setting of bradyarrhythmias, as a result of prolonged periods of asystole. Convulsive syncope in patients with intermittent conduction disease is commonly mistaken for neurologic disease. Sick sinus syndrome (SSS) is most commonly associated with the miniature schnauzer but may occur in other breeds. By the time these dogs are syncopal, easily detected abnormalities exist in the rhythm during auscultation and a routine electrocardiogram (EKG). Multiple periods of asystole typically occur, sometimes oscillating with runs of supraventricular tachycardia. Dogs with third-degree heart block may be syncopal with the initiation of their disease, but in some the arrhythmia is an incidental finding. Many dogs with chronic third-degree heart block are not syncopal, presumably as a result of compensatory changes of the cardiovascular system (volume retention) and a stable escape rhythm. Sudden death is surprisingly rare in both SSS and third-degree heart block. Some dogs and cats are syncopal because of intermittent high-grade A-V block characterized by long periods of ventricular asystole. These animals may have extended periods of sinus rhythm, although signs of conduction disease (first-degree heart block, bundle branch block, and intermittent second-degree heart block) should raise one's suspicion of more severe intermittent heart block. It is also worth noting that the symptoms of asystole (opisthotonus, syncope, seizure) are delayed, usually occurring at the termination of the pause, once the rescue rhythm has resumed. Therefore a bradycardic arrhythmia should not be dismissed based on finding a relatively normal heart rate in a recently collapsed patient.

6.3 APPROACH TO THE SYNCOPAL PATIENT

The evaluation of a patient with syncope involves excluding other disorders of consciousness (e.g., presyncope, dizziness, vertigo, sleep disorders, seizure), then determining the cause for the syncopal episode. Causes for episodic weakness should be considered when collapse occurs without loss of consciousness. Dizziness and vertigo do not result in a loss of consciousness or postural tone. Narcolepsy and cataplexy are rare disorders in animals that may mimic syncope. These disorders are characterized by “sleep attacks” in the former and rapid onset and termination of partial to complete flaccid paralysis in the latter. These are heritable disorders in Doberman pinschers, Labrador retrievers, daschunds, and miniature poodles. Seizure is the primary differential for syncope. Distinguishing syncope from seizure can be difficult. Based on the classical features of each, the differentiation seems straightforward; however, in reality the boundaries can be indistinct (Table 6-1).

The generalized epileptic or motor seizure is the classic manifestation of a primary neurologic event; however, complex partial seizure activity is now recognized in veterinary medicine. The primary abnormality of the complex partial seizure is a decrease in consciousness. Motor activity may occur along with autonomic signs such as salivating, urinating, and defecating. In humans, *temporal lobe syncope* is the term used for complex partial seizure in which a loss of consciousness resembles a syncopal episode.

In approximately 40% of patients with syncope, the cause is undetermined. The cause of syncope is difficult to diagnose in many cases because of the transient and often infrequent nature of the events and the fact that syncope rarely occurs in settings where vital functions such as the heart rate, rhythm, and blood pressure can be monitored while symptoms are being displayed. From the foregoing discussion it should be clear that the cornerstone of evaluation of a syncopal patient is thorough history and physical examination. When carefully performed these will have a greater diagnostic yield (45%) than a battery of laboratory tests. This begins with a detailed history, for which veterinarians must rely on witnesses. Because of the distressing nature of these events, owners are often unable to provide an accurate account of the events. For example, their estimation of time is often exaggerated. The frantic struggling to rise after collapse may be interpreted as the tonic clonic limb motions characteristic of generalized seizure. The key questions that should be part of every history taking should extract information about the event (see Table 6-1), age at first episode, frequency of episodes, interepisode duration, symptoms of underlying disease, medications, relation to meals and administration of medications, and relation to exercise. Breed predisposition for cardiac disease or epileptic seizures can also be important.

Table • 6-1 General Features Differentiating Syncope versus Seizure

	SYNCOPE	SEIZURE
Precipitating event	Exertion, pain, micturition, defecation, cough, stressful event	
Prodrome	Seconds	Minutes to days
	Acute weakness, staggering, vocalization, autonomic stimulation	Atypical behavior (e.g., anxious, more withdrawn, attention seeking) (+/–) Vomit
Aura	None	None (epileptic seizure)
		Marks onset of partial seizure, often with secondary generation
Event characteristics	Opisthotonus	Chomping, hypersalivation
	Motionless	Tonic/clonic limb motion
	Flaccid or rigid extension of limbs	Motor activity
	Exception: convulsive syncope	*Exception:* complex partial seizure or akinetic or temporal lobe seizure
	Duration often transient (<1 minute)	Duration often 1 to 2 minutes (>5 minutes suggests seizure versus syncope)
Recovery	Rapid recovery of normal mentation	Slowness returning to consciousness
	Often able to walk within minutes	Disorientation (commonly 10 minutes or longer)*Exception:* recovery can be rapid
	Exception: neurally mediated syncope (NMS) may be a more prolonged recovery	

A thorough physical examination should then be performed. Because cardiac disorders are most likely to result in a risk of sudden death, it is important to search for any evidence of cardiovascular disease. A neurologic examination is also very important to look for evidence for underlying neurologic disease. Interepisode abnormalities may point to the causes for a subacute or chronically reduced cardiac output (e.g., cardiac tamponade, pulmonary thromboembolism), severe systemic disorders (e.g., hemorrhage, severe anemia), or neurologic disease (e.g., abnormal gait or mentation). Once cardiac disease and other malignant causes for syncope (e.g., pulmonary thromboembolism) are excluded, then more benign causes such as NMS and complex partial seizure must be considered. Thus even in the absence of a definitive diagnosis, an owner's mind can be put at ease in most cases.

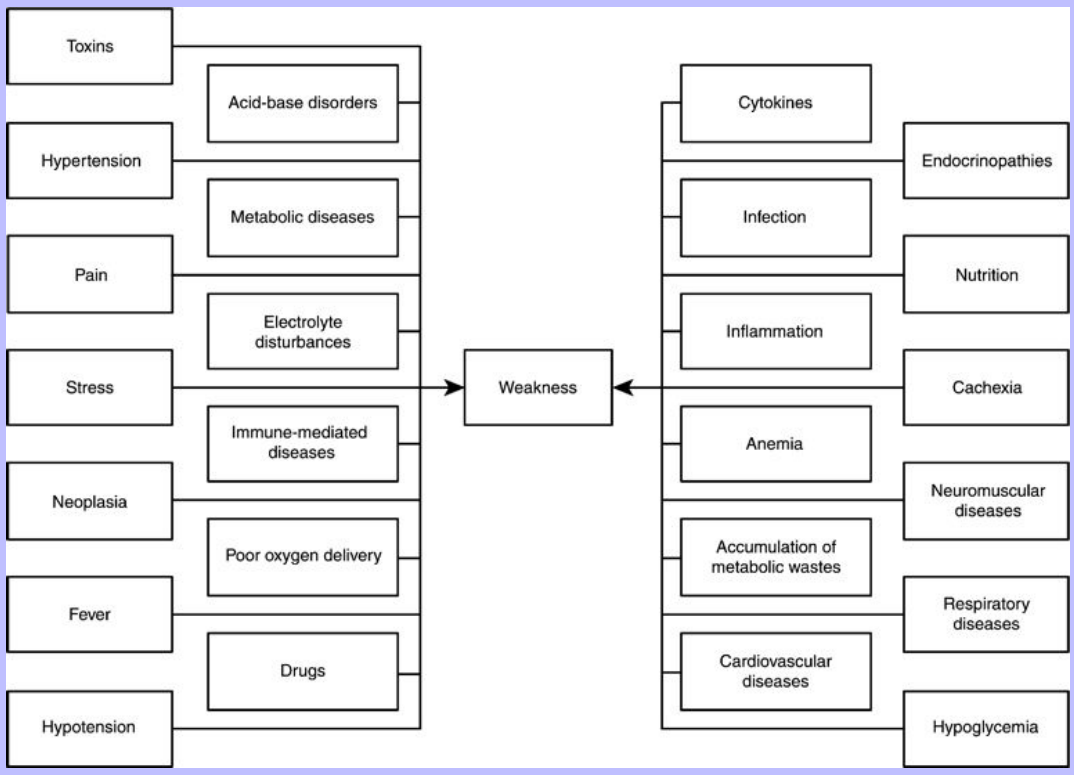
7 CHAPTER • 7 Weakness

Rhonda L. Schulman

Weakness is a common presenting complaint in small animal medicine. In veterinary medicine, the terms *fatigue* and *lethargy* are often used synonymously with weakness. A multitude of diseases can result in weakness, often making this presenting complaint a diagnostic challenge (Figure 7-1).

The patient's history can provide many important clues as to the cause of the weakness. In addition to routine questions regarding time course, concurrent illness, medications, and familial history, the owners should be asked about any associations with either exercise or time of day. For example, patients with disorders of glucose homeostasis may typically display symptoms either after eating or fasting. Classically, myasthenic dogs exhibit profound weakness after short bursts of normal activity.

Figure 7-1 Causes of weakness.



The patient's signalment will assist in ordering the differential list. Purebred animals are susceptible to breed-specific conditions that can result in weakness. The age of the patient may be more in accordance with some differentials. Puppies and kittens will be more likely to suffer from congenital diseases, portosystemic shunts, hypoglycemia, toxin exposure, and infectious diseases, whereas geriatric patients may present secondary to neoplastic conditions or major organ dysfunction. Immune-mediated diseases are more prevalent in female dogs.

A thorough physical examination is mandatory. Pain on manipulation of joints or long bones may suggest an underlying orthopedic problem, manifesting as weakness. Dermatologic signs such as symmetrical alopecia might indicate an endocrine disorder. Primary cardiovascular disease may be apparent during examination of mucous membranes, capillary refill time, thoracic auscultation, and peripheral pulses. Because many neurologic disorders can also result in weakness, a complete neurologic examination is indicated in the weak patient.

28

29

In some cases a specific finding during the initial physical examination and laboratory analysis results in a definitive diagnosis; unfortunately, many of the conditions resulting in weakness have nonspecific clinical signs and laboratory findings. As a result the initial diagnostic evaluation is used to prioritize differential diagnoses and identify additional diagnostic tests. This chapter discusses the different mechanisms and diseases that result in weakness.

7.1 SPECIFIC MECHANISMS AND DISEASES

7.1.1 Metabolic Diseases

Metabolic diseases are among the most common causes of weakness. Major organ dysfunction can result in weakness through many pathways, such as accumulation of metabolic products, cytokine production, electrolyte imbalances, acid-base disorders, anemia of chronic disease, and nutritional disturbances. Renal and hepatic failure are two examples of metabolic diseases that cause weakness by multiple mechanisms. Biochemical evaluation is essential in the diagnosis of metabolic disorders.

7.1.2 Electrolyte Disorders

Electrolyte imbalances accompany a multitude of conditions and are often the component of the disease that leads to the clinical sign of weakness. Mild changes in electrolyte levels rarely cause weakness. Significant hypokalemia may result from excessive loss (gastrointestinal, urinary) or be iatrogenic in nature (fluid diuresis, diuretics). Hyperkalemia, as is seen with hypoadrenocorticism and urinary tract obstruction or rupture, also results in weakness. Sodium imbalances, both increases and decreases, can result in weakness. Hyponatremia is seen in hypoadrenocorticism, congestive heart failure, liver diseases, and losses through the gastrointestinal system and third space. Hypernatremia may be seen with hyperaldosteronism, salt poisoning, and free-water loss. Perturbations in calcium homeostasis are an important cause of weakness. Hypocalcemia produces excessive excitability of the nervous system, manifested as tetany and possibly seizures. Between bouts of tetany, patients may exhibit weakness. Common causes of hypocalcemia include hypoparathyroidism, renal disease, ethylene glycol toxicity, and eclampsia. Hypomagnesemia may also result in weakness. Hypomagnesemia is prevalent in critically ill patients because of renal and gastrointestinal losses coupled with decreased intake.

7.1.3 Acid-Base Disorders

Disturbances in blood pH can accompany many metabolic conditions and can be seen with pulmonary disease. Drugs and toxins may also lead to acidosis or alkalosis. Weakness can be seen with either disorder.

7.1.4 Inflammatory Conditions

Inflammation accompanies many disease processes such as pancreatitis, hepatitis, neoplasia, infectious disease, and immune-mediated conditions. Systemic inflammation can result in pyrexia, negative energy balance, cytokine production, anemia, and acid-base disorders, all exacerbating signs of weakness. Many of these changes

are mediated by increased cytokine production in response to the inflammatory stimuli. Certain cytokines, such as interleukin (IL)-1, IL-6, and interferon (IFN)-α, directly cause fatigue via central pathways. Cachexins, such as IL-1, IL-6, IFN-γ, and tumor necrosis factor (TNF)-α suppress hunger and promote muscle wasting. Cytokine inhibition of erythropoiesis, resulting in anemia, indirectly contributes to weakness.

7.1.4.1 Infectious Diseases

Bacterial, viral, fungal, rickettsial, protozoal, or parasitic agents can infect any organ or body system. The presenting signs typically indicate the involved organ, such as coughing with respiratory disease or dysuria with prostatitis, as well as nonspecific signs of infection, such as weakness and inappetance. The infecting agent may produce toxins that cause weakness in addition to this being related to the resultant inflammation and organ dysfunction secondary to the infection.

7.1.4.2 Immune-Mediated Diseases

Generalized weakness or exercise intolerance is a common component of many immune-mediated disorders. Immune-mediated diseases may lead to anemia, joint or muscle disease with resultant pain, hepatic or renal dysfunction, and inflammation and chronic wasting. Through any or all of these mechanisms, patients suffering from a variety of immune-mediated diseases will display weakness.

7.1.5 Anemia

Anemia, with the resultant decrease in oxygen delivery to the tissues, can cause weakness. The presence of weakness or exercise intolerance does not specify the pathophysiologic mechanism resulting in the anemic state. Often more severe signs will be seen with acute blood loss than will be noted with more chronic cases, even if the magnitude of the anemia is greater in the chronic case. With chronic diseases, the patient has more time to adapt to the anemia, and clinical signs may be subtle.

7.1.6 Endocrine Diseases

Weakness can be seen with almost every endocrine disease including diabetes mellitus, hypothyroidism, hypoadrenocorticism, hyperadrenocorticism, hypoglycemia, hyperparathyroidism, hypoparathyroidism, and pheochromocytoma. Hyperthyroidism uncommonly manifests as weakness. Until a severe crisis occurs, owners and veterinarians miss early, nonspecific episodes of weakness caused by hypoadrenocorticism. Endocrine disturbances can result in weakness via various mechanisms. Many endocrinopathies, such as hypoadrenocorticism, hypo-and hyperparathyroidism, and diabetes mellitus can produce weakness as the result of electrolyte abnormalities. Neuropathies and myopathies may be seen with diabetes mellitus and hypoglycemia, as well as hyperadrenocorticism and hypothyroidism.

7.1.7 Cardiovascular Disease

The physical examination will often be strongly suggestive of cardiovascular disease if the dysfunction is of sufficient severity to induce exercise intolerance. Heart murmurs will frequently be ausculted in these patients. Crackles may be heard if the patient is suffering from left heart failure. Right heart failure can produce a variety of abnormalities that may be detected on physical exam, including jugular pulses, ascites, and decreased heart and lung sounds secondary to pleural effusion. Often, the biggest diagnostic challenge is establishing that a heart murmur does not signify heart disease of a nature sufficient to induce exercise intolerance. Cardiovascular

disease results in the clinical sign of weakness caused by poor cardiac output leading to diminished oxygen delivery to the tissues or by cardiac cachexia. Valvular disease tends to cause exercise intolerance only when it has progressed to congestive failure. Because of the associated septicemia, bacterial endocarditis usually results in extreme lethargy. Arrhythmias may manifest as intermittent weakness. Diseases resulting in pericardial effusion often produce profound weakness and potentially sudden collapse.

7.1.8 Blood Pressure

Alterations in blood pressure can produce weakness, often episodically. Hypotension can result from cardiac dysfunction, hypovolemia, or decreased vascular tone. Hypotension creates poor perfusion and oxygen delivery. Systemic hypertension damages many organs, including the heart, brain, kidneys, and eyes. Systemic hypertension is usually a secondary problem in veterinary patients, with underlying diseases including heart disease, renal disease, hyperthyroidism, hyperadrenocorticism, and diabetes mellitus. Caution must be exercised when treating hypertension to not create hypotension.

29

30

7.1.9 Respiratory Diseases

Similar to heart disease, respiratory disease may be obvious during the initial physical examination. Historical complaints frequently include coughing, alterations in respiration, or nasal discharge. Changes in lung sounds and respiratory rate or effort will be detected when examining the patient. Respiratory diseases that result in exercise intolerance are commonly infectious or inflammatory in nature. Thoracic radiographs, arterial blood gases, and bronchoalveolar lavage or tracheal wash are often necessary diagnostics. Pulmonary hypertension can also lead to weakness. Pulmonary hypertension may occur secondary to heartworm disease or chronic pulmonary disease and carries a guarded prognosis.

7.1.10 Neuromuscular Diseases

7.1.10.1 Brain

Any disorder affecting the brain can cause weakness. The neurologic exam will localize the problem as being central in origin. Encephalitis caused by infectious agents, inflammatory conditions, or immune-mediated disease; cerebral vascular accidents (embolism or hemorrhage); space-occupying lesions (neoplasia, granulomas, or hydrocephalus); vestibular disease (central or peripheral); and idiopathic epilepsy can present as chronic or intermittent weakness. Additionally, many medications act on the central nervous system (CNS) result in lethargy or exercise intolerance. The minimum data base may help further define the cause. Often more advanced diagnostics such as imaging of the brain or analysis of the cerebrospinal fluid (CSF) will be necessary to fully diagnose the underlying condition.

7.1.10.2 Spinal Cord Disease

Lesions affecting the spinal cord between C1 to T2 can result in quadriparesis. More caudal lesions may cause paraparesis. Causes of spinal cord disease include trauma, degenerative disc disease, vascular accidents, neoplasia, infectious diseases, and inflammatory conditions. Chronic, progressive conditions are more likely to result in the vague presentation of weakness compared with the more recognizable problem of acute paraparesis. In addition to the minimum data base, imaging and CSF analysis may be required to determine the underlying cause of spinal cord disease.

7.1.10.3 Neuropathies

Disorders affecting peripheral nerves can result in generalized weakness. The neurologic examination of these patients will typically reflect lower motor neuron dysfunction with reduced or absent reflexes. Causes of polyneuropathy include polyradiculoneuritis; paraneoplastic disorders; endocrine diseases including diabetes mellitus, hyperadrenocorticism, and hypothyroidism; drugs and toxins (vincristine, lead); infectious agents *(Toxoplasma*, *Neospora)*; and developmental disorders. Weakness may also result from disruption of neuromuscular transmission. Myasthenia gravis can be either acquired or congenital. Severe exercise intolerance is often a hallmark of this disorder. Other neuromuscular disorders include tick paralysis and botulism. Specialized testing such as electromyography, nerve and muscle biopsy, and serology for antibodies to the acetylcholine receptor are often necessary to establish the diagnosis.

7.1.11 Neoplasia

Neoplasia can lead to weakness through many different pathways. Associated inflammation will result in the release of a variety of cytokines that can cause fatigue, cachexia, and anemia. Tumors may specifically release substances such as insulin, corticosteroids, thyroid and parathyroid hormones, catecholamines, and estrogen that cause or exacerbate weakness. Some tumors such as hemangiosarcoma can cause severe, acute blood loss. Cancers can also result in anemia via disseminated intravascular coagulopathy (DIC). Neoplastic invasion or embolization can instigate organ failure. Finally, cancer can produce weakness in patients from pain.

7.1.12 Physical and Psychologic Stress

Stress is the major cause of fatigue in humans. Psychologic causes of lethargy are much harder to evaluate in veterinary patients but should not be completely discounted. Events that can cause clinically significant anxiety (thunderstorms, fireworks, boarding) or chronic stress (social status, deprivation, illness, pain) may result in generalized weakness. Stress of any nature can activate the hypothalamic-pituitary-adrenal axis, with resultant increased levels of corticotropin-releasing hormone (CRH) and cortisol. Hyperactivity of this axis can lead to depression and weakness. CRH may play a specific role in the development of fatigue. It has also been suggested that primary hypothalamic dysfunction may be important in the cause of generalized weakness.

Exercise intolerance may be seen in an animal pushed beyond its physical capabilities. This can occur both in animals that are not used to exercise and in fit animals that overexert themselves during activities such as hunting and racing.

7.1.13 Nutritional Derangements

Nutritional derangements may be the patient's primary problem or may be a reflection of chronic disease. Changes or reduction in protein synthesis, altered glucose homeostasis, or dyslipoproteinemias may all result in weakness. Specific vitamin and mineral deficiencies may also cause weakness. Nutritional disorders may arise from an inadequate diet, either in content or calories. The patient may not be able to use or synthesize nutrients appropriately or may lose them excessively. Liver, pancreatic, kidney, and gastrointestinal disease may all cause weakness via nutritional deficits. Lipid disorders can arise from endocrinopathies such as diabetes mellitus, hypothyroidism, and hyperadrenocorticism; renal disease; liver disease; pancreatitis; diet; or familial causes. Any chronic condition can lead to cachexia. The clinical signs of cachexia are anorexia, weight loss, and muscle

wasting. Cachectic patients suffer from a negative energy balance and metabolic derangements. These changes are often mediated by the same cytokines that cause fatigue.

7.1.14 Drugs

A complete history is essential for the patient with lethargy or weakness. Many medications including anticonvulsants, antihistamines, glucocorticoids, tranquilizers, narcotics, antibiotics, chemotherapeutics, diuretics, and cardiovascular agents can result in side effects, including weakness. If the onset of exercise intolerance coincides with the administration of a new medication, it may be prudent to discontinue that medication or lower the dose.

7.1.15 Pain

Patients may appear exercise intolerant if they are in extreme pain. Animals with spinal, bone, or joint pain are often quite reluctant to move. The physical examination should elucidate musculoskeletal or neurologic pain. Abdominal pain can result from distention, inflammation, or ischemia of organs. These patients may display a hunched appearance and resent abdominal palpation. Visceral pain is less localized and may be harder to pinpoint.

8 CHAPTER • 8 Skin and Subcutaneous: The Skin as a Sensor of Internal Medical Disorders

Sandra R. Merchant

Cutaneous manifestations of internal disease are uncommon. As expertise is strengthened in the field of veterinary dermatology, clinicians continue to discover subtle clues of the skin that alert them to further investigate internal organ systems. In certain diseases the skin may provide the first clinical signs noted. In some conditions, cutaneous and systemic signs occur simultaneously, whereas in others, the skin may reflect a general catabolic and cachectic stage brought about by the primary disease process.

8.1 FUNGAL DISEASES

Deep mycoses are fungal infections of internal organs that can spread hematogenously to the skin. Primary inoculation of the skin is rare. Infections that can cause nodules, plaques, and draining tracts include *Blastomyces dermatitidis, Histoplasma capsulatum, Cryptococcus neoformans,* and *Coccidiodes immitis*. Because of the accessibility of the skin, nodules and draining tracts of the skin can be easily biopsied for culture and histopathology to aid in diagnosis and choice of therapy for treatment of systemic mycotic diseases.

Pithium insidiosum, an aquatic oomycete, primarily affects the gastrointestinal tract but can also cause an ulcerative, draining dermatitis of the skin. With *Pithium*, each organ system is inoculated separately by contact with fresh water containing the infective zoospores.

Lagenidium spp. is a recently recognized oomycete pathogen also causing cutaneous or subcutaneous nodules or ulcerated, thickened edematous draining lesions. In contrast to *Pithium*, most dogs with lagenidiosis have lesions in sites other than the gastrointestinal tract.

8.2 VIRAL DISEASES

Canine distemper can cause hyperkeratosis of the nasal planum and foot pad, “hard pad disease.” Young puppies may develop widespread impetigo.

Feline rhinotracheitis is an infection with an alpha herpes virus. Occasionally, cats will develop oral and cutaneous ulcers that are usually multiple and can occur anywhere on the body. An ulcerative and necrotizing facial dermatitis has been recognized in cats that involves the periocular skin, nasal planum, and bridge of the nose. Exfoliative erythema multiforme has been seen after upper respiratory infections in the cat, and ulceration of the foot pads and perineal skin has been seen with cats infected with *Calicivirus.*

Feline leukemia virus (FeLV) most commonly affects the skin by its cytosuppressive actions. Clinical signs include chronic or recurrent gingivitis or pyoderma, seborrhea, exfoliative dermatitis, pruritus, and cutaneous horns. A facially distributed pruritic crusting dermatosis has been seen secondary to FeLV infection.

Feline immunodeficiency virus (FIV)–infected cats may have chronic or recurrent abscesses, chronic bacterial infection of the skin and ears; and increased incidence of fungal, ringworm, and *Demodex* infections. Generalized papules with crusts, alopecia, and scaling more severely affecting the head and limbs have been associated with FIV-positive cats.

8.3 BACTERIAL DISEASES

Lyme disease is a tickborne disorder of dogs caused by the spirochete *Borrelia burgdorferi*. Arthritis and fever are prominent signs. An expanding annular lesion called *erythema chronicum migrans* can characterize early disease in humans. This clinical sign has been documented in affected dogs in Europe.

Dogs infected with *Rickettsia rickettsii* may have erythema, petechia, edema, and occasional necrosis of the oral, ocular, and genital mucous membranes, as well as the skin of the pinna, nose, ventrum, and scrotum.

Dogs infected with *Ehrlichia* spp., may have crusting of the nasal bridge, pustular and purpuric lesions secondary to vasculitis, and an intensely pruritic papular and crusting dermatitis.

8.4 IMMUNE-MEDIATED DISEASES

Erythema multiforme usually has an acute onset of erythematous macules and papules that spread peripherally and clear centrally. The lesions are most commonly seen at the mucocutaneous junctions, nasal mucosa, pinnae, axilla, and inguinal regions. Erythema multiforme can be associated with infectious diseases and neoplasia and less likely as a manifestation of a drug eruption.

Toxic epidermal necrolysis (TEN) is an acute condition believed to be caused by a lymphocyte-and macrophage-mediated mechanism of immunologic injury. Drugs are the most common known inciting cause, but neoplasia and infection have also been documented. The first signs of TEN are widespread erythema of the skin that may be painful on palpation. Rapid and widespread full-thickness necrosis of the epidermis occurs. The most common areas affected are oral mucosa, footpad, face, and skin of the trunk.

Systemic lupus erythematosus (SLE) produces skin lesions that can be highly variable. They may be nonspecific cutaneous lesions or take the form of cutaneous lupus erythematosus lesions that are specific skin syndromes characterized by certain clinical and histopathologic findings. Cutaneous manifestations of SLE include seborrheic disease, alopecia, diffuse or regional erythema, cutaneous or mucocutaneous vesicles and bullae, footpad ulcers and hyperkeratosis, panniculitis, refractory secondary bacterial infection, and nasal dermatitis. Skin lesions commonly affect nonhaired areas. 31 32

Vasculitis is most commonly believed to be immunologically mediated and the result of a drug reaction. It may be initiated by a hypersensitivity reaction, food allergy, insect sting or arthropod bite reaction, canine mast cell tumor, feline collagenolytic granuloma, rabies vaccine reaction and dermatomyositis in the dog, coexisting disease (e.g., infections, malignancies, lupus), precipitating factors (e.g., drugs, vaccines), or idiopathic in origin. Cutaneous lesions include poorly healing ulcers typically located in the center of the footpads, erosions, ulcerations, and crusting that either affect the pinnal margin or form a linear lesion extending down the center of the concave aspect of the pinna. Some animals experience an urticarial form of vasculitis.

Hemolytic uremia syndrome, a cutaneous and renal glomerular vasculopathy has been described in greyhounds. Greyhounds can have this syndrome (with skin disease alone), systemic signs coincident with typical skin lesions, cutaneous disease before systemic signs, or manifestations of azotemia before cutaneous ulcerations. Cutaneous signs include multiple palpable purpura primarily on the limbs varying from pinpoint to 10 cm in diameter that subsequently ulcerate and discharge a serosanguineous fluid. The ulceration may extend into the subcutaneous tissues.

This syndrome is presumed to be a vasculopathy secondary to a verotoxin elaborated by *E. coli* obtained from eating raw beef products. A genetic predisposition or a propensity for feeding raw beef products to greyhounds may explain the breed susceptibility.

Dermatomyositis is a familial, idiopathic (vascular?) condition of the skin and muscle of collies and Shetland sheepdogs and has been recognized in other breeds of dogs. Skin lesions occur in areas of mechanical trauma and are commonly seen on the face, especially around the eyes, on the tips of the ears, on carpal and tarsal regions, on the digits, and on the tip of the tail. Early lesions include pustules, vesicles, papules, or small nodules progressing to crusting or alopecia. Ulceration can be seen in severely affected dogs. Many of these dogs are left scarred.

8.5 NEOPLASIA

Nodular dermatofibrosis is a disease seen primarily in German shepherd dogs but has also been reported in golden retrievers, boxers, German shepherd crosses, and mix-breed dogs. Clinical signs include numerous firm dermal to subcutaneous nodules that vary in size from a few millimeters up to 5 cm that can coalesce. The epidermis overlying the nodules may be intact but can sometimes be ulcerated and inflamed. Alopecia and hyperpigmentation can be seen over the nodules.

Systemic disease seen in association with these multiple skin tumors include renal lesions varying from polycystic kidneys to cystadenomas to cystadenocarcinomas and uterine leiomyomas in intact females. Most kidney involvement is bilateral. Many dogs have multiple small intestinal polyps that are asymptomatic.

8.5.1 Testicular Tumors

Dermatologic manifestations of testicular tumors are uncommon. Dermatologic manifestation occurs most commonly in the male feminization syndrome associated with Sertoli cell tumors. Dogs with male feminization display dermatologic signs of bilaterally symmetric alopecia that is nonpruritic, usually beginning in the perineal and genital regions and spreading to the ventral abdomen, thorax, flank, and neck. In some cases, the alopecia is restricted to the flanks. Other dermatologic manifestations of testicular tumors include seborrhea, ceruminous otitis externa, macular melanosis of the inguinal and perianal skin, and a linear erythematous or melanotic macular change that is present along the ventral aspect of the prepuce extending to the scrotum. Occasionally a dog will have a papular, pruritic eruption.

8.5.2 Pheochromocytoma

Pheochromocytomas are endocrine tumors arising from the adrenal medulla. The clinical signs associated with pheochromocytomas are quite variable and often subtle. Episodic panting or dyspnea and increased bronchovesicular sounds, weight loss, anorexia, depression, weakness, and collapse are some of the systemic abnormalities noted. The dermatologic manifestation is intermittent flushing, especially of the pinna.

8.5.3 Paraneoplastic Syndromes

Paraneoplastic syndromes consist of clinical signs that are associated with malignancies but not directly related to tumor invasion. In the dog these paraneoplastic syndromes include the crusting and fissuring dermatosis associated with necrolytic migratory erythema, nodular skin disease seen with nodular dermatofibrosis, paraneoplastic pemphigus vulgaris associated with a thymic lymphoma, suspect paraneoplastic pemphigus foliaceus from a Sertoli cell tumor or mammary carcinoma, and necrotizing panniculitis associated with

pancreatic carcinoma or severe pancreatitis. In the cat these paraneoplastic dermatoses include the skin fragility syndrome seen with feline hyperadrenocorticism; exfoliative dermatosis associated with feline thymoma; and a unique bilaterally symmetrical, ventral glistening paraneoplastic alopecia associated with pancreatic carcinoma, bile duct carcinoma, and thymoma.

Paraneoplastic pruritus has been seen associated with lymphosarcoma in the dog, squamous cell carcinoma in a cat, and liver disease or cholangiohepatitis in the cat.

8.6 ENDOCRINOPATHIES

8.6.1 Hypothyroidism

Dermatologic manifestations of hypothyroidism consist of a dry scaly coat, bilaterally symmetrical nonpruritic truncal alopecia, rat tail, variable degrees of hyperpigmentation seen on the ventral neck, abdomen, or in a diffuse truncal distribution; lichenification; myxedema; vesicular mucinosis; haircoat color change; comedones; hypertrichosis; seborrhea oleosa; seborrhea sicca; seborrheic dermatitis; and *Malassezia* dermatitis. Pruritus may be seen with the occurrence of secondary dermatologic diseases of seborrhea, *Malassezia* dermatitis, and staphylococcal pyoderma. Many dogs (with the exception of working and breeding dogs) may be examined when dermatologic abnormalities become evident.

8.6.2 Hyperadrenocorticism

Hyperadrenocorticism or *Cushing's syndrome* refers to the constellation of clinical and chemical abnormalities resulting from chronic exposure to excess glucocorticoids. Dermatologic abnormalities may be quite striking. Classic changes include hair loss that is usually bilaterally symmetrical, but focal hair loss may also be seen. Comedones, especially on the ventral abdomen and thin, inelastic skin, are also usually seen. Other changes include hyperpigmentation, seborrhea sicca, telangiectasia, increased prominence of surgical scars, lack of hair regrowth after shaving, and adult-onset generalized demodicosis. One dramatic manifestation seen in 5% of dogs is calcinosis cutis. Adult dogs that have never had bacterial skin disease may show a marked predisposition to recurrent staphylococcal skin infections.

8.6.3 Hyperthyroidism

The most common endocrine disorder of middle-aged to old cats is hyperthyroidism. Many of these cats have an unkempt haircoat, with excessive shedding and matting of the hair. Changes in hair texture, partial hair loss, and increased nail growth also are features of feline hyperthyroidism. In cats with areas of complete alopecia, behavioral changes associated with excessive grooming have been documented.

8.6.4 Diabetes Mellitus

Cutaneous lesions associated with diabetes mellitus are uncommon. The most common dermatologic manifestations are otitis externa, pyoderma, seborrheic skin disease, demodicosis, thin skin, alopecia, and xanthomatosis.

8.7 PARASITIC DISEASES

Leishmaniasis is a protozoal infection caused by a variety of *Leishmania* spp. endemic in many areas of the world, including the United States. It has been reported in foxhound kennels in 20 states in the United States. Skin lesions occur in over 80% of the dogs with visceral involvement. The most common sign is an exfoliative dermatitis primarily on the head, pinnae, and extremities. Nasodigital hyperkeratosis can been seen. Periocular alopecia is also common. An ulcerative dermatitis, onychogryposis, paronychia, sterile pustular dermatitis, nasal depigmentation with erosion, ulceration, and nodular dermatitis may be seen.

Demodicosis of the dog is most often caused by *Demodex canis*. Demodectic mange of the cat is caused by *Demodex cati* and *Demodex gatoi*. Adult-onset canine generalized demodicosis is most likely caused by suppression of the immune system. Several factors have been suggested or documented as initiating canine generalized demodicosis, including administration of immunosuppressive drugs, serious systemic disease to include hyperadrenocorticism, hypothyroidism, diabetes mellitus, blastomycosis and other deep mycoses, lymphosarcoma, hemangiosarcoma, and mammary adenocarcinoma. In addition, estrus, whelping, heartworm disease, and intestinal parasite infestation have all been associated with the onset of generalized demodicosis.

Because most cases of demodectic mange in the cat have occurred in the adult, immunosuppression as a result of an underlying disease has been proposed as the initiating factor. Generalized demodicosis has been seen in cats with diabetes mellitus, respiratory infection, FeLV infection, SLE, toxoplasmosis, feline endocrine alopecia, FIV infection, hyperadrenocorticism, feline infections peritonitis (FIP), and neoplasia. Immunosuppressive drugs (glucocorticoids and progestational compounds) should also be considered potential initiating factors.

Generalized patchy or diffuse alopecia with erythema, scaling, crusting, and follicular plugging may be seen in the dog. Some animals will have prominent hyperpigmentation in affected areas. In some cases the *Demodex* infection is confined to the feet only.

In the cat, signs of generalized demodicosis secondary to *Demodex cati* include multifocal to generalized patches of alopecia with variable scaling, macules, papules, erythema, hyperpigmentation, crusting, and symmetrical alopecia of the head, neck, legs, and trunk. Pruritus, when present, is either intermittent or mild. Clinical signs associated with *Demodex gatoi* include more severe pruritus, mild erythema, broken hairs, and alopecia of the hind limbs, flank, and ventral abdomen.

8.8 NUTRITIONAL DISEASE

Pansteatitis is caused by a deficiency of vitamin E. It has been reported in cats, usually eating diets containing red fish or excess cod liver oil. Affected cats are usually depressed, febrile, anorectic, and sore or painful on palpation of the skin or abdomen. Subcutaneous and abdominal fat may feel firm or lumpy. Draining tracts may be present.

8.9 NECROLYTIC MIGRATORY ERYTHEMA

Necrolytic migratory erythema (diabetic dermatopathy, hepatocutaneous syndrome, superficial necrolytic dermatitis, metabolic necrolytic dermatopathy, metabolic epidermal necrosis) has been seen in older dogs with glucagon-producing pancreatic endocrine tumor, Cushing's disease, hyperglucagonemia from a glucagon-secreting liver metastasis (primary tumor not found), hepatopathy secondary to ingestion of mycotoxins, hepatopathy secondary to phenobarbital or phenytoin administration, and hepatopathy of unknown origin. The disease has also been reported in the cat.

In the dog, necrolytic migratory erythema is an ulcerative dermatosis, displaying, erythema, crusts, and alopecia. It occurs most frequently periorally, periocularly, on the legs, feet, and external genitalia, and often in the groin region. The foot pads are usually hyperkeratotic and may be fissured and ulcerated. Cutaneous signs may precede evidence of internal disease by weeks or months.

9 CHAPTER • 9 Alopecia

Dominique Heripret

A*lopecia* is defined as a loss of hair, varying from partial to complete. Alopecia can be focal or generalized, diffuse or complete. The causes of alopecia are numerous. However, the major cause of alopecia in the dog, and especially in the cat, is self-trauma associated with pruritus. The hair is damaged from licking and scratching or may be easily removed because of inflammation within the hair follicle, such as in pyoderma and demodicosis. Noninflammatory alopecias are also frequent in dogs (e.g., endocrine alopecia, alopecia X) but are rare in cats.

The diagnostic approach to alopecia should be methodical and involve certain fundamental steps; history and clinical examination should allow formation of a differential diagnosis leading to appropriate diagnostic procedures.

9.1 HISTORY

1. Breed: Congenital hypotrichosis (Burmese, Devon rex, miniature poodles, American cocker spaniel, and other breeds); color mutant alopecia (Doberman pinschers, dachshunds, whippets, Chihuahuas, and other breeds); dermatophytosis (Persian cats, Yorkshire terriers); hyperadrenocorticism (Poodles, Boston terriers, dachshunds, and other breeds); alopecia X (Nordic breeds, poodles, and other breeds); sebaceous adenitis (Akita, Vizla, poodles, Samoyeds, and other breeds).

2. Age of onset of signs: Young animal (congenital or hereditary problems, demodicosis, pyoderma), older animals (neoplasia, endocrinopathy, internal disease).

3. Life-style: Outdoor cats and dogs more likely to have parasitic or fungal dermatoses.

4. Transmission to “in-contact” animals or owners: Dermatophytosis, parasitic dermatoses.

5. General symptoms: Polyuria-polydipsia, asthenia.

6. Initial distribution and aspect of the dermatoses.

7. Pruritus present at the beginning or not: If pruritus began after alopecia, one must carefully look for secondary infections.

8. Evolution: Slow progression of alopecia more indicative of a systemic problem (endocrinopathy); seasonality more indicative of recurrent flank alopecia or flea allergy dermatitis (FAD).

9. Previous treatments: Mainly steroids and megestrol acetate (iatrogenic Cushing's disease, interference with thyroid measurements) and their efficacy.

10. General examination: Pendulous abdomen and hepatomegaly (hyperadrenocorticism), enlarged lymph nodes (Leishmaniasis), abnormal testis, feminization of male dogs.

11. Dermatologic examination: Localized or generalized alopecia that is symmetrical (or not), only on the trunk (or not), aspect of hair shafts (broken or not), epilation, follicular casts (demodicosis, sebaceous adenitis), primary or secondary lesions (papules, pustules, scaling, crusts), skin thickness.

9.2 DIFFERENTIAL DIAGNOSIS

The list of differential diagnoses should be organized so that the most likely diagnoses comprise the top two or three differentials (Tables 9-1 and 9-2).

9.3 DIAGNOSTIC PROCEDURES

In practice the approach should include consideration of costs and owner's willingness to perform diagnostic tests. Diagnostic procedures (or therapeutic recommendations) will be determined from the differential diagnosis list.

1. Routine examinations: Microscopic examination of skin scrapings, direct examination of hair shafts (trichogram), Wood lamp examination (+/− fungal culture), cytologic evaluation of impression smears.

2. Second-intention examinations: Skin biopsies, hematology, biochemistry (FeLV, FIV for cats), endocrine measurements, ultrasonography.

See Figures 9-1 and 9-2.

9.4 OUTCOME

The prognosis of complete return of the haircoat to the normal state is dependent on the presence or lack of hair follicles. In some cases if alopecia is present without abnormal systemic condition (e.g., color dilution alopecia, alopecia X), it is important for the veterinarian to explain to the owner that lack of hair is only a cosmetic problem, and that it may be harmful to prescribe drugs (i.e., hormones) to try to have a normal haircoat.

Table • 9-1 Main Causes of Alopecia in the Dog, Classified as Noninflammatory versus Inflammatory Alopecia

NONINFLAMMATORY ALOPECIA
Congenital/Hereditary Alopecia
Ectodermal dysplasia
Follicular dysplasia
— *Tricorrhexis nodosa*
— Pili torti
— Color mutant alopecia
— Black hair follicular dysplasia
Acquired Alopecia
— Telogen effluvium
— Endocrine alopecia
— Hyperadrenocorticism
— Iatrogenic Cushing's syndrome
— Hypothyroidism
— Sexual imbalance
— Alopecia X
— Recurrent flank alopecia
— Anagen effluvium
— Metabolic imbalance (prot, FA*)
Infectious Alopecia
— Dermatophytosis
— Demodicosis
— Bacterial folliculitis
— Viral infection
— Leishmaniasis
Traumatic Alopecia

	— Hypersensitivity — Pruritic parasitic dermatoses — Scares Traction alopecia **Noninfectious/Immune-Mediated Alopecia** — Sebaceous adenitis — Superficial pemphigus — Alopecia areata — Erythema multiforme — Lupus — Epitheliotropic lymphoma **Atrophic Alopecia** — Dermatomyositis — Cutaneous vasculitis — Postrabies vaccination alopecia

* *FA,* Fatty acids

Table • 9-2 Main Causes of Alopecia in the Cat, Classified as Noninflammatory versus Inflammatory Alopecia

NONINFLAMMATORY ALOPECIA
Congenital/Hereditary Alopecia
— Alopecia universalis (sphinx)
— Congenital hypotrichosis
— Hair shaft dysplasia (Abyssinian)
— Follicular dysplasia (Cornish rex)
— Pili torti
Acquired Alopecia
— Paraneoplastic alopecia
— Hyperadrenocorticism
— Iatrogenic Cushing's—Pruritic parasitic dermatoses syndrome
— Hypothyroidism (rare)
— Hyperthyroidism
— Effluvium
Infectious Alopecia
— Dermatophytosis
— Demodicosis
— Viral infection (FIP*, poxvirus)
Traumatic Alopecia
— Self-induced alopecia
— Anxiety
— Allergy (FAD †)
— Dermatophytosis
— Hypersensitivities
— Scares
Noninfectious Alopecia
— Lymphocytic mural folliculitis

— Paraneoplastic exfoliative derm.

— Pseudopelade

— Epitheliotropic lymphoma

* *FIP,* Feline infectious peritonitis.

† *FAD,* Flea allergy dermatitis.

10 CHAPTER • 10 Pruritus

Peter J. Ihrke

Pruritus can be defined as the sensation that elicits the desire to scratch, chew, or initiate other self-trauma. Pruritus is assumed to occur in animals that have self-trauma or erythema, excoriations, alopecia, lichenification, or hyperpigmentation that results from inflammation and self-mutilation. Licking, chewing, rubbing, hair removal, irritability, and even personality change (lack of tolerance, aggressive behavior) can result from pruritus; it is the most common clinical manifestation of disease that causes owners to bring their pets in for treatment. Because skin changes from self-trauma of any cause are similar clinically, pruritic skin diseases often are diagnostically challenging and frustrating.

10.1 PATHOPHYSIOLOGY

The skin functions as an "external nervous system," providing continuous sensory input to the central nervous system (CNS) through a finely arborized network of free nerve endings responsible for transmitting the sensations of touch, temperature, pain, and pruritus. In humans, "sensory spots" or "itch points" coincide with areas of increased density of free nerve endings. This may be true of domestic animals as well because the face, distal extremities, and groin are common sites of self-trauma in many species. The sensations of pruritus and pain are carried centrally by nonmyelinated slow conducting C fibers and, to a lesser extent, along myelinated A delta fibers. Myelinated ganglion cell axons carry the message of itch from free nerve endings to neurons located in the posterior horn of the spinal cord. Axons of second-order neurons transmit the message across the midline to the lateral spinothalamic tract and upward to the thalamus. Thalamic neurons then carry the signal to the postcentral gyrus of the cerebral cortex, where the message is interpreted as the sensation of pruritus.

Pruritus commonly stimulates self-trauma. The mechanisms by which self-trauma relieves itching are unclear. Self-trauma may disturb the amplified, reverberating spinal pathways that perpetuate the sensation of itch. More severe self-trauma probably substitutes pain for pruritus. Severe self-trauma characterized by deep excoriations is more common in cats than in dogs.

Diffusible chemical mediators induce the sensation of itch. Implicated endogenous mediators include histamine, peptides (endopeptidases, bradykinin, substance P, vasoactive intestinal peptide, neurotensin, secretin, enkephalins, endorphins), proteases (trypsin, chymotrypsin, mast cell chymase, fibrinolysin, kallikrein, cathepsins, plasmin), prostaglandins, leukotrienes (especially LTB_4), monohydroxy fatty acids, and opioid peptides. Proteolytic enzymes are thought to be the most important mediators of pruritus in dogs, cats, and humans. Leukotrienes also play an important role. The hypothesized magnitude of the role of histamine has diminished as the importance of other mediators is recognized. Bacterial and fungal endopeptidases also can initiate pruritus. Chemical mediators present in arthropod saliva, venom, body fluids, and on poisonous hairs or spines include proteolytic enzymes, histamine, cantharidin, apamin, mellitin, histidine decarboxylase, kinins, serotonin, endopeptidases, and proteinases.

A "gate control theory" has been hypothesized to explain how the CNS can amplify or reduce the sensation of pruritus. Stress or anxiety may amplify pruritus in humans by releasing opioid peptides. Boredom or other cutaneous sensations such as pain, heat, cold, or touch also can alter the perception of pruritus. Factors such as increased skin temperature, diminished skin hydration, and low humidity can heighten the sensitivity of the skin to pruritic stimuli.

The concepts of *threshold phenomenon* and *summation of effect* are paramount in understanding and managing pruritus. A certain pruritic load may be tolerated without initiating clinical signs, but a small increase in that load can provoke clinical signs. The itch threshold often is reduced at night in humans and animals when other sensory inputs are diminished. *Summation of effect* occurs when additive pruritic stimuli from coexistent skin diseases raise an animal above threshold. As an example, pruritus from mild flea allergy is additive to pruritus from other skin diseases during flea season, thus exacerbating and perpetuating itch-scratch cycles.

10.2 DIAGNOSIS OF PRURITUS

Signalment, history, physical examination, diagnostic testing, and, occasionally, response to therapy are the cornerstones of diagnosis. Because many pruritic skin diseases are visually similar, clinical history coupled with signalment predilections may offer more direct clues to diagnosis than physical examination. Canine and feline scabies and cheyletiellosis may have increased in frequency during the past 5 years because of the popularity of newer, more narrow-spectrum flea control products that do not kill acarids. The effect of newer flea control products on the incidence of pruritic skin diseases is controversial. Although the frequency of flea allergy dermatitis may have declined in regions where newer products are used, flea allergy dermatitis is still common globally. Effective flea control also may have unmasked formerly undiagnosed cases of canine atopic dermatitis where the pruritus was assumed to be due only to flea allergy dermatitis rather than combined flea allergy and atopic dermatitis. The importance of pyoderma and *Malassezia* dermatitis as frequent causes of pruritus cannot be overemphasized.

10.2.1 Signalment

10.2.1.1 Age

Age provides critical information for prioritizing differential diagnoses. Some skin diseases occur more commonly in young animals, whereas other dermatoses are seen more frequently in middle-aged or older animals. As examples, scabies and demodicosis are pruritic skin diseases seen more commonly in young dogs. Similarly, atopic dermatitis, food allergy, and pyoderma occur more commonly in adult animals.

38

39

10.2.1.2 Breed

Breed predilections for skin diseases are becoming increasingly available. Further, some skin diseases are breed specific. As examples, golden retrievers, Dalmatians, and many small terrier breeds are at increased risk for the development of atopic dermatitis. The West Highland white terrier is at increased risk for secondary *Malassezia* dermatitis and the Chinese Shar Pei seems predisposed to atopic dermatitis, food allergy, pyoderma, and demodicosis.

10.2.1.3 Sex

Sex predilections are not common in pruritic skin diseases. However, pruritus may be seen with Sertoli cell tumors, male-feminizing syndromes, and canine female hyperestrogenism.

10.2.2 Historical Findings

10.2.2.1 General History

General history should be sought referable to diet, environment, use, home skin care, recent exposures, other household pets, and the presence or absence of pruritus in other animals or people in the environment. These data are helpful in prioritizing differential diagnoses.

10.2.2.1.1 Diet.

Food allergy or intolerance can cause pruritus in both dogs and cats. However, adverse reactions to food frequently coexist with other allergic skin diseases such as atopic dermatitis and flea allergy dermatitis. In addition, lipid-deficient diets may exacerbate cornification abnormalities (seborrhea).

10.2.2.1.2 Environment and exposure.

The likelihood of contagious pruritic ectoparasitic skin diseases is affected by environmental exposure. Flea allergy, canine and feline scabies, and less common ectoparasitic skin diseases are all seen more frequently in animals permitted to roam free. Feline scabies is endemic to certain geographic urban areas. Recent exposures such as acquisition of a new pet or sheltering a stray animal increase the likelihood of contagious disease. Grooming establishments, kennels, and veterinary practices offer additional opportunities for contagion.

10.2.2.1.3 Other household pets.

Pruritus or lack of pruritus in other animals may offer clues to contagion. However, even though dogs and cats share the cat flea as a common ectoparasite, flea allergy is much more common in dogs. A seemingly unaffected indoor or outdoor cat is often the source of flea acquisition in indoor dogs with flea allergy dermatitis. Although uncommon, asymptomatic carriers of canine scabies do exist because clinical disease requires hypersensitivity.

10.2.2.1.4 Human contacts.

A pruritic papular rash in an owner with a pruritic pet may suggest zoonotic infestation with canine or feline scabies mites or cheyletiellosis. Annular, erythematous lesions may suggest dermatophytosis.

10.2.2.2 Specific History

Specific history relates to the current pruritic skin disease. The initial site of skin lesion development, onset and progression, intensity of pruritus, seasonality or other pattern (predictability), and response or lack of response to previous therapy may aid in establishing a diagnosis.

10.2.2.2.1 Site, onset, and progression.

Knowledge of the initial sites of skin lesions may be useful, if the disease has generalized before veterinary care is sought. For example, canine scabies often begins on the margins of the pinnae before generalizing. Rapid-onset pruritus should increase suspicion for ectoparasitic diseases and, less commonly, adverse drug reactions. Pruritus of insidious onset is more suggestive of slowly progressive, chronic skin diseases such as atopic dermatitis, food allergy, pyoderma, cornification abnormalities, and Malassezia dermatitis.

10.2.2.2.2 Intensity.

Most animals do not exhibit pruritus in examination rooms. Canine and feline scabies, canine flea allergy dermatitis, and feline food allergy are notable exceptions. Frequency and intensity of pruritus may be inferred from asking the owner how many times the animal will scratch (or chew or lick) if it is ignored while the owner observes the animal at home.

10.2.2.2.3 Seasonality or pattern (predictability).

Atopic dermatitis and flea allergy dermatitis are seasonal in many regions of the world. Malassezia dermatitis may occur more frequently during months of higher humidity. Cyclical pruritus without seasonality can sometimes signify contact dermatitis associated with change of environment. Psychogenic pruritus may began as a predictable, attention-getting device. Pruritus seen with food allergy should be continuous unless the diet is changed.

10.2.2.2.4 Response to previous therapy.

Response or lack of response to previous medications, particularly corticosteroids, antibiotics, or parasiticides, may offer additional clues. Although allergic diseases all respond to corticosteroids to some degree, food allergy may be less responsive to corticosteroids than atopic dermatitis or flea allergy dermatitis. Prior diminished pruritus in response to antibiotics in dogs is often overlooked and indicates the likelihood of pyoderma. Pruritus as the result of pyoderma may also diminish in response to corticosteroids.

10.2.3 Physical Findings

A complete physical examination is extremely important when evaluating any animal with skin disease. Skin disease may be seen secondary to internal medical disorders (see Chapter 8). Proper lighting is of paramount importance. The clinician should observe the animal for general demeanor and signs of pruritus while taking the history. Examination of the skin, mucocutaneous junctions, oral cavity, ears, genitals, and lymph nodes should be emphasized. Objective signs of pruritus include excoriations and broken or barbered hairs with a dry lusterless haircoat. In the dog, worn incisors (buccal surface) and canine teeth (mesial surface) most frequently indicate chronic flea allergy dermatitis.

Pruritus may occur with or without primary skin lesions. If present, primary skin lesions such as papules or pustules may be helpful in establishing a diagnosis. Coexistent alopecia may offer additional clues (see Chapter 9). Unfortunately, self-trauma often leads to the obliteration of initial, more diagnostic primary skin lesions substituting excoriations, lichenification, and alopecia. The concept of “a rash that itches” indicates primary skin lesions that are itchy, and “an itch that rashes” indicates that pruritic patients without primary lesions traumatize

themselves. Ectoparasitic skin diseases, pyoderma, and cornification abnormalities are among the more common pruritic skin diseases where primary skin lesions are identified. Conversely, primary lesions are much less common in atopic dermatitis and food allergy. The distribution of lesions, presence or absence of bilateral symmetry, and major foci of pruritus can be valuable aids to diagnosis. Primary or secondary lesions, if present in a particular site, may be highly suggestive of specific diseases (Tables 10-1 and 10-2).

10.2.4 Diagnostic Plan

Diagnostic plans should be formulated based on prioritization of differential diagnoses using signalment, history, and physical findings. Diagnostic procedures are selected based on the most likely differential diagnoses. The algorithm in Figure 10-1 offers an overview of possible diagnostic plans.

Table • 10-1 Pruritic Canine Dermatoses

DISEASE	SITE	LESIONS
Flea allergy dermatitis A, E, F	Bilaterally symmetric, dorsal lumbosacral, caudal thighs, groin, axilla, caudal half of body	Papules, macules, alopecia, erythema, lichenification, hyperpigmentation, excoriations, fibropruritic nodules
Canine scabies A	Ventrum, pinnae margins, face, elbows, partially bilaterally symmetric	Macules, papules, erythema, alopecia, crusts, excoriations
Demodicosis A	Periorbital, commissures of mouth, forelegs, generalized	Alopecia, erythema, crusts, follicular plugging, hyperpigmentation, secondary pyoderma
Pyoderma A	Groin, axilla, ventrum, interdigital webs, generalized, pressure points	Pustules, crusted papules, erythema, alopecia, target lesions, coalescing collarettes, hyperpigmentation
Atopic dermatitis A, F	Face, periorbital, ears, caudal carpi and tarsi, feet (dorsum), otitis externa, axilla, generalized	Erythema, alopecia, excoriations, lack of primary lesions, lichenification, hyperpigmentation
Malassezia dermatitis A, E, F	Ventral neck, groin, skin folds, face, feet, ventrum	Erythema, exudative or dry, alopecia, hyperpigmentation, lichenification
Cornification defects A, E, F	Generalized, ears, preen body	Scales, crusts, alopecia, erythematous plaques
Acral lick dermatitis A	Anterior carpal, metacarpal, radial, metatarsal, tibial regions	Firm, alopecic plaque, central irregular ulcer, hyperpigmented halo
Food allergy B	Face, feet, ears, generalized	Erythema, alopecia, excoriations, lack of primary lesions
Contact dermatitis C	Hairless areas, feet (ventrum), genitals, groin, axilla, generalized	Erythema, exudation, lichenification, hyperpigmentation, papules
Drug eruptions C	Anywhere, localized or generalized, face, ears, scrotum	Pleomorphic, erythema, papules, coalescing target lesions
Endoparasitic migration in puppies C	Face, feet, generalized	Erythema, alopecia, excoriations, lack of primary lesions
Cheyletiellosis B, E	Dorsum of thorax, generalized	Large scales, crusts, alopecia, erythema
Chiggers B, E, F	Ventrum, legs, anywhere	Erythema, scales, crusts, papules, alopecia
Superficial necrolytic dermatitis C	Footpads, face, mucocutaneous junctions, genitals, groin	Adherent crusts, ulcers, excoriations, erythema, fissured pads
Psychogenic pruritus C	Carpi, tarsi, feet (especially forelegs), perianal, generalized	Erythema, alopecia, excoriations, lack of primary lesions
Pediculosis C, E, F	Dorsum, generalized	Scales, crusts, alopecia, papules
Tail-dock neuroma C	Previously docked tail	Erythema, excoriations, alopecia
Rhabditic dermatitis D, E, F	Ventrum, legs, groin	Erythema, papules, alopecia, crusts, scales

A, Common; *B,* less common; *C,* uncommon; *D,* rare or controversial; *E,* regional; *F,* seasonal.

39

10.2.4.1 Skin Scrapings

Multiple skin scrapings should be performed on all pruritic dogs and cats. Affected areas should be gently clipped, and then a no. 10 scalpel blade or spatula, dipped in mineral oil, should be scraped perpendicular to the skin surface in the direction of hair growth. The acquired debris should then be dispersed on a slide, a cover slip applied, and the specimen examined microscopically using low light.

Demodectic mites usually are readily demonstrable (except in chronic pododemodicosis and in the Chinese Shar Pei). Scabies mites are documented in less than half of affected dogs, underscoring the need for trial therapy in suspected cases. Dry scrapings may be stained as smears to look for *Malassezia pachydermatis*.

10.2.4.2 Exfoliate Cytology

Affected skin, intact pustules, or exudates should be smeared, stained with a rapid stain such as Diff Quik®, and examined microscopically for the presence of bacteria, *Malassezia* organisms, and inflammatory cells. Clear tape preparations may demonstrate *Cheyletiella* mites, and stained tape preparations may demonstrate bacteria or *M. pachydermatis*.

Table • 10-2 Pruritic Feline Dermatoses

DISEASE	SITE	LESIONS
Flea allergy dermatitis A, E, F	Neck, dorsum, lumbosacral, caudal and medial thighs, groin, ears	"Miliary dermatitis," erythema, alopecia, eosinophilic plaques
Eosinophilic plaque A, E, F	Ventral abdomen, medial thighs, anywhere	Raised, ulcerated, erythematous alopecic plaques, secondary to allergy (primarily flea allergy dermatitis)
Otodectic acariasis A	Ears, head, neck, rarely generalized	
Food allergy A	Head, neck, ears, generalized	Erythema, excoriations, alopecia, lack of primary lesions, "miliary dermatitis"
Self-induced pruritic hair loss (atopic dermatitis, food allergy, flea allergy) B	Bilaterally symmetric, caudal and lateral thighs, ventral abdomen, perineum	Alopecia, hair stubble, erythema, papules, underlying skin may be normal
Self-induced psychogenic hair loss B	Bilaterally symmetric, stripe(s) on dorsal thorax, caudal and lateral thighs, ventral abdomen, perineum, forelegs	Alopecia, hair stubble, normal underlying skin
Cheyletiellosis B, E	Dorsum of thorax, generalized	Large scales, crusts, seborrhea, "miliary dermatitis"
Demodicosis B, E	Trunk, ventral, generalized	Alopecia, scaling
Mosquito-bite hypersensitivity C, E, F	Bilaterally symmetric, dorsal muzzle, planum nasale, periorbital, pinnae, paw pad margins	Papules, crusts, alopecia, erosion, exudation, fistulation
Pediculosis C, E, F	Dorsum, generalized	Scales, crusts, alopecia
Feline scabies C, E	Head, ears, neck, generalized, partially bilaterally symmetric	Erythema, papules, crusts, excoriations, alopecia
Pruritic dermatophytosis C	Head, neck, ears, generalized	Erythema, alopecia, hair stubble, "miliary dermatitis," hyperpigmentation
Atopic dermatitis B, F	Head, neck, ears, generalized	"Miliary dermatitis," erythema, excoriations, alopecia
Drug eruptions C	Anywhere, localized or generalized, pinnae, face	Pleomorphic, erythema, papules, coalescing target lesions
Pemphigus foliaceus D, E?, F?	Bilaterally symmetric, face, planum nasale, ears, interdigital webs, nipples, generalized	Crusts, vesicopustules, alopecia

A, Common; *B,* less common; *C,* uncommon; *D,* rare or controversial; *E,* regional; *F,* seasonal.

10.2.4.3 Fecal Examination

Fecal examination may document endoparasite infestation in pruritic puppies and may reveal mites or other ectoparasites in any animal.

10.2.4.4 Skin Biopsy

Skin biopsy is especially valuable if primary skin lesions free of self-traumatic excoriations are present. If only self-traumatic lesions are present, definitive diagnosis is less likely, but results may aid in prioritizing or ruling out various differential diagnoses.

10.2.4.5 Fungal Culture

Most dogs and cats with dermatophytosis are not pruritic. However, fungal culture may be warranted because many cases of dermatophytosis are not visually distinctive.

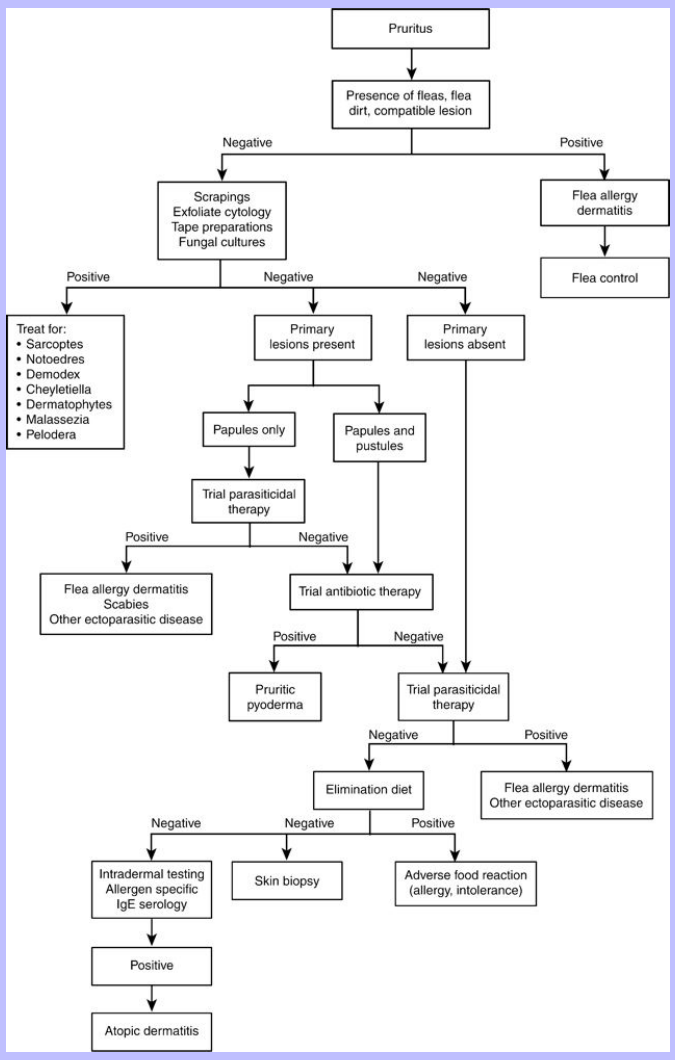
10.2.4.6

Elimination Diets

Animals suspected of having food allergy or food intolerance as a cause of pruritus should be fed a home-cooked diet consisting of one protein and one carbohydrate source for 8 to 12 weeks. Alternatively, newer "limited antigen" or "hydrolyzed" diets are available. Commercial restricted diets are recommended for long-term maintenance. Nothing is specifically "hypoallergenic" about any food source. Foods are selected based simply on lack of previous exposure. Whitefish, rabbit, venison, pork, cottage cheese, or tofu mixed with either potatoes or other novel carbohydrate sources are commonly used in the dog. Mutton, lamb, and chicken are no longer as useful because they are frequently used in commercial dry dog foods. Cats may be fed rabbit, venison, pork, or mutton without an added carbohydrate source, or they may be fed commercial restricted or hydrolyzed diets.

41 43

Figure 10-1 Algorithm for diagnosis and management of pruritus.



10.2.4.7 Intradermal Testing

Substantial training is required to select appropriate candidates suspected of having atopic dermatitis, to choose antigens, to develop and maintain a reproducible technique, and to interpret results. Consequently, skin testing is most effective when practiced by dermatologists or other clinicians with a strong interest in dermatology.

10.2.4.8 Allergen-Specific IgE Serology (enzyme-linked immunosorbent assay [ELISA] or radioallergosorbent test [RAST])

In vitro testing for atopic dermatitis offers convenience and accessibility. Reproducibility of test results has increased dramatically over the past decade. However, problems still remain with antigen selection, grouped testing, and standardization of results.

10.2.4.9 Environmental Restriction

If allergic contact dermatitis is suspected, an animal may be housed in a markedly different environment (water-rinsed kennel) for 10 days.

10.2.4.10 Response to Trial Therapy

Trial therapy with parasiticidal agents is used routinely in suspected cases of scabies or flea allergy dermatitis. Flea allergy dermatitis remains the most common cause of canine and feline pruritus despite effective modern products. Because the lesions seen with canine superficial pyoderma may be pleomorphic, trial use of antibiotics may be indicated in undiagnosed pruritic crusted papular dermatoses. Although response to corticosteroids is suggestive of underlying allergic disease, superficial pyoderma will frequently respond partially to corticosteroid therapy.

10.2.4.11 Cost Containment

Skin scrapings, fungal culture, exfoliate cytology, trial therapy for ectoparasites, and, surprisingly, skin biopsy, are the most cost-effective diagnostic procedures for the pruritic animal.

10.3 GOALS OF THERAPY

Successful long-term management of a pruritic dog or cat usually requires definitive diagnosis. Repetitive parasiticidal therapy on a weekly basis for 3 or 4 weeks will rule out most contagious ectoparasitic diseases such as canine or feline scabies. However, management of flea allergy dermatitis is a lifelong endeavor encompassing control of fleas on the affected animal and all in-contact dogs and cats, as well as environmental control. Atopic dermatitis responds best to allergen-specific immunotherapy. Secondary pyoderma and *Malassezia* dermatitis are common sequelae to most pruritic skin diseases and must be assessed for and managed long-term. If corticosteroids are used adjunctively for the long-term management of allergic skin disease, short-acting oral corticosteroids such as prednisone, prednisolone, or methylprednisolone are recommended on an alternate-day basis. Corticosteroids are contraindicated in the treatment of canine demodicosis and pyoderma. Many pruritic animals require long-term adjunctive topical management with shampoos and emollients or antipruritic rinses.

11 CHAPTER • 11 Cutaneous and Subcutaneous Lumps, Bumps, and Masses

Didier N. Carlotti

Cutaneous and subcutaneous lumps, bumps, and masses include hematomas, abscesses, urticaria and angioedema, neoplasms and pseudoneoplasms.

11.1 CLINICAL AND HISTOPATHOLOGIC DEFINITIONS

A hematoma is a focal extravasation of blood with purpura (bruising) and pain, whereas an abscess is a localized collection of pus with pain, heat, and sometimes purpura. Urticaria is referred to as a group of wheals (sharply circumscribed, raised, edematous lesions) that appear and disappear rapidly. Angioedema is a large swelling in a distensible region such as the face and limbs.

Clinically, pseudoneoplasms and neoplasms appear as nodules, plaques, and tumors. Ulceration always indicates a severe pathologic process. Pseudoneoplasms include cysts, nevi, keratoses, granulomas, and pyogranulomas and other lesions. *Pseudoneoplasm* is a better term than *pseudotumor* because the term *tumor* is clinical and should refer to a localized hypertrophy of a tissue or an organ, neoplastic or not. Cysts are epithelial lesions containing grayish keratinous material or serous material, such as apocrine cysts, which appear fluctuant, bluish, and well circumscribed. A hamartoma is a malformation formed by components of a normal organ arranged erroneously. A nevus is a cutaneous hamartoma that may arise from any skin component. Collagenous nevi are single or multiple nodules characterized histopathologically by large areas of collagen hyperplasia. In German shepherds, multiple collagenous nevi may appear, particularly on the limbs, in association with renal adenocarcinomas and uterine leiomyomas (nodular dermatofibrosis syndrome). Organoid (i.e., pilosebaceous) and epidermal nevi are variable in shape and may be linear. Vascular nevi are seen on the scrotum in dogs. Keratoses are solid, elevated, and circumscribed lesions characterized by a hyperproduction of keratin. They show up as greasy nodules and plaques (seborrheic keratoses), squamocrustous plaques (actinic keratoses, lichenoid keratoses on the ear pinnae), or cutaneous horns.

A granuloma is a circumscribed tissue reaction characterized by an organized infiltration of mononucleated phagocytes (histiocytes and macrophages) that may occur when foreign bodies, bacteria, fungi, parasites, or any material penetrates or deposits into the skin. If an acute inflammatory process does not destroy the “invader,” macrophages become epithelioid. A granuloma may persist until the cause has been eliminated. “Pyogranuloma” means granulomatous reaction with many neutrophils.

Lesions of calcinosis circumscripta are pink-colored plaques located on pressure points or in the tongue that contain grayish material. Hard erythematous plaques containing whitish material characterize calcinosis cutis, as seen in canine Cushing's disease. Eosinophilic lesions in the cat are indolent ulcer, eosinophilic plaque, and collagenolytic granuloma (the latter often appearing linear). Nodular sterile panniculitis is characterized by deep nodules that fistulize, expressing an oily material. Canine juvenile cellulitis is characterized by facial swelling. Nodular lesions, particularly on the face, with a “clown nose” appearance, may characterize canine histiocytosis.

Other various pseudoneoplasms include acral lick dermatitis, idiopathic lichenoid dermatitis (coalescent plaques), feline plasma cell pododermatitis or stomatitis, and idiopathic focal mucinosis seen in Doberman pinschers.

11.2 CAUSE AND PATHOPHYSIOLOGY

Hematomas are the result of trauma causing the rupture of blood vessels. They appear frequently after minor trauma in dogs with coagulopathies. Abscesses are the result of the collection of degenerated neutrophils and necrotic tissue cells when an infectious agent has penetrated into and under the skin. Usually a peripheral membrane forms from necrotic tissue and fibrin. Urticaria and angioedema are caused by immediate hypersensitivity reactions generated by insect bites (e.g., hymenoptera); food; drugs; airborne allergens (atopy), and nonimmunologic stimuli such as contact with irritant material (e.g., weeds, such as *Urtica dioica*; insects, such as *Thaumetopoea pityocampa* [caterpillar]; physical stimuli, such as cold, heat, and sunlight; and even psychogenic factors). Cysts may be traumatic (epidermoid), hereditary (dermoid), follicular, or pilar (i.e., trichilemmal) caused by retention of material (i.e., keratin, glandular products) as a result of congenital or acquired loss of follicular orifices. Apocrine cysts are idiopathic. Nevi may be congenital, and the mechanism of their formation is unknown. However, nodular dermatofibrosis is due to an autosomal dominant gene. Keratoses are idiopathic except actinic keratoses and some cutaneous horns, which are associated with various skin neoplasms or feline leukemia virus (FeLV) infection in the cat.

Bacterial granulomas and pyogranulomas include canine furunculosis caused by cocci such as *Staphylococcus intermedius,* botryomycosis (bacterial pseudomycetoma) caused by various bacteria that may cause a granulomatous reaction, and nocardiosis and mycobacterioses (atypical mycobacterial infection, feline leprosy, tuberculosis, which is very rare). Fungal granulomas and pyogranulomas include kerions (inflammatory reaction to a dermatophyte) and pseudo-mycetomas caused by the subcutaneous development of a dermatophyte (*Microsporum canis* in cats, mainly), subcutaneous (intermediate) mycoses (sporotrichosis, pythiosis, mycetomas, phaeohyphomycosis, zygomycosis), and deep (systemic) mycoses (blastomycosis, coccidioidomycosis, histoplasmosis, aspergillosis, cryptococcosis, protothecosis, paecilomycosis, trichosporonosis).

Endogenous or exogenous foreign bodies can cause granulomas. Endogenous foreign bodies are usually hair and keratin (leading to bacterial furunculosis), calcium (calcinosis circumscripta, idiopathic, Cushing's disease), and lipids (xanthomas in case of hyperlipidemia in cats, associated with diabetes mellitus or hereditary). Exogenous foreign bodies include sutures and weed material. Parasitic granulomas include tick bites, canine dracunculosis, canine filariasis, canine leishmaniasis (the nodular form is seen more frequently in short-haired dogs such as the boxer), feline toxoplasmosis, and canine cysticercosis. Arthropod bites (e.g., mosquitoes, spiders) lead to eosinophilic furunculosis (particularly on the face in dogs and cats) with a granulomatous reaction. Some granulomas are idiopathic: lesions of the feline eosinophilic granuloma complex (although most of the cases are caused by flea allergy dermatitis, feline atopic dermatitis, or food allergy or intolerance), canine eosinophilic granuloma, sterile pyogranulomatous dermatosis, nodular sterile panniculitis (the result of an inflammatory process of subcutaneous fat), canine juvenile cellulitis (perhaps viral), canine cutaneous histiocytosis (caused by a proliferation of normal histiocytes), canine erythema nodosum-like granuloma, canine sterile sarcoidal granulomatous skin disease, and amyloidosis. Acral lick dermatitis is often a deep bacterial folliculitis and furunculosis caused by constant licking attributed to an allergic pruritus or behavioral disorder. Lichenoid dermatitis may be idiopathic or an immune-mediated disease such as feline plasma cell pododermatitis and stomatitis sometimes associated with FeLV, feline immunodeficiency virus (FIV)-infection, or both.

Cutaneous and subcutaneous neoplasms include epithelial (epidermal and follicular), glandular (sebaceous, sweat, and hepatoid gland), mesenchymal (fibrocytic, histiocytic, vascular), and melanocytic and round cell tumors (mast cell, histiocytic, lymphoma).

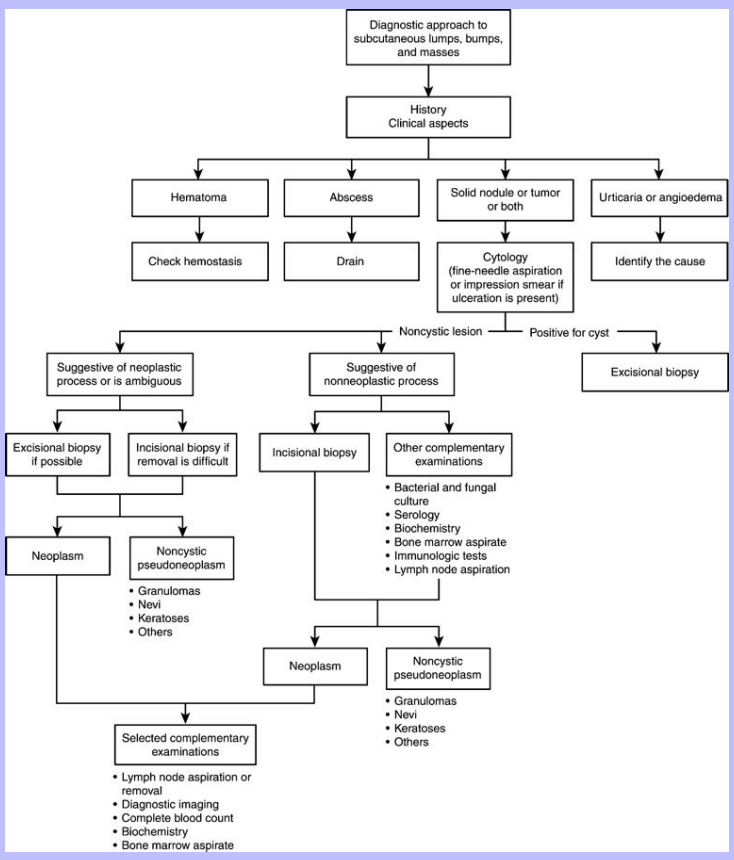
Mammary neoplasms can be considered as subcutaneous. Most of the neoplasms have an unknown cause. Viruses can cause specific tumors such as papillomas in dogs and fibrosarcomas and carcinomas in situ (Bowen's disease) in

cats. Other causes include irritation, trauma, and actinic exposure. The latter is likely to be the cause of squamous cell carcinoma of the face and ears in the cat (particularly of white color). It is not clear whether repeated vaccinations can lead to fibrosarcomas in cats. Benign neoplasms can be harmful if they reach a large size, are located in particular areas (face, eyelids, external ear canal, mouth, feet, genitals, anus), or both. Malignant neoplasms are invasive and will cause the necrosis of surrounding cells, leading to ulceration.

11.3 DIAGNOSIS

Diagnosis of cutaneous and subcutaneous lumps, bumps, and masses is based upon history, physical examination, and complementary aids (Figure 11-1). Signalment of the animal may be of some importance. Neoplastic lesions occur mostly in adults and old dogs. However, viral papilloma and histiocytoma (Langerhans' cell tumor) will be seen mainly in young animals. Intact male cats are prone to develop abscesses as the result of fighting. Mammary tumors and their cutaneous metastases occur in female dogs, whereas perianal gland tumors occur most frequently 44
in intact males. Most neoplasms, however, have no sex predilection. Breed predispositions are recognized for many 45
superficial neoplasms. The boxer is known to be predisposed to many of them, as it is for nodular leishmaniasis. The German shepherd is predisposed to keratinous cysts and nodular dermatofibrosis. Persian cats are predisposed to dermatophytic pseudomycetoma.

Figure 11-1 Algorithm for diagnostic approach to subcutaneous lumps, bumps, and masses.



History of the lesions should be taken into account. Important points are the existence of previous similar lesions, association to general disease, known trauma, and rapidity of onset. Obviously, hematomas, abscesses, urticaria, and angioedema appear rapidly. Some lymphomas can develop rapidly. Feline eosinophilic plaques, urticaria and angioedema, some cases of calcinosis cutis, and mast cell tumors are pruritic. Hematomas, abscesses, and some tumors may be painful.

45

46

Physical examination should include evaluation of the lesions, local lymph nodes, and distant sites such as lungs. This strategy applies to most lumps, bumps, and masses, using the TNM approach (tumor, node, metastasis). The lesions should be characterized by localization, size, shape, pedunculated appearance, consistency, depth, and whether or not they are freely movable, ulcerated, or both. For instance, feline collagenolytic granuloma and canine epidermal nerves can be linear; hematomas and most benign neoplasms are not attached to underlying tissues, whereas most of abscesses and malignant neoplasms are attached. Abscesses evolve from firm to fluctuant stages, whereas most pseudoneoplasms and neoplasms are firm (except apocrine cysts and some angiomas and angiosarcomas). Benign neoplasms can be pedunculated. Feline indolent ulcer, eosinophilic plaques, some malignant neoplasms, and canine acral lick dermatitis ulcerate. Enlargement of local lymph nodes can be caused by inflammation (even in case of a neoplastic process) or metastasis. General lymph node enlargement can result from severe infections and lymphosarcoma. Metastasis can rarely be suspected clinically, except for cutaneous metastasis of mammary neoplasms and when an abnormal abdominal mass is palpated.

Cytologic techniques usable for lumps, bumps, and masses are impression, scrape, swab, and fine-needle aspiration smears. No contraindications exist. Cytology allows rapid identification of cell types. High cellularity and a homogeneous cell population characterize neoplasms. Cytologic criteria of malignancy include pleomorphism, high nucleocytoplasmic ratios, large nucleoli, and atypical mitoses. In many nonneoplastic lesions, the cytologic examination is highly suggestive of the diagnosis (e.g., pyoderma, fungal diseases, eosinophilic plaques). Fine-needle aspiration cytology of a local lymph node can help to differentiate an inflammatory reaction from malignancy.

Histopathology has a fundamental role in establishing specimens' diagnoses. Incisional biopsy specimens can be obtained with a scalpel or a punch, particularly when cytology is ambiguous. Results aid in selecting appropriate medical therapy, surgery, or both. The sample should be biopsied at the margin of the lesion to incorporate some normal-looking tissue, should not be larger than 1 cm, and should be put in 10 times its volume of 10% formalin. No contraindication exists for incisional biopsy because it does not increase risk of metastasis. The wound should be repaired, and the biopsy site should be removed by further surgery. General anesthesia may be required, and wound repair can be difficult. Excisional biopsy can also be performed, particularly when cytology is ambiguous, when the surgical removal of the lesion is easy, and when physical examination suggests a nonneoplastic or benign neoplastic lesion. If lesions are multiple, excisional biopsy of a typical mass should be considered. The removal of a lymph node for histopathologic analysis can be helpful and has no harmful consequence. Radiology, ultrasonography, or both are useful in many instances (e.g., a lesion appearing to be attached to an underlying bone or suspicion of lung or abdominal metastasis).

11.4 PROGNOSIS

The prognosis of cutaneous or subcutaneous (or both) lumps, bumps, and masses is obviously linked to diagnosis, location of the lesion or lesions, and continuing evaluation (TNM). Establishing a prognosis based on physical examination only and clinical neglect (waiting for a possible enlargement of the lesion or lesions), are unacceptable errors.

11.5 TREATMENT

Treatment should be based upon diagnosis and prognosis. Medical treatment of urticaria and angioedema, hematomas, and abscesses is almost always successful. The result of treatment of granulomatous pseudoneoplasms can lead to complete cure, particularly when a bacterial or superficial fungal agent has been identified. Surgical excision of cysts, nevi, keratoses, feline plasma cell podal lesions, and benign neoplasms is usually successful. Treatment for malignancies is rarely curative, but long remissions can be obtained, particularly if the owners wish to cooperate.

12 CHAPTER • 12 Erosions and Ulcerations

Ian S. Mason

Erosions and ulcers are skin defects with a wide range of causes. Erosions are superficial breaks in the continuity of epithelia that fail to breach the intact basement membrane and usually heal without scarring. Ulcers are deeper and extend through the basement membrane into the underlying dermis. They heal slowly and residual scarring is common. It may be impossible to distinguish between ulcers and erosions without histology. In some diseases, ulcers and erosions occur concurrently, whereas in other conditions only one type of lesion may be present.

Ulcers and erosions may result from a variety of conditions (Box 12-1). Trauma, including self-trauma associated with pruritus, may lead to eroded and ulcerated lesions. Infectious diseases can lead to defects in the epithelial surface. In canine skin, bullae and vesicles are thin walled and rupture promptly after formation, leading to erosions and ulcers. Chemical and physical factors such as urine scalding, irritant contact dermatitis and thermal injury may also be responsible for defects in cutaneous continuity.

12.1 Box • 12-1 Differential Diagnosis Of Ulcers And Erosions Affecting Skin And Mucous Membranes

12.1.1 Canine Diseases

Infectious:

Bacterial pyoderma:

Surface:

Acute moist dermatitis (pyotraumatic dermatitis)

Intertrigo

Deep:

Folliculitis/furunculosis (including pyotraumatic folliculitis)

Oral bacterial infections (aerobic/anaerobic)

Fungal:

Yeast infections (*Malassezia pachydermatis, Candida* spp.)

Systemic/subcutaneous

Parasitic:

Demodicosis

Metabolic:

Calcinosis cutis (hyperadrenocorticism)

Uremia/renal failure

Necrolytic migratory erythema/metabolic epidermal necrosis

Neoplastic:

Epitheliotropic lymphoma

Squamous cell carcinoma

Physical, chemical:

Drug reactions

Solar injury

Thermal injury (freeze or burn)

Urine scald

Immune-mediated/autoimmune:

Discoid lupus erythematosus

Pemphigus group

Uveodermatologic syndrome

Miscellaneous autoimmune subepidermal vesiculobullous diseases:

Bullous pemphigoid

Epidermolysis bullosa acquisita

Linear IgA bullous disease

Mucocutaneous pemphigoid

Bullous systemic lupus-type 1

Miscellaneous:

Arthropod bites

Dermatomyositis

Dystrophic epidermolysis bullosa

Idiopathic ulceration of collies

Junctional epidermolysis bullosa

Toxic epidermal necrolysis/erythema multiforme

12.1.2 Feline Diseases

Infectious:

Viral:

Calicivirus and herpesvirus

Bacterial:

Atypical mycobacteriosis

Fungal:

Subcutaneous and systemic mycoses

Cryptococcosis

Sporotrichosis

Metabolic:

Uremia/renal disease

Neoplastic:

Fibrosarcoma

Lymphoma

Squamous cell carcinoma

Physical/chemical:

Drug reactions

Thermal

Immune-mediated/autoimmune:

Bullous pemphigoid

Pemphigus foliaceus

Toxic epidermal necrolysis/erythema multiforme

Miscellaneous/idiopathic:

Arthropod bites

Dystrophic epidermolysis bullosa

Eosinophilic plaque

Idiopathic ulceration of dorsal neck

Indolent ulcer

Junctional epidermolysis bullosa

Erosive and ulcerative diseases in dogs and cats may affect the mucous membranes with or without concurrent cutaneous involvement. Animals with oral lesions usually have halitosis, dysphagia, or both. Clinicians often suspect autoimmune and immune-mediated diseases in animals with erosions and lcerations. However, these diseases are uncommon or rare.

12.2 APPROACH TO THE DIAGNOSIS

Diagnosis may be difficult. Ulcers and erosions have many possible causes. Therefore the diagnostic approach must be carefully planned and thorough (Figure 12-1).

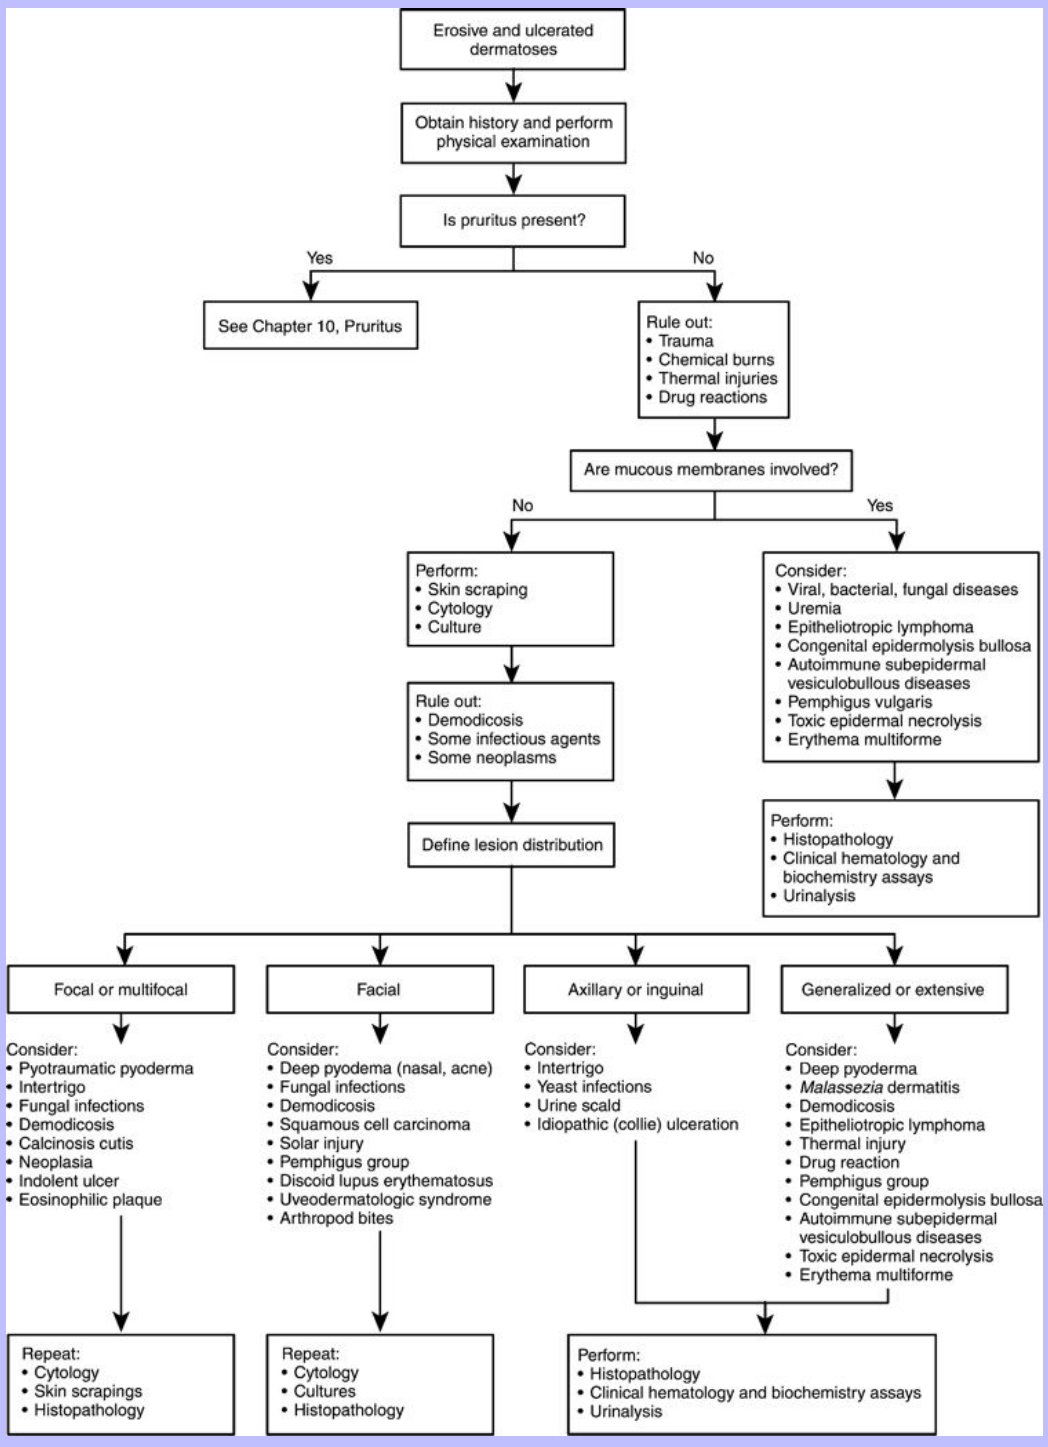
History may yield important clues. Obese or short-legged breeds of dogs are predisposed to intertriginous (or body fold) pyoderma and urine scalding. Older animals are more susceptible to metabolic and neoplastic disorders. Concurrent systemic signs may indicate that lesions are the result of metabolic disease or a drug eruption (assuming the animal has received therapy). Determining whether pruritus is present and at which stage it developed is helpful. If early pruritus is present, then it is possible that this is a primary pruritic disease, such as that caused by hypersensitivity or ectoparasitism, and that the lesions are the result of self-trauma. Late onset of pruritus may be more difficult to assess and may arise in a large number of diseases. Chronic sun exposure, especially of poorly pigmented skin, may lead to actinic lesions including neoplasia.

47

General and dermatologic examination will greatly aid the establishment of a differential diagnosis and enable the clinician to identify any concurrent systemic disease. The distribution of lesions may be extremely helpful (Box 12-2). Involvement of mucous membranes indicates that uremia, renal failure, or both; viral, bacterial, or yeast infection; certain immune-mediated disorders (bullous pemphigoid, pemphigus vulgaris), or epitheliotropic lymphoma is present.

49

Figure 12-1 Algorithm for evaluation of erosive and ulcerated dermatoses.



Initial diagnostic tests such as cytologic examination of impression smears and microscopy of skin scrapings are useful. However, the majority of causes will be identified by histopathology, and biopsy specimens should be taken early in the development of this group of diseases.

12.3 INFECTIOUS CAUSES OF EROSIONS AND ULCERS

12.3.1 Viral Diseases

Feline calicivirus and feline herpesvirus (FHV) infections usually cause upper respiratory tract disease and conjunctivitis. Rarely, they may lead to cutaneous ulceration, typically on the feet. A tentative clinical diagnosis of feline calicivirus and FHV can usually be based on results of the history and physical examination.

12.3.2 Bacterial Disease

Pyoderma and other bacterial diseases may be difficult to recognize because these infections are pleomorphic. If doubt exists as to whether the lesions are the result of bacterial infection, then histopathology should be performed. Concurrent systemic antimicrobial therapy is indicated while awaiting the pathologist's findings. If histopathology results indicate that the lesions are bacterial in origin but little improvement has been seen after antimicrobial therapy, then it is likely that the infection is secondary. A second biopsy sampling is indicated after antibacterial therapy to allow examination of tissue without secondary infection.

Surface bacterial infections in dogs are characterized by erosion. Intertrigo (skin fold pyoderma) affecting lip, vulvar, facial, tail, or body folds is readily recognized clinically. Impression cytology and culture of the folds may reveal evidence of bacterial infection, usually *Staphylococcus intermedius*, but the yeast *Malassezia pachydermatis* may also be involved. Pyotraumatic dermatitis (“hot spots” or acute moist dermatitis) is another form of canine surface pyoderma that is readily recognized clinically. However, in some cases, the infection is deeper than it would appear on clinical examination (this is termed *pyotraumatic folliculitis*). The distinction between these two forms is made by histopathology and is important because glucocorticoid therapy is contraindicated in the deeper form.

Deep pyoderma in dogs may be characterized by erosion and ulceration; examples include nasal pyoderma and German shepherd dog pyoderma. These may be confused with immune-mediated disorders. As previously discussed, histopathology and antimicrobial therapy may be of value. Aerobic and anaerobic bacterial infection may affect the mucous membranes. Such infections are often secondary to dental disease, immunosuppression, and systemic diseases.

Opportunist or atypical mycobacterial infections may occur when feline skin is inoculated with soil or water harboring the organism via traumatic injury. Affected cats exhibit chronic nonhealing wounds and ulcers with draining tracts. Systemic signs are usually absent.

12.3.3 Fungal Disease

In recent years, infection of the skin surface associated with the yeast *M. pachydermatis* has been recognized in dogs. Ulceration is not a feature, but the affected skin may be eroded. Lesions usually occur in intertriginous regions, particularly in predisposed breeds (Basset hounds, West Highland terriers, and English cocker spaniels). 49
The lesions are characterized by intense erythema, a yellow waxy crust, and malodor. Dermatophytosis may lead 50

to eroded and ulcerated lesions in dogs and cats. Diagnosis is based on cytology, culture, and response to antifungal therapy.

12.3.3.1

Box • 12-2 Distribution of Ulcers and Erosions as a Diagnostic Clue

Axillary/Inguinal:

Fungal (*Malassezia pachydermatis*, *Candida* spp.) (D)

Idiopathic ulceration of collies (D)

Intertrigo (D)

Urine scald (D)

Focal/Multifocal:

Calcinosis cutis (D)

Demodicosis (D)

Eosinophilic plaque (C)

Indolent ulcer (C)

Intertrigo (D)

Neoplasia (D, C)

Pyoderma (principally pyotraumatic dermatitis or folliculitis) (D)

Systemic/subcutaneous mycosis (D, C)

Facial:

Arthropod bites (D, C)

Bullous pemphigoid (D, C)

Deep pyoderma (D)

Demodicosis (D)

Dermatomyositis (D)

Discoid lupus erythematosus (D)

Linear IgA bullous disease (D)

Pemphigus foliaceus/erythematosus (D, C)

Solar injury (D, C)

Squamous cell carcinoma (C)

Systemic/subcutaneous mycosis (D, C)

Uveodermatologic syndrome (D)

Mucocutaneous:

Bacteria (aerobic/anaerobic) (D, C)

Bullous pemphigoid (D, C)

Bullous systemic lupus-type 1

Epidermolysis bullosa aquisita (D)

Epitheliotropic lymphoma (D)

Fungal (*M. pachydermatis, Candida* spp.) (D)

Mucocutaneous pemphigoid (D)

Pemphigus vulgaris (D)

Toxic epidermal necrosis/erythema multiforme (D, C)

Uremia (D, C)

Viral infection (calicivirus/herpesvirus) (C)

Generalized/Extensive:

Bullous pemphigoid (D)

Deep pyoderma (D)

Demodicosis (D)

Drug reaction (D, C)

Epitheliotropic lymphoma (D)

Malassezia dermatitis (D)

Pemphigus group (D, C)

Thermal injury (D, C)

Toxic epidermal necrolysis/erythema multiforme (D, C)

D, Dog; *C*, Cat.

Subcutaneous and systemic fungal infections are far less common. Impression smears and histopathology are indicated. Therapy is dependant on the organism involved.

12.4 OTHER CAUSES OF EROSIONS AND ULCERS

12.4.1 Parasitic Infections

Infestation with mites such as *Sarcoptes scabiei* or *Cheyletiella* spp. may lead to self-induced erosions and ulcers. Severe cases of demodicosis may, less commonly, lead to ulceration. Skin scrapings are diagnostic and mandatory.

12.4.2 Metabolic Disease

Calcinosis cutis is caused by accumulation of calcium in the skin, usually as a result of hyperadrenocorticism (naturally occurring or iatrogenic). Ulcers may develop over these mineral plaques. Histopathology is diagnostic. Treatment of the underlying systemic disease is usually curative.

Hepatic cirrhosis or pancreatic adenocarcinomata may lead to cutaneous ulceration that particularly affects the feet and perineum of older dogs. This disease has a range of synonyms, including hepatocutaneous syndrome, necrolytic migratory erythema, and metabolic epidermal necrosis.

Uremia as the result of renal failure may lead to oral ulceration. In cats, diabetes mellitus and hyperadrenocorticism may also lead to this phenomenon. Signs of systemic disease are usually present (e.g., anorexia, depression, dehydration). Halitosis is a feature. Urinalysis along with clinical biochemistry and hematology are usually diagnostic.

12.4.3 Neoplasia

Squamous cell carcinoma is a common feline neoplasm particularly affecting the extremities of white or lightly pigmented cats (e.g., ear tips, planum nasale). White English bull terriers are also predisposed. The prevalence of squamous cell carcinoma is greater in warmer climates. Waterproof, high sun protection factor cream should be applied to animals at risk. Ideally, access to sunshine should be restricted.

Epitheliotropic lymphoma leads to nodular, scaling, eroded and erythematous skin lesions in older dogs. Oral lesions (erythema, erosion) occur in the majority of cases. The prognosis is grave, with therapy having little influence on survival time.

Diagnosis of cutaneous neoplasia is by histopathology, although cytology of fine-needle aspirates and impression smears may be helpful.

12.4.4 Physical and Chemical Diseases

Such diseases can usually be diagnosed with history: exposure to extreme cold or scalding, recent treatment with medicaments, or (in the case of urine scalding) clinical examination. Solar-induced disease may be more difficult to diagnose because the onset is chronic and some manifestations of solar dermatoses may resemble other diseases.

12.4.5 Immune-Mediated and Autoimmune Diseases

Although this group is ascribed much significance by clinicians, these diseases are uncommon or rare. Lesions arise when tissue is damaged as a result of an inappropriate immunologic response. In autoimmune diseases, antibodies directed against a tissue component elicit an inflammatory response that may lead to cleavage of the epidermis from the underlying dermis (e.g., bullous pemphigoid, epidermolysis bullosa aquisita) or splitting within the epidermis itself (e.g., the pemphigus group). In some diseases, the precise pathologic mechanism is unknown (e.g., discoid lupus erythematosus).

The differentiation of the different immune-mediated diseases is important and made by histopathology. The different diseases respond to different forms of therapy, and the prognosis varies between them. If a definitive diagnosis is not obtained, then there is a risk of treating a benign disease too aggressively with immune-suppressive agents.

12.4.6 Miscellaneous Diseases

Dermatomyositis is a hereditary disorder primarily affecting the face and distal limbs of rough and Shetland collie (shelties) pups, leading to alopecia, erosions, ulceration, and scarring. It probably arises from immune-mediated vasculitis. Idiopathic ulceration is also seen in these breeds; previously it was thought that it may share its cause and pathogenesis with dermatomyositis. However, recent evidence suggests that it may be a form of lupoid dermatitis.

Idiopathic ulceration principally affects the ventral abdomen and groin and usually occurs in middle-aged rough and Shetland collie dogs. The prognosis is guarded because it is refractory to treatment in most cases.

Congenital diseases may affect the basement membrane and lead to ulceration and erosion. Examples include junctional epidermolysis bullosa and dystrophic epidermolysis bullosa.

13 CHAPTER • 13 Pustules and Papules

Edmund J. Rosser, Jr.

Pustules and papules are the most common primary skin lesions in dogs. Bacterial skin diseases are the most frequent cause of these lesions. The discussions will be limited to bacterial skin diseases of the dog because the development of a pyoderma is an extremely rare event in the cat.

13.1 CUTANEOUS BACTERIOLOGY

Bacteria that are isolated from the skin of dogs are commonly divided into three categories: (1) resident organisms, (2) transient organisms, and (3) common pathogenic organisms. Resident bacterial organisms can be routinely and repeatedly isolated and cultured from the surface of the skin, hairshafts, hair follicles, nares, oropharynx, and anal ring of the dog and normally live in harmony with the host without causing clinical disease. The resident bacteria of the canine skin surface include coagulase-negative staphylococci (*Staphylococcus epidermidis, S. cohnii, S. saprophyticus, S. hominis, S. haemolyticus, S. capitis, S. warneri, S. xylosus, S. simulans,* and *S. sciuri*); coagulase-positive staphylococci *(S. intermedius); Micrococcus* spp.; alpha-hemolytic streptococci; *Clostridium* spp.; *Propionibacterium acnes;* and *Acinetobacter* spp. The resident bacteria of canine hairshafts are *Micrococcus* spp., various gram-negative aerobes, *Bacillus* spp., and *S. intermedius. Propionibacterium acnes*, *Micrococcus* spp., streptococci, *Bacillus* spp., and *S. intermedius* have been isolated from within the hair follicles. The resident bacterium of the nares, oropharynx, and anal ring is *S. intermedius*. Transient bacterial organisms are not routinely or repeatedly isolated and cultured from the skin and haircoat of the dog. Under normal circumstances these organisms do not multiply on the dog but occasionally become pathogens by secondary invasion. They include *Escherichia coli, Proteus mirabilis, Pseudomonas* spp., *Corynebacterium* spp., and *Bacillus* spp.

Primary pathogenic organisms are capable of tissue invasion and creating disease. They are usually coagulase-positive staphylococci *(S. intermedius, S. aureus, S. hyicus)*, and *S. intermedius* is the most common isolate from canine skin infections.

13.2 PATHOPHYSIOLOGY

The bacterium *S. intermedius* is a normal resident of healthy canine skin, hairshafts, hair follicles, nares, oropharynx, and anal ring. They are also the most common causative organisms in superficial and deep pyodermas. These skin infections can be classified as *primary* or *secondary*. Secondary infections are undoubtedly the most common and are easily recognized by the tendency of the infection to be recurrent. Recurrence is the result of an underlying disease process allowing *S. intermedius* to become an opportunist and invade the stratum corneum, hair follicle, or both. These underlying disease processes may alter the skin directly as the result of local trauma, irritants, or scratching from parasitic and other pruritic skin diseases (see Chapter 10). Alternatively, the disease may act systemically to decrease resistance to cutaneous infections as in metabolic and immune-mediated skin diseases (see Chapter 269). Primary skin infections are so classified because once they are appropriately treated, they do not recur. However, it seems most likely that some transient insult occurs to the skin that allows *S. intermedius* to become a temporary opportunist and pathogen.

In either primary or secondary pyodermas, *S. intermedius* begins by overcolonizing the surface of the skin and either invading the stratum corneum (as in impetigo) or the hair follicle (as in superficial folliculitis). In cases of impetigo, the invasion of the stratum corneum results in the formation of primarily nonfollicular pustules (i.e., the pustules do not have a hairshaft in the center), which rupture and often form crusts and epidermal collarettes. The

lesions are usually nonpruritic and tend to be associated with minimal inflammation. In cases of superficial folliculitis, the invasion of the hair follicle results in the formation of follicular papules and pustules (i.e., hairshafts are present in the center of the lesions) that also rupture and often form crusts and epidermal collarettes. The lesions are usually pruritic and associated with inflammation and erythema. The older lesions often evolve into annular areas of alopecia and hyperpigmentation.

Deep pyodermas invariably begin as a superficial folliculitis and occur in cases where the underlying disease processes have not been appropriately identified. The infection travels into the deeper portions of the hair follicle and subsequently ruptures the hair follicle into the surrounding dermis, causing a furunculosis. The infection may continue to invade the deeper dermal and subcutaneous tissues, resulting in cellulitis.

13.3 CLINICAL FEATURES

A *pustule* is defined as a small, elevated, purulent fluid-filled cavity in the epidermis that is less than 0.5 cm in diameter. The base of the pustule is often erythematous. Pustules are most commonly associated with a superficial pyoderma. A *papule* is defined as a small, elevated, solid skin lesion up to 0.5 cm in diameter caused by the infiltration of inflammatory cells. They are usually pinkish or reddish in color. When they are oriented around a hair follicle, they usually indicate a superficial bacterial folliculitis. They are also commonly observed in cases of scabies and flea allergy (see Chapter 10). The presence of pustules and papules caused by a bacterial infection is frequently associated with concurrent pruritus owing to the production of proteolytic enzymes by the bacteria present in these lesions (primarily *S. intermedius*). These lesions may then rupture spontaneously or be altered in their appearance as a result of pruritus-induced self-trauma. Therefore these primary lesions may be transient, leaving behind only the presence of secondary lesions such as erosions, crusts, epidermal collarettes, posttraumatic alopecia, and excoriations. As the disease becomes more chronic in nature, additional skin changes may develop, such as hyperpigmentation and lichenification.

51

52

13.4 SUPERFICIAL PYODERMAS

13.4.1 Impetigo (Puppy Pyoderma)

Impetigo is most often observed in young dogs before puberty. This infection is considered to be an opportunistic or secondary pyoderma most frequently associated with poor nutrition, dirty environment, viral infections, ectoparasites, and intestinal parasitism. The disease is associated with the formation of superficial pustules that do not involve hair follicles and affects the inguinal and ventral abdominal regions (and occasionally the axillary region). Minimal erythema is noted, and the puppy is usually nonpruritic. Impetigo is often an incidental finding by the owner or is noticed on routine physical exam.

13.4.2 Superficial Folliculitis

A folliculitis is an inflammation of the hair follicle that can be caused by bacteria (staphylococcal folliculitis), fungi (dermatophyte folliculitis), and parasites (demodicosis, pelodera dermatitis).

Superficial bacterial folliculitis begins with the presence of pustules and papules initially affecting the inguinal and ventral abdominal regions. The papules and pustules are oriented around hair follicles and the dog is usually pruritic. As the disease progresses, epidermal collarettes form with varying degrees of central hyperpigmentation and marginal erythema, and additional areas affected may include the axillary regions and ventrolateral thorax.

When the truncal skin is affected, the haircoat often takes on a “moth-eaten” appearance (especially in short-coated breeds of dogs).

13.5 DEEP FOLLICULITIS AND FURUNCULOSIS

Furunculosis is an inflammation of hair follicles with subsequent follicular rupture extending into the surrounding dermis and subcutaneous tissue. The lesions initially observed include papules, pustules, and epidermal collarettes followed by the presence of exudation, crust formation, and deep draining tracts. As the process of folliculitis and furunculosis continues and the lesions coalesce, areas may become nodular and indurated or a cellulitis may develop. Another lesion occasionally observed in these patients is a hemorrhagic bulla. The lesions are usually first noticed in inguinal, ventral abdominal, and axillary regions as a superficial folliculitis. However, when the underlying disease process is not appropriately treated, deep folliculitis and furunculosis may develop. With this complication, involvement of the entire ventrum or a generalized process may ensue. Occasionally the lesions are most severe over the pressure and wear areas of the body such as the elbows and lateral aspects of the stifle, hip, and chest region. In most cases, the lesions seem to be pruritic or painful.

Signs of systemic involvement may be evident, including anorexia, depression, weight loss, lethargy, and fever. This is often the indication of the development of bacteremia, septicemia, or both. A peripheral lymphadenopathy is also a common finding.

13.6 RECURRENT PYODERMAS

13.6.1 History and Physical Findings

Recurrent pyodermas may appear initially as a superficial folliculitis, deep folliculitis, or furunculosis (or a combination of these symptoms). Invariably, a recurrent pyoderma has some underlying reason for reappearing. Therefore the underlying problem needs to be identified and appropriately treated. One should first make certain that a recurrent pyoderma is not iatrogenic in nature. Iatrogenic recurrent pyodermas may be the result of previously inadequate drug therapy, including inappropriate antibiotic selection; inadequate dose, frequency and duration of antibiotic therapy; and the chronic use of corticosteroids as an adjunct to the treatment of a pyoderma.

13.6.2 Diagnostic Approach

The first part of the diagnostic approach to a patient with a pyoderma is to recognize the various lesions that indicate its presence. One of the commonly misinterpreted lesions on dermatologic examination is the epidermal collarette, especially when its margins are erythematous. It is often thought to be an indication of a dermatophyte (ringworm) infection but is more commonly an indication of a superficial spreading pyoderma. In addition, the presence of papules in patients with pruritus is frequently thought to be associated with primary allergic skin diseases and is treated solely with a corticosteroid. However, in many cases, closer inspection reveals the presence of a pinpoint pustule on top of the papule or a hairshaft exiting the center of the papule, which indicates the presence of a folliculitis. When one is uncertain as to whether the lesion present may be an indication of a bacterial skin disease, a skin biopsy should be performed.

When considering treatment of a dog with an antibiotic-responsive but recurrent pyoderma, the first step is to systematically evaluate the patient for some of the more common causes of a recurrence. One should consider obtaining the following tests: skin scrapings, flea combing, hair plucking and microscopic examination, skin surface impression cytology, cytology of pustules, and acetate (Scotch) tape preparations (Figure 13-1). When

these test results are negative and the cytology or culture of pustules and papules indicate the presence of a pyoderma, an appropriate antibiotic must be selected. Either the antibiotic is empirically chosen (Table 13-1) or, preferably, is chosen based on the results of culture and susceptibility testing. The next step involves the use of the dog's response to therapy as an aid to the definitive diagnosis. In a majority of dogs with a recurrent pyoderma, some degree of pruritus is present. However, at this stage of the workup, the use of a corticosteroid (or any other antipruritic drug) needs to be avoided. The dog is then treated *only* with the appropriate antibiotic and shampoo therapy (benzoyl peroxide shampoo) for a period of 3 consecutive weeks and then reevaluated (Figure 13-2). This initial duration of therapy is usually adequate in cases of superficial folliculitis but may need to be increased to 6 to 8 consecutive weeks in cases of deep folliculitis and furunculosis. If the recheck examination reveals that the pyoderma has noticeably improved or resolved but the pruritus has persisted, the dog needs to be further evaluated for the presence of an underlying primary pruritic skin disease including flea allergy dermatitis, atopic dermatitis, food allergy, scabies, demodicosis, allergic contact dermatitis, and seborrheic dermatitis. On the initial visit the owner should also be advised to observe the areas on the dog's body where the pruritus is persisting or most severe (i.e., the distribution pattern of pruritus) to assist the clinician in establishing the underlying differential diagnosis (see Chapter 10). However, if the recheck examination reveals that the pyoderma has resolved and the dog has become nonpruritic in response to the antibiotic and shampoo therapy alone, then it is necessary to establish whether the pyoderma is truly recurrent. In this case the appropriate antibiotic and shampoo therapy should be continued for a total treatment time of 8 weeks. After having done this, some patients with a history of a recurrent pyoderma will experience permanent resolution of their disease. If the pyoderma recurs after this treatment, then the following diseases should be ruled out: hypothyroidism, Cushing's disease, diabetes mellitus, reproductive hormone imbalances, demodicosis, cheyletiellosis, staphylococcal hypersensitivity, and cell-mediated immunodeficiencies (see Chapter 8).

52

54

Table • 13-1 Systemic Antibiotics Recommended in the Treatment of Staphylococcal Pyodermas

ANTIBIOTIC	RECOMMENDED ORAL DOSE
Clindamycin	5.5 mg/kg q12h, or 11 mg/kg q24h
Erythromycin	15 mg/kg q8h
Cephalexin	22 mg/kg q8h, or 33 mg/kg q12h
Cefadroxil	22 mg/kg q12h
Trimethoprim/sulfadiazine	15–30 mg/kg q12h
Ormetoprim/sulfadimethoxine	55 mg/kg on day 1, then 27.5 mg/kg q24h
Amoxicillin/clavulanate	13.75 mg/kg q12h
Enrofloxacin*	5–20 mg/kg q24h

* Only recommended in instances of recurrent pyodermas when culture and susceptibility testing indicate its required use.

14 CHAPTER • 14 Scaling and Crusting Dermatoses

Kinga Gortel

Jonathan D. Plant

14.1 PATHOPHYSIOLOGY

Scaling and crusting are common findings in many cutaneous diseases (Table 14-1). Scaling refers to the accumulation of loose fragments of cornified cells on the skin surface. Normal desquamation of cornified cells is not visible to the naked eye, so scales are only seen when loss occurs in larger flakes. Scales are usually secondary lesions in chronically inflamed skin but may also be primary lesions in conditions such as seborrhea and ichthyosis. Crusting occurs when dried exudates or secretions adhere to the surface of the skin. Crusts may be composed of pus, blood, serum, other exudates, or thick scales. They are also usually secondary, occurring on skin traumatized as a result of pruritus or in any pustular dermatosis. Crusts may be primary in some conditions such as miliary dermatitis and zinc-responsive dermatosis.

14.2 SIGNALMENT

14.2.1 Age

Puppies and kittens developing scaling within the first few weeks of life should be evaluated for transmissible infections and congenital dermatoses. Juveniles should be screened for infectious diseases, such as parasites, hereditary dermatoses, nutritional dermatoses, and environmental diseases. Differential diagnoses for similarly affected adult dogs and cats include the diseases listed for younger animals, as well as allergic, immune-mediated, endocrine, and metabolic diseases; keratinization disorders; and cutaneous neoplasia.

14.2.2 Breed

Breeds with an inherited predisposition to the development of primary scaling and crusting disorders include American cocker spaniels, English springer spaniels, West Highland white terriers, Basset hounds, Irish setters, Doberman pinschers, and Labrador retrievers. Breed predispositions are also noted in many other dermatoses that lead to scaling and crusting, including canine atopic dermatitis, hypothyroidism, and sebaceous adenitis.

14.3 HISTORICAL FINDINGS

The history can be helpful in narrowing the list of differential diagnoses in an animal with scaling or crusting. The age of onset should be established. The owner should also be questioned as to the seasonality of the scaling and crusting. An important consideration is the degree of accompanying pruritus. Diseases that are often severely pruritic include sarcoptic acariasis, atopic dermatitis, fleabite hypersensitivity, food hypersensitivity, *Malassezia* dermatitis, and cutaneous lymphoma.

14.4 PHYSICAL EXAMINATION

14.4.1 Lesions

Scaling and crusting are often encountered concurrently. The skin should be examined for pustules, papules, excoriation, erythema, ulceration, and the shape of crusts or scaly areas should be noted (e.g., epidermal collarettes).

14.4.2 Distribution

Scaling and crusting dermatoses may be generalized or have site predilections. Generalized conditions include dermatophytosis, cheyletiellosis, primary seborrhea, and sebaceous adenitis. Site predilections include the nasal planum (e.g., pemphigus foliaceus, discoid lupus erythematosus, squamous cell carcinoma), footpads (e.g., pemphigus foliaceus, zinc-responsive dermatosis, superficial necrolytic dermatitis, plasma cell pododermatitis), and ear pinnae (e.g., sarcoptic mange, ear margin seborrhea).

14.5 DIAGNOSTIC PLAN

Skin scrapings and cytology are simple and often useful for evaluation of dogs and cats with scaling and crusting (Figure 14-1). Skin scrapings are most useful for diagnosing demodectic mange in dogs and *Notoedres cati* in cats. They are less sensitive for canine *Sarcoptes scabiei. Cheyletiella* mites are easiest to find by acetate tape impressions.

Samples for cytologic examination of the skin may be collected directly from the surface of the skin by impression smears if the skin is greasy or moist or after the removal of crusts or adherent scales. If pustules are present, their content should be smeared on a slide. Waxy or dry samples benefit from gentle heat fixing. A modified Wright's stain (e.g., Diff Quick) is used to examine the slides. Cytology is most useful for confirming presence of bacteria and yeast. The inflammatory response of the skin can also be evaluated because neutrophils, eosinophils, and mononuclear cells are easily differentiated. The presence of numerous acantholytic cells among neutrophils suggests pemphigus but is occasionally encountered in other inflammatory conditions.

Examination for fungi should be attempted when dermatophytosis is suspected. Cats with scaling and crusting should always be checked for dermatophytes unless another cause is readily identified. A Wood's light examination should be performed. A dermatophyte test medium (DTM) fungal culture should always be inoculated if dermatophytosis is suspected. Direct examination of hair for dermatophytes is less sensitive.

Skin biopsy is needed to make a definitive diagnosis in some scaling and crusting disorders, including immune-mediated diseases, neoplastic conditions, and primary keratinization disorders. Crust and scale must be included in the biopsy, so the biopsy site should never be cleaned or scrubbed. Hair may be gently cut with scissors without disrupting any surface material.

Table • 14-1 Scaling and Crusting Diseases of Dogs and Cats

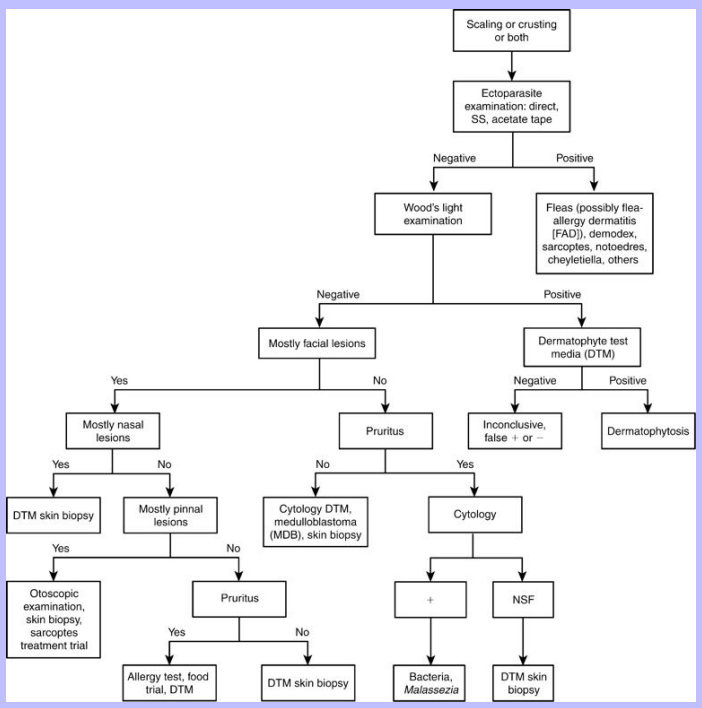
DISEASE	LESIONS	SPECIES	SIGNALMENT	LESION DISTRIBUTION	FREQUENCY	PRURITUS	DIAGNOSIS
Bacterial							
Superficial folliculitis	Crusts, scales, collarettes, pustules	Dog >cat	Varies	Trunk	C	–to ++	CS, Cyt, BC, Bx
Deep pyoderma	Crusts, ulcers	Dog >cat	Varies	Trunk, feet	C	+	CS, Cyt, BC, Bx
Mucocutaneous pyoderma	Crusts, ulcers	Dog	German Shepherd or others	Lips, peribuccal	U	+(painful)	CS, Bx
Pyotraumatic dermatitis	Moist crust, exudation, erythema	Dog	Any (often flea-related)	Face, neck, caudal trunk	C	+++	CS
Fungal							
Dermatophytosis	Crusts, scales, alopecia, erythema	Cat >dog	Young most frequently	Head, extremities, trunk	C	–to ++	DTM, light
Malassezia dermatitis	Crusts, scales, erythema, lichenification	Dog >cat	Adult most frequently	Axillary, groin, interdigital, facial	C	+++	Cyt
Parasitic							
Ctenocephalides felis (flea)	Scales, erythema	Dog >cat	Any	Lumbosacral, neck	C	+	CS, parasite exam
Sarcoptes scabiei	Crusts, scales, excoriations, alopecia, erythema	Dog	Any	Pinnal margins, lateral elbows, ventrum	C	+++	SS, response to therapy
Demodex canis	Crusts, scales, exudation, alopecia, erythema	Dog	Young or immunocompro-mised adults	From single lesions on the head to generalized	C	–to +	SS
Cheyletiella spp.	Scales	Dog, cat	Young most frequently	Dorsal trunk to generalized	U	–to ++	SS, tape impression
Notoedres cati	Crusts, scales	Cat	Any	Head, feet, generalized	U	–to +++	SS
Viral							
Feline leukemia virus (FeLV)	Crusts, scales, erosions	Cat	Any	Face, pinnae, perioral, feet, trunk	U	++	Serology, Bx
Allergic							
Atopic dermatitis	Erythema, alopecia, crusts (excoriation), scales, and others	Dog >cat	All, dogs often 1–5 years old	Face, ears, feet, ventrum	C	+to +++	CS, IDST, IgE
Food hypersensitivity	Erythema, crusts (excoriation), and others	Dog, cat	All, any age	Any	U	+to +++	Food trial
Flea bite hypersensitivity	Erythema, crusts (excoriation), and others	Dog, cat	All	Caudal dorsum, ventrum, thighs	C	++to +++	Response to flea control

Miliary dermatitis	Small hemorrhagic crusts	Cat	All (often associated with fleas)	Dorsum	C	++	CS
Endocrine and Metabolic							
Hyperadrenocorticism	Alopecia, cutaneous atrophy, calcinosis cutis, crusts (pyoderma)	Dog >cat	Middle aged, older	Trunk	C	–(occ. +)	MDB, hormone assays, imaging, Bx
Hypothyroidism	Scaling, dry skin, pyoderma, +/–alopecia	Dog	Middle aged, often large breed	Generalized	C	–	MDB, thyroid assay
Necrolytic migratory erythema	Severe adherent crusting	Dog (cat)	Old	Muzzle, footpads, pressure points	R	+to ++ (painful)	Bx, MDB, liver assays, imaging
Immune Mediated							
Pemphigus foliaceus	Crusts, pustules	Dog, cat	Any age and sex; Akita, chow chow, and others	Nasal planum, muzzle, pinnae, foot pads, trunk	U	–to +	Bx
Discoid lupus erythematosus	Crusts, depigmentation erosions, ulcers	Dog, cat	Collies, Shetland sheepdog, and others	Nasal planum, muzzle	U	–	Bx
Erythema multiforme	Crusts, vesicles erythema, target lesions, erosions, ulcers	Dog, cat	Any	Axillae, groin, mucocutaneous junctions	U	–	Bx
Congenital and Hereditary							
Primary seborrhea	Excessive scaling or greasy skin	Dog (cat)	Onset before 6 months, American cocker spaniel and others	Generalized	U	–to ++, esp. with secondary infections	Bx
Schnauzer comedo syndrome	Comedones that may become crusted	Dog	Miniature schnauzer	Dorsum	C	–	CS, Bx
Familial canine dermatomyositis	Alopecia, scaling, depigmentation	Dog	Onset before 6 months, collie, Shetland sheepdog, and others	Face, pressure points	U	–	Cs, Bx
Keratinization Defects							
Secondary seborrhea	Excessive scaling or greasy skin	Dog, cat	Any age	Depends on primary cause	C	–to +++depending on cause	CS, any appropriate tests for primary disease
Vitamin A—responsive dermatosis	Marked follicular plugging, hyperkeratotic plaques	Dog	Cocker spaniel and others Adult onset	Generalized, more pronounced on ventrum	U	–to ++	CS, Bx
Ear margin dermatosis	Follicular casts and scaling	Dog	Dachshund and others	Ear margins, lateral and medial	U	–, may become painful	CS, Bx
Environmental							

Solar dermatitis	Erythema, scaling, may progress to exudation and crusting	Dog >cat	Light-haired animals, outdoor exposure	Pinnae, nasal planum (cat), bridge of nose, ventrum (dog)	C	–to +	CS, Bx
Nutritional							
Zinc-responsive dermatosis	Crusts, scales, erythema, alopecia	Dog	Siberian husky, Alaskan malamute; young adults	Periocular, perioral, mucocutaneous junctions, pressure points	U	–to +	Bx
Fatty acid deficiency	Scales	Dog, cat	Any	Generalized	U	–to ++	Dietary hx
Other							
Cutaneous lymphoma	Lesions highly variable but may include severe scaling	Dog >cat	Older animals	Generalized or localized	U	–to +++	Bx
Granulomatous sebaceous adenitis	Hyperkeratosis, alopecia, follicular casts, may be erythematous	Dog (cat)	Young to middle-aged, standard poodle, Akita, vizsla, and others	Face, trunk, pinnae, become generalized	C	–to ++	CS, Bx
Otitis externa	Scale, erythema, otic exudate	Dog >cat	Any	Pinnae, ear canal	C	++	Otoscopic examination, Cyt, BC

BC, Bacterial culture; *Bx,* skin biopsy; *C,* common; *CS,* clinical signs; *Cyt,* cytology; *DTM,* dermatophyte test medium fungal culture; *Hx,* history; *IDST,* intradermal skin test; *IgE,* allergen-specific serum IgE assay; *MDB,* minimum database; *NSF,* no significant findings; *R,* rare; *SS,* skin scraping; *U,* uncommon; +, positive; –, negative.

Figure 14-1 Diagnostic approach to scaling and crusting in dogs and cats.



A minimum database is most useful in middle-aged and older animals when endocrine or metabolic causes are suspected. Bacterial culture should be performed when bacteria are identified on cytology or when crusting does not completely resolve after appropriate antibiotic treatment for pyoderma.

14.6 TREATMENT

It is beyond the scope of this chapter to address the specific treatment of each disease that may result in scaling and crusting. In general terms, treatment can be divided into topical and systemic therapeutic approaches.

14.6.1 Topical Therapy

To reduce scaling and crusting, the goal is to normalize cell proliferation, differentiation, and desquamation and to reduce exudation from the skin surface. Active ingredients should be selected based on the underlying condition, and are most frequently applied as shampoos and conditioners. Active ingredients may be keratolytic, keratoplastic, degreasing, antimicrobial, antiparasitic, antiinflammatory, antipruritic, or moisturizing. Most animals with generalized scaling and crusting disorders will benefit from frequent bathing (twice a week or more).

59

60

14.6.2 Systemic Therapy

For secondary scaling and crusting, attempts should be made to correct the underlying cause. For primary scaling and crusting disorders of dogs, vitamin A or synthetic retinoid therapy are variably helpful. Vitamin A is given at a dose of 800 to 1000 mg/kg/day. The synthetic retinoid acetretin has been used to treat primary seborrhea in dogs at a dose of 1 mg/kg/day. The principal effect is to normalize epithelial keratinization. Possible adverse reactions include teratogenicity, keratoconjunctivitis, elevated liver enzymes, and hypertriglyceridemia. Its use is limited by expense.

15 CHAPTER • 15 Changes in Pigmentation

Zeineb Alhaidari

Pigmentation changes are frequently seen in veterinary medicine; they not only have potential cosmetic importance but they could also imply medical or zootechnical consequences because possible causes include systemic diseases, genodermatoses, or both. Evaluation of pigmentation changes requires developing a differential diagnosis (Figure 15-1).

The term *leukoderma* refers to a loss of melanin pigmentation of the skin. The term *leukotrichia* or *poliosis* refers to a loss of melanin pigmentation of the hair. Similarly, *melanoderma* refers to an increased melanin pigmentation of the skin, and *melanotrichia* refers to an increased pigmentation of the hair.

15.1 HYPOPIGMENTATION

15.1.1 History

15.1.1.1 Breed

A marked breed predilection exists for most noninfectious focal hypopigmentation disorders.

- *Vitiligo,* characterized by the symmetrical development of achromic macules on the facial mucocutaneous junctions, has a breed predilection in the Tervueren, Rottweiler, Doberman pinscher, Newfoundland, Collie, German shorthair pointer, Old English sheepdog, (all the breeds, with or without majascule) and Siamese cat.
- The *uveodermatologic syndrome,* an autoimmune disorder targeting ocular and cutaneous melanocytes and resulting in uveitis and skin depigmentation, has been described mainly in northern breeds such as the Siberian husky, Samoyed, and Akita.
- *Acquired idiopathic hypopigmentation of the nose,* an idiopathic gradual loss of nasal planum pigment, is widespread in some canine breeds such as the Labrador retriever, Siberian husky, Samoyed, Poodle, and German shepherd.
- *Discoid lupus,* a presumed autoimmune photoaggravated disorder limited to the skin, affects mainly Collies and German shepherds.
- *Dermatomyositis* is a genodermatosis described in the Collie, Shetland sheepdog, and Beauceron shepherd breed. Crusting, ulceration, and depigmentation of the skin, affecting preferentially the face and extremities, are associated with varying degrees of muscle involvement.

15.1.1.2 Age of Onset

The age of onset is often helpful in the diagnosis of certain depigmenting disorders. An early age of onset usually suggests a genodermatosis. *Dermatomyositis* is classically first observed in 3-to 4-month-old puppies, with variably affected individuals in the litter. Symmetric unpigmented macules involving the mucocutaneous junctions of the face in a young dog, aged 8 months to 3 years, are highly suggestive of *vitiligo. Discoid lupus,*

which has a similar clinical appearance to vitiligo, also affects dogs of a similar age. The old animal is more prone to develop *bullous autoimmune dermatoses* and neoplastic disorders such as *epitheliotrophic lymphomas*.

15.1.1.3 Evolution

Evolution of the hypopigmentation should be carefully documented. Circumstances of onset should be investigated. Local trauma, including physical or chemical causes, must be considered as a potential etiology of melanocyte dysfunction or destruction. Any drug administration preceding the onset of symptoms should be noted.

The nature and location of the initial lesion could be of major interest, especially in the differential diagnosis of nasal depigmentation. Unpigmented macules developing at the junction between the planum nasale and haired skin are highly suggestive of *bullous autoimmune diseases. Contact dermatitis* usually affects the rostral nares. Depigmentation developing on the floor of one nostril and associated with a purulent discharge is highly suggestive of *aspergillosis*.

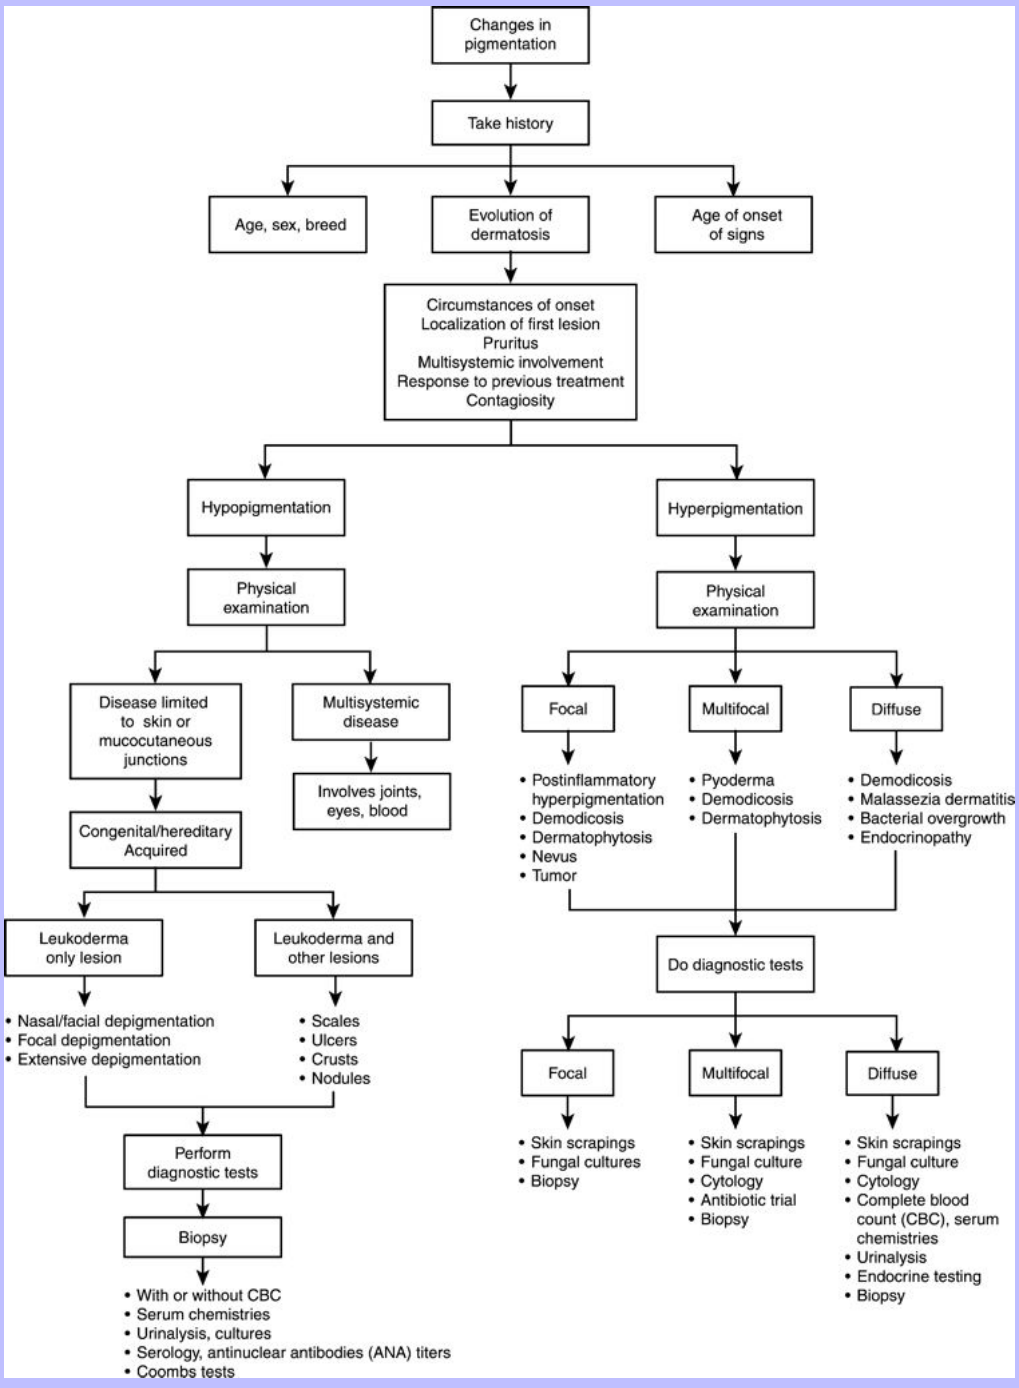
Because *lupus erythematosus* or *pemphigus erythematosus* lesions are exacerbated with sun exposure, seasonality of symptoms is an interesting observation. Reported concurrent clinical signs, such as lameness, can be indicative of *leishmaniasis* or *systemic lupus erythematosus* (SLE). Ocular involvement suggests *uveodermatologic syndrome, leishmaniasis,* or *systemic mycoses,* such as *cryptococcosis* or *blastomycosis*. Weight loss, fever, and anorexia can be manifestations of *neoplastic diseases, SLE, bullous autoimmune disorders, systemic mycoses,* or *leishmaniasis*.

15.1.2 Physical Examination

Physical examination is the second important step in the diagnosis of pigmentary changes. The physical evaluation should help determine whether a disease is limited to the skin or multisystemic (see Figure 15-1). If the disease is limited to the skin and if leukoderma, leukotrichia, or both is the only skin lesion present, then one has to consider the topography of the lesions.

If the depigmentation is limited to the nose or facial mucocutaneous junctions, the persistence of normal nasal surface architecture favors a noninflammatory cause, such as *vitiligo* or *acquired idiopathic hypopigmentation*. Alternatively, if the normal surface architecture has been altered, an inflammatory dermatosis should be suspected. However, ultraviolet radiation associated with sunlight can induce an actinic dermatitis on a lesion that is initially simply unpigmented, with subsequent erythema, ulcers, crusts, and disappearance of cutaneous surface markings.

Figure 15-1 Algorithm for evaluation of changes in pigmentation.



If the unpigmented lesion is focal, then a history of *trauma* should be investigated. Extensive acquired leukotrichia can follow an immunologic attack directed primarily against the hair follicles in *alopecia areata,* resulting in alopecia and occasional regrowth of white hairs.

If leukoderma, leukotrichia, or both is associated with other skin lesions such as scales, ulcers, or crusts, *leishmaniasis* or *autoimmune dermatoses* should be considered.

Infiltrative lesions are usually indicators of *systemic mycoses* or *tumors*.

Multisystemic involvement is seen in *leishmaniasis, SLE, systemic mycoses,* or *tumors*. Arthritis and glomerulonephritis are frequent features of both *SLE* and *leishmaniasis*. Hematologic disorders, such as hemolytic anemia, leukopenia, and thrombocytopenia, can be associated with *SLE*. Nonregenerative anemia, leukopenia, and monocytosis frequently are observed in *leishmaniasis*. In the *uveodermatologic syndrome,* uveitis and subsequent glaucoma usually precede the cutaneous manifestations. The eye is also a frequent target in *leishmaniasis* and in *systemic mycoses,* such as *cryptococcosis* and *blastomycosis*.

15.1.3 Diagnostic Tests

Skin biopsy is the fundamental diagnostic procedure when faced with hypopigmentation (see Figure 15-1). Specimens should be taken both from the center and from the margins of lesions, especially if the disease is active and spreading. Biopsies can demonstrate the presence or absence of an inflammatory infiltrate and the presence or absence of melanocytes. The presence or absence of melanocytes is difficult to ascertain because special stains such as Fontana-Mason or dopa reaction cannot differentiate between nonfunctional and absent melanocytes. If inflammatory infiltrates and melanocytes are absent, one can suspect either *vitiligo* or a *postinflammatory depigmentation* with complete destruction of melanocytes. If melanocytes are present, *acquired idiopathic hypopigmentation* can be suspected. Inflammatory infiltrates are associated with several depigmenting diseases. Of particular interest are lichenoid infiltrates, which are chiefly lympho-cytic in *lupus erythematosus* and *epitheliotrophic lymphomas* and are granulomatous in *uveodermatologic syndrome*. Infectious agents such as leishmania, mycobacteria, or fungal organisms are sometimes demonstrated on histologic sections of inflamed unpigmented lesions. If a pyogranulomatous or granulomatous nodular-to-diffuse infiltrate is observed, special stains should be requested in an attempt to identify the presence of microorganisms.

Depending on biopsy results, diagnosis will be completed by other tests such as complete blood count (CBC), serum chemistry profile, urinalysis, cultures, serologic testing for leishmaniasis or systemic mycosis, antinuclear antibodies dosage, and Coombs' test.

15.2 HYPERPIGMENTATION

15.2.1 History

15.2.1.1 Breed

Demodicosis and most *endocrinopathies* occur more frequently in specific breeds. Doberman pinschers, Shar Peis, West Highland white terriers, Scottish terriers, Boston terriers, Great Danes, and Weimaraners are breeds known to have a high prevalence of *demodicosis*. Great Danes, Irish setters, Doberman pinschers, and Old English sheepdogs are predisposed to *hypothyroidism,* whereas poodles, boxers, Boston terriers, beagles, and dachsunds are predisposed to *hyperadrenocorticism*.

15.2.1.2 Age of Onset

Age of onset is an important clue to the diagnosis of hyperpigmenting disorders. An infectious cause, such as *pyoderma, demodicosis,* or *dermatophytosis*, should be suspected primarily in young animals, whereas older animals may be at risk for endocrinopathies or tumors.

15.2.1.3 Evolution

The evolution of the hyperpigmentation should be carefully investigated. The age of onset and distribution of the initial lesions should be described. Any *trauma* can result in postinflammatory hyperpigmentation. Posttraumatic hyperpigmentation is observed more frequently in certain breeds such as the poodle (especially apricot or gray) or the Siamese cat. Scratching is a common cause of skin trauma. Thus any chronic pruritic skin condition (e.g., *atopy, adverse food reactions, pyoderma, Malassezia dermatitis, sarcoptic mange*) can potentially result in lichenification and hyperpigmentation. This makes pruritus a criterion of primary importance in the differential diagnosis of hyperpigmentation. Response to previous therapeutic trials, including doses and duration of therapy, should be reported. Spread to other animals in the environment or to owners increases the suspicion for contagious diseases such as *dermatophytosis* or *acariasis* (e.g., *scabies, cheyletiellosis*).

15.2.2 Physical Examination

When dealing with hyperpigmentation, the distribution of lesions is of major importance. If the lesion is solitary, the differential diagnosis should include *postinflammatory hyperpigmentation* (carefully review history), *demodicosis, dermatophytosis, nevus,* and *tumor*. If the lesions are multifocal and coin shaped with peripheral expansion, *pyoderma, demodicosis,* and *dermatophytosis* are primary suspects. In cases of diffuse nonpruritic hyperpigmentation, *demodicosis* and *endocrinopathies* should be considered. The latter are usually associated with systemic signs such as lethargy and obesity in the case of hypothyroidism, and polyuria/polyphegia (PU-PD) in the case of Cushing's syndrome.

15.2.3 Diagnostic Tests

Multiple skin scrapings are an extremely important diagnostic aid in almost every dermatologic case. They can give a quick, inexpensive, and easy diagnosis of demodicosis, scabies, or cheyletiellosis, although the latter two mites can be difficult to demonstrate. To confirm or eliminate the diagnosis of dermatophytosis, Wood's lamp examinations, direct examination of hairs or scales, and fungal culture should be performed in every case of focal, multifocal, or diffuse hyperpigmentation. Cytology is another easy test to use when dealing with hyperpigmentation. It can reveal yeast, such as *Malassezia pachydermatis,* or cocci. If the previous diagnostic tests fail to reveal a specific causative agent, an antibiotic trial is indicated when presenting with multifocal coin-shaped hyperpigmented lesions in dogs because pyoderma is common in dogs. Antibiotics with known activity against staphylococci, including beta-lactamase–resistant penicillins; first-generation cephalosporins, macrolides, and related molecules (i.e., lincomycin and clindamycin); potentiated sulfonamides; or fluoroquinolones should be prescribed for 4 to 6 weeks before rechecking the dog. In dogs with diffuse hyperpigmentation, a CBC, serum biochemistry panel, and urinalysis should be performed after skin scrapings have excluded the possibility of demodicosis and cytology has excluded bacterial overgrowth of *Malassezia* dermatitis has been cytologically excluded. These diagnostic tests might provide helpful clues leading to the identification of specific underlying endocrinopathies. For example, increases in serum alkaline phosphatase,

62

63

alanine aminotransferase (ALT), and cholesterol may raise the suspicion of hyperadrenocorticism. Thyroid function can be evaluated by a basal T_4 concentration, endogenous thyroid-stimulating hormone (TSH) level, or TSH response test. Adrenal function can be evaluated using adrenocorticotropic hormone (ACTH) stimulation, low-dose dexamethasone suppression, or urine cortisol: creatinine ratio tests. Sex hormone imbalances can be evaluated by basal estradiol and progesterone concentrations in female dogs and by human chorionic gonadotropin (HCG) stimulation tests in male dogs. The last and least rewarding procedure when dealing with skin hyperpigmentation is skin biopsy. A biopsy generally gives only vague clues or eliminates certain possible causes. It can, however, in conjunction with history and physical examination, furnish a high suspicion index for specific diseases such as *seasonal flank alopecia.* Seasonal flank alopecia is a cyclic follicular dysplasia characterized clinically by recurrent symmetric hyperpigmented alopecic flank lesions and an unpredictable prognosis. Biopsies demonstrate follicular atrophy and infundibular hyperkeratosis, which extend into the ostia of the secondary follicles and sebaceous ducts, mimicking the appearance of a malformed foot.

As always in dermatology, a definitive etiologic diagnosis is a mandatory prerequisite to successful management. Pigmentation changes, including both hypopigmentation and hyperpigmentation, are no exceptions.

16 CHAPTER • 16 Fleas, Flea Allergy, and Flea Control

Candace A. Sousa

Flea infestations of pets and the home environment are a common occurrence. Fleas are responsible for the production and transmission of several diseases of humans and their pets. The flea that causes most of the problems is *Ctenocephalides felis felis*, the common cat flea. In one study it accounted for 92% to 99% of the fleas found on dogs and cats, respectively.[1]

The flea passes through four stages in its life cycle. It undergoes a complete metamorphosis at each stage.[2] At any time approximately 57% of the fleas are eggs, 34% are larva, 8% are pupa, and only about 1% are present as adults. The life cycle can be completed in as little as 12 days or take as long as 174 days and is dependent on the ambient temperature and humidity.[3]

Flea eggs are oval, pearly white, nonsticky, and about 0.5 mm in length.[4] The egg hatches between 1 and 10 days of being deposited on the host and falling off into the environment, depending on the ambient temperature and humidity (ideal conditions are 70% relative humidity and 35°C (95°F).[2–4]

Flea larvae emerge from the eggs after hatching. The larva of *C. felis felis* has three stages or larval "instars." The larvae are about 2 mm long, slender, white, and covered with short hairs. They feed on organic debris and blood-containing feces from adult fleas. The larvae are negatively phototactic (move away from light) and positively geotactic (move toward the ground).[2,4] Therefore when indoors the larvae avoid direct sunlight and move under furniture, appliances, and into carpet fibers. Outdoors, they move into shaded areas under bushes, trees, and leaves. Five to 11 days are required for the larvae to molt twice, during which they grow to about 5 mm in length. The larvae are extremely susceptible to heat and desiccation. They can survive only if the relative humidity is greater than 50% or when soil moisture is between 1% to 20%.[3]

Temperatures greater than 35°C (95°F) and less than 3°C (35°F) for more than 40 hours per month are also deleterious to survival. The mature larvae produce a sticky cocoon in which to pupate. Environmental debris may adhere to the cocoon, which helps it go undetected and provides excellent protection against insecticides. Pupation lasts from 5 to 9 days. Environmental locations suitable for a high rate of larval survival are termed *hot spots* or *source points*.

The preemerged adult flea is the stage that can extend the longevity of the flea. They can survive for up to 140 days in the cocoon if protected from desiccation. In the cocoon they are also protected from most insecticides. Physical pressure and changes in light, temperature, and carbon dioxide are thought to be stimuli for emergence of the adult flea.

Newly emerged fleas can survive in the environment from 10 to 62 days, again depending on the temperature and humidity.[8] Once on the host, the flea begins feeding within seconds and becomes an obligate parasite. The animal's grooming activity is the primary cause of mortality of ectoparasites. The flea feeds by piercing the skin of the host and inserting the tip of the labrum epipharynx to extract capillary blood.[5] Saliva is introduced by way of the salivary pump and used as an anticoagulant.[4] The female flea consumes an average of 14 µl of blood per day (equivalent to 15% of her body weight).[6] About 72 female fleas will remove 1 ml of blood daily. Male fleas consume less blood than females but feed more frequently.[2] Once fleas feed and initiate reproduction, they become dependent on a constant source of blood or they will die within a couple of days. During feeding, female fleas excrete large quantities of incompletely digested blood ("flea dirt") in long tubular coils or fine pellets.[2]

The first of multiple matings occurs on the host within 8 to 24 hours. Egg production begins within 36 to 48 hours of the first blood meal, reaches maximum production between 4 and 9 days, and may continue for more than 100 days. Egg production peaks at 40 to 50 per day and averages 27 eggs per day for the first 50 days. A single female flea may deposit over 2000 eggs during her lifetime.[4,7]

Flea allergy dermatitis (FAD) is the most common veterinary dermatologic condition in the world. It begins with the bite of a flea. The saliva of the flea contains amino acids, aromatic compounds, fluorescent materials, polypeptides, and phosphorus.[9] In the dog the antigenic substances carry a molecular weight of 18,000–45,000Da with the major allergen weighing 30,000–32,000 Da.[10] Dog owners notice scratching, chewing, licking, biting, and other signs of pruritus. Sixty-one percent of flea-allergic dogs develop clinical signs between 1 and 3 years of age.[11] As animals age, with continued exposure to fleas, the degree of hypersensitivity may wane. FAD is uncommon in dogs less than 6 months of age. Patients usually have papules, crusts, salivary stains, excoriations, and erythema in a wedge-shaped pattern over the lumbosacral region, caudal thighs, proximal tail, ventral abdomen, and around the umbilicus. With chronic itching the areas become alopecic, lichenified, and hyperpigmented and the dog develops an odor related to secondary infections with *Staphylococcus intermedius* and *Malassezia pachydermatis*.

Figure 16-1 Dorsal lumbosacral region of an Afghan hound with FAD. Note the distribution of the alopecia. Skin is erythematous and crusted.

A diagnosis of FAD is based on the age of onset of the pruritus, the distribution of the pruritus and clinical signs, and the observation of fleas, flea feces, or both. Many dogs that are allergic to the bite of a flea have very few fleas on them at any time because their excessive grooming activity removes the fleas. Cats are especially efficient at removing fleas. Some of those patients will have recurrent tapeworm *(Dipylidium caninum)* infestations from ingestion of the fleas. The diagnosis of FAD can be confirmed with an intradermal skin test with flea antigen.

Treatment of FAD is a 3-step process. Most important is the elimination of the fleas from the animal and prevention of re-infestation with the use of both on-animal and-premise flea control. The second step involves providing the animal with relief from the allergic reaction and pruritus. Moderate doses of short-acting oral corticosteroids used for 5–10 days will usually be sufficient. Lastly, any secondary infections need to be treated with the appropriate oral and/or topical medications.

The goals of flea control are to eliminate the adult fleas on *all* the animals in the house and immature fleas in the environment. The best approach incorporates mechanical, physical, and chemical measures. Source points should be identified and treated aggressively. Carpets, pet bedding, and resting areas in the home should be well vacuumed using a vacuum with a power head. Pet bedding should be washed. Dead vegetation should be cleaned away from animal resting areas outside. A wide variety of chemicals can be used on pets and in the environment; however, no single, “miracle” flea product exists that can be used on both animals and their surroundings.

Botanical products are the closest things we have to “natural” insecticides. *Pyrethrins* are derived from a certain species of chrysanthemum. Six naturally occurring pyrethrins exist. They are minimally toxic to mammals (oral LD50 in rats, 1500 mg/kg body weight).[12] Because pyrethrins are unstable in the presence of ultraviolet light, moisture, and air, most are found combined with synergists (e.g., piperonyl butoxide) that inhibit oxidative and hydrolytic degradation of the compounds. *Pyrethroids* (e.g., permethrin, sumethrin, resmethrin, d-trans-allethrin, tetramethrin, fenvalerate) are synthetic insecticides derived from the molecular structure or sharing the same mechanism of action of pyrethrins. They are more stable than pyrethrins but are slightly more toxic. The mechanism of action of pyrethroids is based on changes in ion conductance, mainly through delayed closing of the sodium activation gate of the nerve cells.[13]

64

65

Figure 16-2 Same dog as in Figure 16-1. Dermatitis extends onto the caudal thighs.

Figure 16-3 Cat with FAD. Pruritus has resulted in partial alopecia of the entire caudal half of the trunk.

Rotenone is an extract of the root of the derris plant and contains two active ingredients. It is slightly more toxic than pyrethrins and is very toxic to fish.[12] It is safe for use in small animals but not used in many products. *D-limonene* and *linalool* are derived from citrus pulp. They have a solvent action on the cuticular lipids of the exoskeleton of the flea that results in desiccation and death of the flea.[14] They are relatively effective but very short acting, and there have been reports of severe toxic reactions in cats.

Carbamates (e.g., carbaryl, propoxur, bendiocarb) and *organophosphates* (e.g., malathion, ronnel, chlorpyrifos, fenthion, dichlorvos, cythioate, diazanon, propetamphos, phosmet) are cholinesterase inhibitors. They act mainly as adulticides but are potentially very toxic to pets, particularly to cats and young animals. These ingredients are found in a variety of formulations for use on the animal and in the environment. Cythioate and fenthion are also formulated as systemic insecticides.

Nitenpyram (Capstar™, Novartis Animal Health) is a neonicotinoid that acts at the nicotinic acetylcholine receptor of insects. It has a very low mammalian toxicity. It is supplied as an oral medication that can be given to dogs and cats to kill adult fleas within 6 hours after administration. The product is rapidly eliminated in the urine and does not kill new fleas after 24 hours of administration.

Imidacloprid (Advantage™, Advantix™, Bayer) is a topical adult flea killer that acts by binding to nicotinergic receptors in the nervous system of the insect. Claims are that most fleas are killed within 24 hours, before they have a chance to lay eggs. It is used as an on-animal spot treatment once a month and is very safe for use on mammals; however, it can be washed off if the pet is bathed, which will decrease its efficacy.

Fipronil (Frontline®, Frontline Plus®, Merial) is another topical adult flea killer that is found as both a spot treatment and spray. It is a phenylpyrazole and acts by blocking the passage of chloride ions through gamma-aminobutyric acid (GABA)–regulated chloride channels. It is highly specific to invertebrates. One hundred percent of adult fleas are killed within 24 hours. Once used, claims are made that fleas will be killed for up to 3 months and that after 48 hours the animal can be bathed as often as needed without affecting the efficacy of the product because the active ingredient

is incorporated within the sebaceous secretions. Frontline Plus® also contains methoprene, which acts to prevent the production of viable flea eggs and larvae.

Selamectin (Revolution®, Pfizer Animal Health) is an FDA-approved avermectin that is applied as a spot-on product once monthly to dogs or cats. A single application kills more than 98% of the fleas within 24–36 hours. The flea-killing effects persist for 1 month, even with bathing. Selamectin also has ovicidal and larvicidal activity against fleas.

Sodium polyborate (SPB) is a powder that is used in the indoor environment to interrupt the flea life cycle. It is believed that the flea larvae ingest the powder and are killed before they can pupate. Elimination of fleas in the indoor environment may require 3 to 6 weeks. SPB has a high margin of safety around mammals (oral LD50 in rats, 3479 mg/kg).

Insect growth regulators (IGRs) (e.g., methoprene, fenoxycarb, pyriproxyfen) mimic the juvenile hormone that the flea larvae produce during pupation. When the egg and larvae are exposed to this hormone, the egg will not hatch and the larvae will not pupate. These products have no effect on pets and people because these hormones are specific for insects. (Oral LD50 in dogs for methoprene, 5000 to 10,000 mg/kg; oral LD50 for fenoxycarb in rats, 16,000 mg/kg) IGRs are commonly found in both on-animal and in-premises products.

Insect development inhibitors (IDIs) (i.e., lufenuron, Program®, Sentinel®, Novartis Animal Health) are chitin synthesis inhibitors that prevent the flea larvae from hatching from the egg. The product is fed to pets once monthly and deposited in the fat stores of treated animals. It is slowly released from tissues, allowing maintenance of effective blood levels of drug for weeks after administration. The female flea ingests the product when feeding where it becomes incorporated into the flea egg. These products will not kill the adult flea. No known contraindications or side effects exist in mammals, and lufenuron is very safe (oral LD50 in rats >2000 mg/kg).

Many formulations exist for the deliverance of the insecticides to the pet. Shampoos act to mechanically remove the fleas, but because they are rinsed off, they have minimal residual action. This problem with residual flea control can be overcome by using a final rinse (dip) that contains an insecticidal product. Many flea sprays are alcohol-based and quickly kill adult fleas. Unfortunately, most contain pyrethrins, and unless the chemical is microencapsulated, their duration of action is less than 1 day. Powders, foams, concentrated solutions (spot treatments), and collars are all available that are formulated with a variety of chemicals; several of the chemicals are also sold in oral formulations.

In the indoor environment, hand spraying either by a professional or the owner is the preferred method of delivering the chemicals. This allows the product to be applied directly on the areas most frequented by the pets (“source points”). Large pieces of furniture must be moved to ensure that the spray reaches the areas of larval migration.

Outdoors, sprays are very useful and their application should be concentrated in the areas frequented by the animals, especially those that are shaded, have a mild temperature, and contain organic matter.

17 CHAPTER • 17 Other External Parasites

Karen L. Campbell

External parasites are major causes of distress and disease in dogs and cats. Some parasites cause only mild irritation, whereas others are associated with severe inflammation and secondary infections. Many ectoparasites serve as vectors or intermediate hosts of other diseases. It is important to know the clinical features, identification, and appropriate treatments for external parasites affecting dogs and cats (Table 17-1).

17.1 FAMILY DEMODICIDEA

Demodex spp. live as commensals in the skin of most mammals. Most species (including *D. canis* and *D. felis*) spend their entire life cycle in the hair follicles and sebaceous glands of their host. A few species (including *D. gatoi* and the short-tailed demodectic mite of dogs) are found within the epidermis. It is thought that most follicular infections develop during the early weeks of life, with the commensal population in bitches and queens being transferred to in-contact areas of puppies and kittens. However, the short-tailed forms of the mites may be transferred between adult animals of the same species.

Localized demodicosis in dogs is most common in puppies between 3 to 6 months of age. Skin lesions develop secondary to localized overgrowth of mites on the face or forelimbs and consist of one or more localized areas of alopecia, erythema, and scaling. Clinicians make the diagnosis by doing deep skin scrapings and finding the characteristic “cigar-shaped” mites with short, stubby legs. Counts should be made of all life stages (eggs, larvae, nymphs, and adults). Dogs with normal immune systems will naturally resolve early, localized lesions. Factors that may predispose dogs to *Demodex* overgrowth include other parasites, poor nutrition, immunosuppressive drug therapy, and stress—these factors should be identified and corrected. Specific antimite therapy is rarely warranted. Topical benzoyl peroxide gel or lotion may be applied once daily to help prevent secondary bacterial infections and aid in mite removal from the follicles. Skin scrapings should be repeated in 4 weeks. If lesions are still present and the mite count is still high with a large proportion of immature forms, the condition may be progressing to generalized demodicosis. Rotenone or benzyl benzoate-containing lotions or creams may be applied to the lesions once daily.

Generalized demodicosis in dogs may be classified as juvenile onset (affecting dogs 3–18 months of age) or adult onset (affecting middle-aged to older dogs, often immunocompromised animals with underlying hyperadrenocorticism, hypothyroidism, diabetes mellitus, immunosuppressive drug therapy, or neoplasia). Clinical signs are variable and may start with localized lesions that spread. Patchy to multifocal alopecia, erythema, and silvery-gray scales are common. The affected skin may become lichenified, hyperpigmented, pustular, and crusted or ulcerated. Secondary bacterial infections may progress to life-threatening sepsis. Peripheral lymphadenopathy is common. Deep skin scrapings will reveal numerous demodectic adults, nymphs, and larvae or ova (or both). Mixed infections with *D. canis* plus short-tailed and long-bodied forms of *Demodex* mites may be identified by their characteristic microscopic features. An assessment of the general health of the dog should be made, and any underlying diseases or concurrent infections should be treated.

With the recent withdrawal of Mitaban® (amitraz, Fort Dodge) from sale in the United States, no licensed products are approved for use in treating demodicosis.* It should be noted that amitraz is an Environmental Protection Agency (EPA)-registered pesticide in the United States; although alternative forms of amitraz are available, it is a violation of United States federal law to use an EPA-registered pesticide in a manner inconsistent with its labeling. Both ivermectin and milbemycin are effective alternatives to amitraz in the treatment of generalized demodicosis;

however, high doses and long courses of therapy are required. Ivermectin toxicosis is well recognized in collies and has also been reported in many other breeds of dogs. It is recommended that therapy be initiated with 0.05 mg/kg PO on days 1 to 2, with an increase to 0.1 mg/kg PO on days 3 to 4, and continuing to increase by increments of 0.05 mg/kg until 0.4 mg/kg/day is reached. Ivermectin should be discontinued immediately in any dog showing depression, ataxia, mydriasis, or other signs of toxicity. Collies and other breeds that cannot tolerate high doses of ivermectin may be treated with milbemycin oxime. A recommended protocol for milbemycin is 0.5 mg/kg PO days 1 to 2, with increases of 0.5 mg/kg increments until 2.0 mg/kg/day is reached. Signs of milbemycin toxicosis include mydriasis, ataxia, lethargy, and stupor. Therapy should be continued until two negative skin scrapings have been obtained at monthly intervals.

Localized demodicosis is rare in cats and usually affects the eyelids, periocular region, ear canal, or head and neck. Lesions include patchy alopecia with scaling and crusting or a ceruminous otitis externa (pruritus is variable). Clinicians make the diagnosis by finding mites on superficial and deep skin scrapings, ear swabs, or both. Treatment may include topical rotenone or lime sulfur solution.

Generalized demodicosis is rare and less severe in cats than in dogs. It may be associated with an underlying immunosuppressive or metabolic disease such as feline immunodeficiency virus (FIV), feline leukemia virus (FeLV), toxoplasmosis, systemic lupus erythematosus, or diabetes mellitus. Clinical signs include variable pruritus; multifocal, patchy, or symmetrical alopecia with or without erythema; scaling; crusting; macules; and hyperpigmentation. Clinicians make the diagnosis by finding mites on superficial *(D. gatoi)* or deep *(D. felis)* skin scrapings. Most cats will respond favorably to weekly dips with 2% lime sulfur solution. *D. gatoi* may be contagious, thus in-contact cats should be evaluated and treated if infected.

* In 2004, Pfizer Animal Health acquired the rights to sell Mitaban (amitraz) for the treatment of generalized demodicosis in dogs. This is the only product licensed for use in treating generalized demodicosis in the United States.

66

67

17.2 FAMILY SARCOPTIDAE

Sarcoptes scabiei var *canis* primarily affects dogs but can also cause disease in cats, foxes, and humans. Dogs can be infested with mites from foxes and humans. The life cycle is approximately 21 days and completed on the host. Off-host survival time depends upon the relative humidity and temperature. Adult mites are small (200 to 400 μm), oval, and white with two pairs of short legs. The pretaris have long, unsegmented pedicels. The anus is at the posterior edge of the body. The mites initially affect relatively hairless areas of skin such as the ear pinnae and elbows. Female mites burrow through the epidermis at a rate of 2 to 3 mm/day. They lay their eggs in the resulting tunnel. Eggs hatch into larvae that burrow to the surface of the skin where they feed. Many dogs develop a hypersensitivity reaction to mite antigens. As few as 10 to 15 mites may produce severe clinical signs in a hypersensitive individual. Clinical signs include an intensely pruritic, nonseasonal dermatitis with papules, excoriations, and hair loss. Affected areas typically develop a thick yellowish crust. Lesions may rapidly generalize, but the dorsum is usually spared.

Diagnosis is based on history of a contagious, nonseasonal, intensely pruritic dermatitis involving the pinnal margins, elbows, hocks and ventral abdomen, and chest plus finding mites or mite eggs or feces in superficial skin scrapings. A presumptive diagnosis is made based on response to treatment trials. Effective licensed treatments include weekly applications of 2% lime sulfur solution or monthly applications of 6 to 12 mg/kg selamectin. Effective extra label treatments include ivermectin 0.2 to 0.3 mg/kg PO every 7 days for four to six treatments or milbemycin oxime at 2 mg/kg PO every 7 days for four to six treatments. As in the treatment of demodicosis, it is advisable to initiate treatment with either ivermectin or milbemycin at much lower doses with daily increases until the target dose is reached without evidence of side effects. The target dose is then given once weekly for at least 3

weeks past resolution of clinical signs. In-contact dogs should be treated to eliminate possible asymptomatic carriage of the mites.

Notoedres cati primarily parasitizes cats but may also affect foxes, dogs, rabbits, and humans. Notoedric mange is highly contagious and frequently occurs in epizootics in endemic areas. The mites are smaller than *S. scabiei*, have medium-length unjointed sucker-bearing stalks on their legs, more body striations, and a dorsal anus. Clinical signs include intense pruritus and dry, crusted lesions that first appear on the medial edges of ear pinnae and spread over ears, head, face, and neck. Some cases also involve the feet and perineal regions. Diagnosis is confirmed by finding the mites, nymphs, larvae, and ova in superficial skin scrapings. Traditional therapy is 2% lime sulfur solution applied weekly for 4 to 8 weeks. Other effective treatments include selamectin (6 to 12 mg/kg topically every 30 days), ivermectin (0.3 mg/kg PO or SQ every 14 days for two treatments), or doramectin (0.3 mg/kg SQ once).

17.3 FAMILY PSORPTIDAE

Otodectes cynotis infests the external ear canal and adjacent skin of dogs, cats, foxes, and ferrets. The prevalence in feral cats in the United States has been reported at 25% to 37%. Although ear pruritus and copious production of a dark "coffee grounds-like" cerumen are common, 10% of infested animals may exhibit no clinical signs. Diagnosis is made by finding mites on otoscopic examination or on microscopic examination of material from ear swabs or ear flushes (flushing the ear canal with 1 to 2 ml of mineral oil may have a higher mite yield than use of a cotton swab that traps mites in its fibers). Adult mites are 300 to 400 μm, white, with a terminal anus and four pairs of legs. All legs of the male have short, unjointed stalks with suckers. Only the front two pairs of legs of female mites have suckers; the fourth pair of legs are rudimentary and do not extend beyond the body margin. The mites feed on epidermal debris and tissue fluid. Hosts may develop hypersensitivity reactions to mite antigens. Topical ceruminolytics should be used to remove cerumen and debris from the external ear canal. Topical otic acaricidal products are effective as is topical selamectin. Systemic ivermectin has been used with variable results. Fipronil spray or spot-on may also be effective; however, fipronil should *not* be used in the ear itself. In-contact animals should be evaluated and treated as appropriate for the species.

17.4 GENUS LYNXACARUS

Lynxacarus radovski is a hair-clasping, fur mite of domestic cats. These mites have elongated bodies, 430 to 520 μm long, with a flaplike sternal extension containing the first two legs that are used to grasp the hair of the host. The mites may be found in such large numbers as to give a "salt and pepper" appearance to the haircoat. Some cats develop widespread papular crusts, whereas others show no clinical signs from the infestation. Clinicians make the diagnosis by collecting the mites from acetate tape impressions, hair plucks, or superficial skin scrapings. Effective treatments include topical pyrethrin sprays, 2% lime sulfur dips, or systemic ivermectin. The mite is contagious to other cats and may cause a papular rash in humans; it is not considered contagious to dogs.

17.5 FAMILY CHEYLETIELLA

Cheyletiella spp. mites are easily recognized by their big palpal claws, M-shaped gnathosomal mouthparts, and comblike tarsal appendages. The sensory organs on genu I may be used to identify different species. The sensory organ of *C. yasguri* (primary host is dog) is heart shaped, of *C. blakei* (primary host is cat) is cone shaped, and of *C. parasitovorax* (primary host is rabbits) is globe shaped. These three mite species are freely contagious from one host species to another and can transiently affect humans. The mites do not burrow but move rapidly in pseudotunnels in epidermal debris. The entire life cycle is completed on the host. The ova are smaller than louse nits and are attached to host hairs by fine fibrillar strands. Adult female mites may live up to 10 days in the environment. Clinical signs associated with infestation include a dorsally oriented dry scaling and variable pruritus.

Some cats develop miliary dermatitis. Diagnosis is made by finding mites or ova on acetate tape impressions, on superficial skin scrapings, or in fecal flotations. Affected and in-contact dogs, cats, and rabbits should be treated with topical parasiticides (e.g., 2% lime sulfur dip, fipronil, pyrethrin, selamectin). Systemic ivermectin is also effective. Treatment should be continued for 4 to 8 weeks, and the environment should be also be treated with an acaricidal spray approved for use in homes.

17.6 FAMILY TROMBICULIDAE

Larvae of the family *Trombiculidae* (chiggers) are parasitic, whereas the nymphs and adults are free living. The six-legged larvae are bright red or orange and may be found on the skin or in the ears of dogs and cats. Chiggers remain on the skin for several days, their saliva disintegrates the host skin cells, and a tube called a *stylostome* is formed that holds the mite to the skin until feeding is completed or the mite is dislodged by the host's scratching or biting. Chiggers may be found on skin scrapings. Topical fipronil is an effective treatment.

67

68

17.7 FAMILY IXODIDAE

Ixodid (hard) ticks possess a sclerotized dorsal shield plate on the idiosoma known as a *scutum*. These ticks are intermittent feeders, remaining attached for several days. The number of hosts upon which they feed varies from one to three among the different species of ticks. Ticks are important as vectors of protozoan, viral, and rickettsial diseases. Some are also involved in producing tick paralysis. When animals are infested with a small number of ticks, manual removal can be accomplished by soaking the tick in alcohol, grasping the head with a forceps, and applying firm traction. With heavier infestations the animal may be treated with fipronil or a pyrethrin or pyrethroid (dogs only). Amitraz collars may be used to prevent tick attachment. Environmental control includes mowing and cutting of brush and grass, plus use of environmental pesticides approved for control of ticks.

Rhipicephalus sanguineus is the brown dog tick. It is a three-host tick with all life stages feeding on dogs and occasionally humans, cats, rabbits, and horses. It is identified by its inornate scutum, ventral plates on males, and presence of festoons. *Dermacentor variabilis* is the American dog tick. It is also a three-host tick. The principal hosts of the larvae and nymphs are field mice and other small rodents. The principal host of the adult is the dog, but other mammals and humans may also serve as hosts. Its is identified by its ornate scutum with eyes and festoons. The males lack ventral plates. *Dermacentor andersoni* is the Rocky Mountain wood tick. It is a three-host tick. The adults feed on wild and domestic herbivores. Larvae and nymphs feed on rodents. It is identified by its ornate scutum with legs having the same pattern of brown and gray as the body.

Amblyomma americanum is the Lone Star tick. It has a single white spot on the scutum of the reddish brown adult female. The adult male is small with two pairs of symmetrical spots near the head and pale strips on its sides. It is a three-host tick with larvae and nymphs feeding on rodents, rabbits, and birds. Adult ticks feed on larger mammals. *Ixodes dammini* is the deer tick. It is a three-host tick with larvae and nymphs feeding on rodents and the adults on white tail deer or other mammals. It is a small, inornate tick that lacks eyes and festoons. It is the primary vector of *Borrelia burgdorferi*.

17.8 FAMILY ARGASIDAE

Argasid ticks are soft bodied and lack a scutum. The only argasid tick of importance in small animals is the spinose ear tick, *Otobius megnini*. Adult ticks are not parasitic; however, larvae and nymphs infest the external ear canals of dogs and rarely cats. Clinical signs include an acute onset of otitis externa with severe inflammation and waxy exudate. Diagnosis is made by visualizing the mites and removing them.

17.9 ORDER PHTHIRAPTERA

Lice are highly host specific, with their life cycles completed on the host. Most can only survive a day or two off a host. The body of a louse is divided into a head, thorax, and abdomen. The body is flattened dorsoventrally and has stout legs and claws for clinging tightly to hair, fur, or feathers. Two suborders exist: (1) the sucking lice *(Anoplura)* and (2) the biting lice *(Mallophaga)*.

Sucking lice have mouthparts adapted for sucking the blood of the host. *Linognathus setosus*, the "long-nosed" louse, is the only sucking louse found on dogs. These lice are bluish black and have dark-blue eggs. These lice are relatively slow moving and easy to capture using flea combs or acetate tape. Biting lice have relatively larger heads and ventrally located mouthparts. The claws are smaller than those of sucking lice. The only louse found on cats is *Felicola subrostrata*. The most common biting louse on dogs is *Trichodectes canis*. This louse is short, broad, yellowish in color, and can be a vector for *Dipylidium caninum*. A second biting louse affecting dogs is *Heterodoxus springer*, found only in tropical and subtropical regions. Biting lice can move rapidly and are harder to capture than sucking lice. During a life span of approximately 1 month, female lice lay 200 to 300 operculate eggs ("nits") that are glued to the hair of the host. Light infestations may be asymptomatic. Heavier infestations with *Linognathus* can cause blood-loss anemia, whereas heavier infestations with biting lice produce irritation and pruritus. Pediculosis can result in miliary dermatitis in cats or a pattern of alopecia and excoriations similar to fleabite dermatitis in dogs. Lice are easily killed by 2% lime sulfur dips, pyrethrin or carbaryl powders or sprays, and most other parasiticides used for fleas. Grooming equipment should be thoroughly cleaned.

17.10 ORDER DIPTERA

Diptera is one of the largest orders in class Insecta, with over 120,000 species. All of these species have a complex (complete) metamorphosis. In some species the adults are parasitic on mammals, whereas in other species the larvae are parasitic.

Flies of the genus *Phlebotomus* in the Old World and *Lutzomyia* in the New World are of primary importance as vectors of the protozoan *Leishmania* spp. The fly bites themselves are not associated with significant disease; however, the protozoan often leads to the development of a chronic, exfoliative dermatitis of the face, pinnae, and feet of infected dogs and may also produce severe systemic disease.

Mosquitoes are in the family *Culicidae*. Most animals develop a pruritic papule at the site of a mosquito bite. Some animals (most commonly cats) develop a hypersensitivity reaction to the antigens in mosquito saliva and develop a pruritic, erosive, crusting dermatosis on the bridge of the nose, papular to nodular lesions on ear pinnae, and hyperkeratosis with swelling of footpads. The lesions may be characterized histologically as a diffuse eosinophilic dermatitis, an eosinophilic furunculosis, or an eosinophilic nodular dermatitis with collagen degeneration. Mosquitoes are also important as vectors of *Dirofilaria immitis*.

Flies of the families *Simuliidae* (black flies), *Tabanidae* (horse flies), and *Muscidae* (stable flies, horn flies, houseflies) frequently attack the ear pinnae of dogs housed outdoors. The ear tips, margins, or folds may develop erythema and hemorrhagic crusts. Affected dogs should be housed indoors and treated with topical antibiotic-corticosteroid cream or lotion until the lesions heal and the source of the flies has been eliminated.

Myiasis occurs when fly eggs are laid in damp areas of the skin or haircoat, and the larvae develop in the underlying tissue of the host. True screwworms, *Cochliomyia hominivorax*, can attack healthy tissue. Blowflies (*Calliphora, Lucilia, Protophormia,* and *Phormia*) feed on dead tissue, whereas flesh flies *(Sarcophaga, Wohlfahrtia)* can attack living tissue. Proteolytic enzymes produced by the larvae are highly destructive and can

result in "punched-out" round holes in the skin. Treatment includes débridement of wounds, supportive care, and control of any underlying or predisposing factors (e.g., injuries, urinary incontinence, diarrhea, unkempt haircoat).

Table • 17-1 Scheme for Identification of Arthropod Ectoparasites of Dogs and Cats

Adults with Eight Legs, Two Body Divisions (Cephalothorax, Abdomen), No Antennae, Simple Eyes, and No Wings	**Class *Arachnida***
Flattened dorsoventrally, mouthparts of chelicera, hypostome, palp	Suborder *Metastigmata* (ticks)
Dorsal shield (scutum)	Family *Ixodidae*
Inornate scutum, anal groove forming an arch, lack festoons	Genus *Ixodes*
Inornate scutum, has festoons, basis capituli is hexagonal	Genus *Rhipicephalus*
Ornate scutum, has festoons, basis capituli is rectangular	Genus *Dermacentor*
Ornate scutum, has festoons, mouthparts are longer than basis capituli, the second palpal segment is twice as long as the third	Class *Amblyomma*
Soft bodied	Family *Argasidae*
Mite with respiratory pore in middle of body	Suborder *Mesostigmata*
Chelicerae long and styletlike, 750–1000 µm body, long legs, red color after feeding, found near bird roosts or nests	Genus *Dermanyssus*
Mite without a respiratory pore	Suborder *Astigmata*
Round body 400–430 µm, terminal anus, short stubby legs with long unsegmented pedicels	Genus *Sarcoptes*
Round body 200–500 µm, dorsal anus, legs with medium-length unsegmented pedicels	Genus *Notoedres*
Oval body 300–400 µm, terminal anus, anterior legs are long with short unsegmented pedicels and large suckers, rear legs have suckers in males and are rudimentary with whiplike setae in females	Genus *Otodectes*
430–520 µm elongated body, flaplike sternal extensions, terminal suckers on all legs, found "clasping" hairs on cats	Genus *Lynxacarus*
Mite with stigmata opening on the gnathosoma	Suborder *Prostigmata*
100–400 µm slender "cigar-shaped" body	Family *Demodicidae*
Found in hair follicles of dogs	*Demodex canis*
Found in subcorneal location in dogs, stubby body	*Demodex* unnamed species
Found in hair follicles of cats	*Demodex felis*
Found in subcorneal location in cats, stubby body	*Demodex gatoi*
400 µm oval body with large palpal claws, *M*-shaped gnathosomal mouthpart	Family *Cheyletiellidae*
Found on cats, cone-shaped sensory organ on genu I	*Cheyletiella blakei*
Found on dogs, heart-shaped sensory organ on genu I	*Cheyletiella yasguri*
Found on rabbits, globose-shaped sensory organ on genu I	*Cheyletiella parasitovorax*
Adults with Six Legs, Three Body Parts (Head, Thorax, and Abdomen)	**Class Insecta**
Adults wingless, laterally flattened	Order *Siphonaptera* (fleas)
Head with genal and pronotal combs	Genus *Ctenocephalides*
Flat head (length of head ≥twice height of head)	*Ctenocephalides felis*
Round head (length of head <twice height of head)	*Ctenocephalides canis*
No combs on head, angular forehead	Genus *Echidnophaga*
No combs on head, rounded forehead	Genus *Pulex*
Adults wingless, flattened dorsoventrally, stout legs with claws	Order *Phthiraptera* (lice)
Long nose, sucking mouthparts	Suborder *Anoplura* (sucking lice)
On dog	*Linognathus setosus*
Wide head, biting mouthparts	Suborder *Mallophaga* (biting lice)
On cat	*Felicola subrostrata*
On dog in United States (broad body)	*Trichodectes canis*
On dog in tropics (slender body)	*Heterodoxus spiniger*
Adults with one pair of wings	Order *Diptera* (flies)

68

69

The family Oestridae consists of bot flies. The only bot fly of importance in small animals is *Cuterebra*. The adult fly resembles a bumble bee and lays its eggs along rabbit runs and near rodent burrows. As animals brush past, the

eggs hatch and the larvae crawls onto the host's fur and enters a body opening or wound. Larvae migrate subcutaneously and produce a nonpainful nodular swelling that fistulates. Lesions are most commonly found on the head, neck, or trunk during late summer to early fall. Treatment involves enlarging the hole and carefully extracting the larva.

17.11 HELMINTH PARASITES

Hookworm dermatitis develops when larvae of *Ancylostoma braziliense, A. caninum,* or *Uncinaria stenocephala* enter the skin of areas in direct contact with the ground. Clinical signs include red papules progressing to erythematous, thickened, alopecic areas of skin on the feet, sternum, ventral abdomen, posterior thighs, and tail. Diagnosis is based on history of contact with hookworm ova-containing feces, contaminated soil, or organic material. Treatment involves appropriate anthelmintic treatment of all dogs in the kennel or household, environmental decontamination, and symptomatic treatment.

Pelodera dermatitis occurs when larvae of *Pelodera strongyloides* invade the hair follicles of skin in contact with damp soil or decaying organic debris. Clinical signs include mild-to-intense pruritus with erythema, papules, and crusting of skin in contact with the ground (feet, legs, ventral abdomen, and tail). Diagnosis may be made by finding the 600 to 650 μm larvae on skin scrapings. Treatment involves removal of the contaminated bedding or soil and dipping the dog in a parasitic dip (e.g., 2% lime sulfur).

Dracunculus insignis is a parasite of dogs and wild carnivores. The intermediate host is a *Cyclops* ingested from contaminated water. The larvae develop in the host, and adults are located in subcutaneous tissues of the abdomen and limbs. A nodule forms at the site and fistulates. When the nodule contacts water, the female worm comes to the surface and releases large numbers of larvae. Surgical excision of the worms is the treatment of choice.

18 CHAPTER • 18 Edema

Marc R. Raffe

Jennifer Roberts

18.1 INTRODUCTION

The well-being of cells and tissues depends not only on an intact circulation but also on intercompartmental fluid homeostasis to deliver oxygen and nutrition. Approximately 60% to 70% of lean body weight is water; of this value about two thirds is contained in the intracellular space and one third in the extracellular space. Most extracellular water (approximately 70%) is contained in the interstitium, a matrix of connective tissue and gel-like substrate that is the area between the vascular compartment and the cell membrane.

When this relationship is disturbed, increased water retention in the interstitial compartment often results. Abnormal collection of water in the interstitial space is defined as *edema*. Collection of water in body cavities (hydrothorax, hydropericardium, ascites) and generalized profound subcutaneous swelling (anasarca) are included in the edema category.

18.2 PATHOGENESIS

Under normal conditions, continuous water movement occurs across fluid spaces. Water is shifted from the vascular network into the interstitium; ultimately it crosses cell membranes to become incorporated in the intracellular cytoplasm or is returned back to the vascular network. Water return to the vascular space is controlled by transcompartmental pressure changes induced by the presence of large molecular weight proteins (colloids) in the vascular network. Because of a slight pressure difference between the hydrostatic force displacing water from the arterial-capillary network and the colloidal force promoting water return to the capillary-venous network, residual water remains in the interstitial compartment. This residual volume is drained back into the systemic circulation by lymphatic tributaries. Under normal conditions, no net transfer of water across tissue compartments occurs (Figure 18-1). A defined physiologic relationship governs intercompartmental water balance. This relationship, known as *Starling's law of the capillary*, represents two major factors in water distribution: hydrostatic and oncotic (osmotic) forces. The relationship between hydrostatic and oncotic forces have been extensively investigated and is described as the following mathematical relationship:

$$\text{Net filtration} = Kf[(P_{cap}-P_{if})-(\pi_p-\pi_{if})]$$

where Kf represents net capillary wall permeability, P_{cap} represents hydrostatic pressure generated by the heart, P_{if} represents hydrostatic pressure generated by tissues, π_p represents oncotic forces in plasma, and π_{if} represents oncotic forces in tissues generated by protein and mucopolysaccharides (see Figure 18-1).

Under normal conditions, negative pressure is present in the interstitium. Negative pressure is maintained by the combination of oncotic forces and lymphatic drainage, with a combined drainage capacity that exceeds hydrostatically induced shift of water from the intravascular compartment. When factors associated with this relationship are changed, the outcome is often abnormal interstitial water retention creating a positive interstitial pressure. The conversion from negative to positive interstitial pressure is believed to be a key factor in edema formation (Figure 18-2). Pathophysiologic changes commonly associated with edema formation include increased vascular permeability, decreased protein and mucopolysaccharide concentration in the interstitial matrix, and

reduced lymphatic drainage. Five categories of edema have been described based on changes in Starling's law of the capillary: (1) increased hydrostatic pressure, (2) reduced osmotic pressure, (3) lymphatic obstruction, (4) sodium retention, and (5) inflammation. Specific clinical syndromes associated with each category are listed in Table 18-1.

Figure 18-1 Starling's law of the capillary.

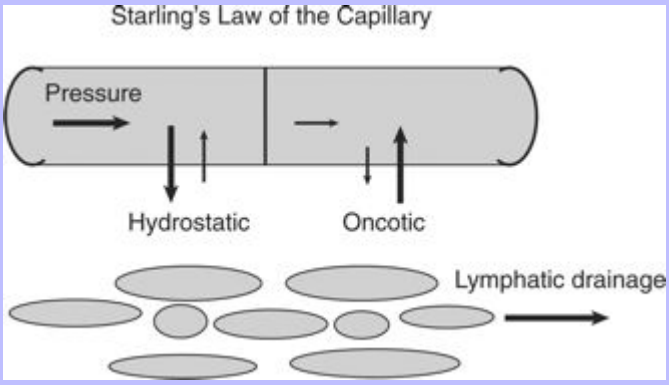

Figure 18-2 Effect of increasing interstitial fluid pressure on volumes of total interstitial fluid, gel fluid, and free fluid.

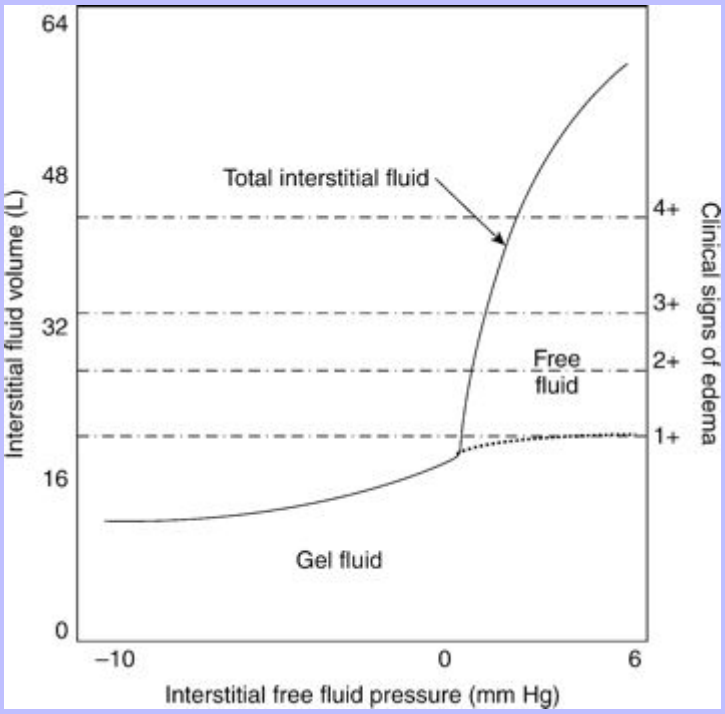

Table • 18-1 Causes of Edema

CAUSE	CONTRIBUTING FACTOR	SPECIFIC CLINICAL SYNDROMES
Increased hydrostatic pressure	Impaired venous return	Congestive heart failure Constrictive pericarditis Ascites (cirrhosis) Venous obstruction or compression (thrombosis, external pressure, extremity inactivity)
	Small-caliber arteriolar dilation	Heat Neurohumoral dysregulation
Reduced plasma osmotic pressure	Hypoproteinemia	Protein-losing glomerulonephropathy (nephritic syndrome) Cirrhosis (ascites) Malnutrition Protein-losing gastroenteropathy
Lymphatic obstruction	Anemia	Various inflammatory Neoplastic Postsurgical Postirradiation
Sodium retention	Excessive dietary intake with renal insufficiency	
	Increased tubular sodium reabsorption	Renal hypoperfusion Increased renin-angiotensin-aldosterone secretion
Inflammation	Acute inflammation Chronic inflammation Angiogenesis

18.3 CLINICAL PRESENTATION AND DIAGNOSIS

Edema is a secondary feature of many clinical presentations. Historical findings suggestive of edema include limb swelling, increase in abdominal girth, and postural dyspnea. Physical findings include limb swelling in gravity-dependent regions, swelling of the ventral aspect of the mandible, prepuce, scrotum or mammary glands, periorbital swelling, increased breath sounds characterized by rales and rhonchi, and fluid presence in the abdomen or thorax. Superficial edema in subcutaneous tissue can be confirmed by applying digital pressure over the swollen area. Displacement of interstitial water leaves a finger-shaped depression that refills after a short time. This finger-shaped depression is called “pitting edema.”

Diagnostic procedures are focused on confirming edema presence and determining possible cause. Evaluation of the physiologic components of water balance (plasma protein concentration, erythrocyte mass, serum electrolyte levels, and system blood pressure) are important to determine which factor or factors associated with water balance are affected. Evaluation of underlying inflammation (white blood cell [WBC] count, differential, platelet count) is warranted in specific underlying causes. 71

Electrocardiographic and echocardiographic imaging is indicated in cases where edema may be associated with primary or secondary heart failure. Ultrasonographic imaging of the peritoneal space, thoracic space, and pericardial space is warranted if physical finding indicate cavity-based fluid collection. 72

Collection of edema fluid and fluid analysis may be helpful in determining the underlying disease process. The clinicopathologic features of edema fluid are typically a protein-poor transudate with a specific gravity less than 1.012 that has poor cellularity. In inflammation, increased protein content is noted; fluid is generally an exudate with a specific gravity greater than 1.020 and has the presence of inflammatory cell morphology (macrophages, degenerated white blood cells).

18.4 TREATMENT

Treatment of life-threatening edema is an immediate goal irrespective of cause. Typically these presentations are associated with primary heart failure. Administration of parenteral furosemide or vasodilator drugs (or both) is considered the primary step for emergency management. The rationale for furosemide selection includes its known actions producing increased renal sodium excretion facilitating edema mobilization from interstitial sites, pulmonary and systemic vasodilatation, and increased lymph flow in the thoracic duct. All of these responses positively affect transcompartmental water balance and reduce edema formation, especially in the lung. Vasodilators (hydralazine, nitrates) are used to reduce edema; they produce their primary actions through relaxation of systemic arterioles and venules promoting redistribution of central blood volume and reducing hydrostatic pressure. In fulminant cardiac failure, a sympathomimetic such as dobutamine (1 to 5 μg/kg/min constant rate infusion [CRI]) is started and titrated to achieve positive inotropic response. This will improve the Starling's relationship and help to mobilize edema.

Nonemergent edema management is achieved by using goal-directed therapeutic intervention to rebalance the Starling's relationship. Furosemide or other potent loop diuretics (bumetanide, spironolactone, triamterene, amiloride, and thiazide-class) may be used to promote edema mobilization by initiating physiologic responses previously noted for furosemide. Administration of plasma products (fresh plasma, fresh frozen plasma, and cryopoor plasma), hetastarch, or dextran 70 will increase intravascular oncotic pressure and favor water redistribution from the interstitial to intravascular compartment. These products are considered in cases demonstrating decreased oncotic pressure (hypoproteinemia), decreased osmotic balance (anemia), or increased endothelial permeability (inflammation). Decreasing osmotic forces by dietary modification to reduce sodium and chloride intake or through use of loop diuretics to increase sodium and chloride loss is an additional consideration in primary cardiac disease patients.

18.5 PROGNOSIS

The prognosis for successful management of edema is based on the ability to treat and resolve the underlying clinical disorder. Edema secondary to inflammatory states, colloid imbalance, or primary cardiac disease is often successfully managed or resolved. Edema secondary to lymphatic pathology often requires long-term management to successfully correct.

19 CHAPTER • 19 Hepatocutaneous Syndrome

Catherine A. Outerbridge

Hepatocutaneous syndrome (HS) is an uncommon skin disease associated with systemic metabolic disease. It has also been called *superficial necrolytic dermatitis* (SND), *metabolic epidermal necrosis*, *diabetic dermatopathy*, and *necrolytic migratory erythema* (NME). This disease was first described in a dog in 1968. The first English language reference comparing the disease to the human disease NME was in 1986, when the disease was described in four dogs with diabetes mellitus and was thus first called *diabetic dermatopathy*. The disease has been most commonly described in older dogs, although a histologically equivalent disease occurring in cats and the black rhinoceros has been reported. The etiopathogenesis of this disease is unclear, but it is likely multifactorial. Because different disease processes appear to cause similar histologic skin lesions, it might be more correct to refer to the skin disease as either *SND* or *metabolic epidermal necrosis*.

19.1 COMPARATIVE ASPECTS WITH NECROLYTIC MIGRATORY ERYTHEMA AND THEORIES OF PATHOGENESIS

NME is a histologically similar disease that is seen in humans. Most often NME occurs in association with a glucagon-secreting tumor. Glucagonoma syndrome in humans is characterized by the skin lesions of NME, hyperglycemia resulting from carbohydrate intolerance or diabetes mellitus, weight loss, hypoaminoacidemia, and anemia. Humans with NME usually have a profound hypoaminoacidemia, presumed to result from the catabolic gluconeogenic effects of glucagon. However, NME has been diagnosed in some humans with normal plasma amino acid concentrations, and these have often been patients with nonglucagonoma-associated disease. Nonglucagonoma-associated NME has been reported in humans with celiac disease, chronic malabsorption, cirrhosis, nonalpha islet cell tumors, pancreatitis, hepatitis, inflammatory bowel disease, and heroin abuse. 73

Unlike people with NME, association with glucagonoma has not been consistently demonstrated in the majority of dogs with the skin lesions of SND. Afflicted dogs commonly have a characteristic concurrent hepatopathy, thus the use of the name HS. The hepatic pathology seen in dogs with HS has not been reported to occur in those dogs with confirmed glucagonoma-associated SND. In addition to the association with hepatic pathology, some dogs with the skin lesions of SND have a history of phenobarbital or primidone administration, mycotoxin ingestion, or gastrointestinal signs and malabsorption.

The severe vacuolar liver disease seen in the majority of dogs with the skin lesions of SND and the association in some dogs with concurrent diabetes mellitus suggests that an underlying hormonal or metabolic disturbance is occurring in dogs with HS. Diabetes mellitus has been reported to occur in 25% to 40% of dogs with HS.

Hypoaminoacidemia has been documented to occur in all dogs with SND skin lesions that have, thus far, had concentrations of plasma amino acids measured. Most dogs had nonglucagonoma-associated disease or HS, and only two dogs were confirmed to have a pancreatic tumor. The pattern of the plasma amino acid panels in dogs with SND appears to be significantly different from that seen in dogs with acute or chronic hepatitis.

The liver plays a critical role in amino acid balance. In chronic and acute hepatitis, compromised hepatic metabolism results in increased concentrations of many plasma amino acids. However, this is not seen in dogs with SND because the majority of individual plasma amino acid concentrations are less than 60% of normal. Total amino acid concentrations documented in dogs with SND are approximately 30% of the concentrations documented in healthy dogs or dogs with acute or chronic hepatitis. These differences suggest that the pathogenesis of

hypoaminoacidemia in dogs with SND cannot be explained by compromised hepatic metabolism. The ratio of branch chain amino acids (BCAA) to aromatic amino acids (AAA) has been recognized as an indicator of hepatic insufficiency, and this ratio decreases with the severity of hepatic dysfunction or portal-systemic shunting. The mean BCAA: AAA ratio in dogs with SND in a recent study was 2.6:1.0, which is not indicative of severe hepatic dysfunction. It seems probable that an as yet unexplained increase in hepatic catabolism of amino acids might account for the severity of the hypoaminoacidemia documented in the dogs with SND. Intravenous administration of amino acids initially bypasses the portal circulation resulting in the delivery of amino acids to peripheral tissues before hepatic uptake and catabolism can occur. The fact that some dogs respond better to therapy with intravenous amino acid infusions rather than oral protein hyperalimentation supports the hypothesis that dogs with SND have increased hepatic catabolism of amino acids.

The etiopathogenesis of the hepatic pathology seen in the majority of dogs with SND remains unknown, and it is unclear what metabolic pathway or pathways may link liver or pancreatic disease with the skin lesions seen in SND. Hyperglucagonemia, if it were present, could explain the risk for the development of diabetes mellitus and hypoaminoacidemia seen in dogs with SND. Glucagon secretion can increase threefold without significant increases in peripheral plasma glucagon concentrations. Glucagon is not a hormone routinely measured in dogs, and assays may not detect all biologically active metabolites of glucagon. The catabolism of almost all amino acids is influenced by glucagon except tryptophan. Tryptophan concentrations are not significantly decreased in dogs with SND. It is possible that a disturbance in glucagon metabolism may have a role in the HS form of SND.

The actual etiopathogenesis for the skin lesions seen in dogs with SND or in humans with NME is not known. Humans with NME have had resolution of their lesions after surgical excision of their glucagonoma or after the use of somatostatin analogues. This suggests that hyperglucagonemia may have a direct role in the development of the skin lesions. It has been suggested that in NME, hyperglucogonemia results in increased epidermal arachidonic acid, and the resultant metabolites are responsible for the inflammatory changes in the skin. However, evidence exists that glucagon alone cannot explain the development of NME lesions in all affected humans because some have had resolution of skin lesions despite increased glucagon concentrations. Approximately 50% of humans with nonglucagonoma-associated NME have plasma glucagon concentrations within reference limits. Some patients with nonresectable pancreatic tumors have had NME skin lesions resolve with administration of intravenous amino acids. This finding, along with the hypoaminoacidemia seen in the majority of glucagonoma NME patients has led to the hypothesis that increased gluconeogenesis triggered by hyperglucagonemia results in low plasma amino acid concentrations, epidermal protein depletion, and then the skin lesions of NME. Hypoaminoacidemia was proven to result from increased hepatic clearance in one human patient with a glucagonoma. Essential fatty acid and zinc deficiencies have both been proposed to contribute to the development of NME because the histologic appearance of skin lesions in patients with zinc deficiency or essential fatty acid deficiency shares some similarities to those seen in NME. Some patients have had improvement of their NME skin lesions after zinc or essential fatty acids (EFA) supplementation, but neither has proven to be helpful for long-term resolution of the skin lesions in NME.

In dogs with SND, pancreatic tumor excision or treatment with somatostatin has resolved skin lesions. Because different disease processes appear to be able to produce the same characteristic histologic skin lesion, this suggests that they may perhaps all result in a common metabolic disturbance. The fact that severe hypoaminoacidemia is documented to occur in all cases of SND in which plasma amino acids have been measured, regardless of associated disease, makes it likely that this metabolic derangement is directly contributing to the cutaneous lesions seen in affected dogs.

19.2 CLINICAL PRESENTATION

The disease is typically diagnosed in older dogs. The mean age of affected dogs is 10 years of age, with a range of 4 to 16 years. Male dogs comprise 64% of reported cases. Shetland sheepdogs, West Highland white terriers, Cocker

spaniels, and Scottish terriers may have a predisposition to develop HS because they appear to be overrepresented (Table 19-1).

The most common clinical sign is the development of visually distinctive skin lesions with a characteristic distribution. The skin lesions in dogs with HS may precede any other clinical signs. Skin lesions include erythema, crusting, exudation, ulceration and alopecia involving footpads, periocular or perioral regions, anal and genital regions, and pressure points on the trunk and limbs. A marked crusting, fissuring, and ulceration of the footpads is suggestive of SND (Figure 19-1). Secondary cutaneous infections with bacteria, yeast *(Malassezia, Candidia)*, or dermatophytes, particularly involving the feet, are often present in dogs with SND. Lameness secondary to footpad lesions, inappetence, and weight loss can also be associated with SND. Polydipsia and polyuria may be present when concurrent diabetes mellitus or significant liver dysfunction is present.

73

74

Table • 19-1 Survey of Breeds of Dogs Affected with Hepatocutaneous Syndrome Based on Reported Cases*

	NUMBER		NUMBER
Mixed breed	25	Bichon frise	1
Terrier mix	6	Cairn terrier	1
Shetland sheepdog	11	Cavalier King Charles spaniel	1
Cocker spaniel	11	Golden retriever	1
West Highland white terrier	10	Keeshond	1
Scottish terrier	5	Labrador retriever	1
Jack Russell terrier	5	Maltese	1
German shepherd	5	Miniature poodle	1
Border collie	4	Old English sheepdog	1
Lhasa apso	3	Pomeranian	1
Beagle	3	Rough collie	1
Welsh corgi	3	Samoyed	1
Schipperke	2	Springer spaniel	1
American Eskimo	1	Standard poodle	1
Australian shepherd	1	Yorkshire terrier	1

* 110 compiled cases.

istopathologic findings of representative skin biopsies are unique and confirm the diagnosis. These findings include a marked parakeratotic epidermis with striking inter-and intracellular edema, keratinocyte degeneration in the upper epidermis, and hyperplastic basal cells that create the characteristic “red, white, and blue” histologic lesion. The evaluation of serum biochemistry panels often demonstrates an increase in liver enzyme activities and a decrease in serum albumin concentration. Serum bile acid evaluations are abnormal in about half of affected dogs. A review of reported cases found hypoaminoacidemia in all dogs, elevated glucagon in 4 out of 4 dogs that had a glucagonoma, and increased serum insulin concentrations in 8 out of 11 dogs.

Abdominal ultrasound may demonstrate a unique “honeycomb” pattern to the liver consisting of variably sized hypoechoic regions surrounded by hyperechoic borders. Hepatic histopathology often documents a distinctive vacuolar hepatopathy with parenchymal collapse. Grossly, the liver may appear irregular, have multiple nodules, and be mistaken for being cirrhotic. There exists some contradiction as to whether the hepatic lesions in HS reflect true cirrhosis. Despite some histologic descriptions of micronodular cirrhosis, one study, using special stains, confirmed only a minimal increase in collagen within portal areas. Extensive fibrosis and reduced liver size characteristic of chronic cirrhosis is not seen in HS.

Table • 19-2 Percentage of Reported Cases (101 Dogs) Displaying the Commonly Reported Clinical and Laboratory Finding s in Dogs with Hepatocutaneous Syndrome

CLINICAL FINDINGS	%	LABORATORY FINDINGS	%
Hyperkeratotic and fissured footpads	94%	Elevated serum alkaline phosphatase	98%
Perioral or periocular skin lesions	62%	Elevated serum alanine transferase	71%
Perianal or perineal skin lesions	33%	Anemia	37%
Elbow skin lesions	30%	Hypoalbuminemia	33%
Perivulvar or scrotal or preputial skin lesions	28%	Diabetes mellitus	33%

The prognosis for dogs with SND is generally poor and the majority of dogs have survival times of less than 6 months. However, 20% of the dogs in a recent study were maintained for 12 months or more with oral protein hyperalimentation and periodic parenteral IV amino acid infusions.

19.3 DIAGNOSIS

Diagnosis of HS is based on obtaining skin biopsies with the typical histopathologic changes. The characteristic dermatohistopathology can be focal within a given lesion. Whenever possible, multiple representative samples should be obtained and submitted. Biopsies should be chosen, if possible from easily accessible sites, and attempts to avoid general anesthesia should be taken because these dogs are not often good candidates for anesthesia. The documented occurrence of abnormal laboratory findings as listed in Table 19-2 should increase the clinical suspicion of HS in dogs with compatible cutaneous lesions. If abdominal ultrasound is available, it can provide further support for the diagnosis if the characteristic “honeycomb” pattern is documented. If this ultrasonographic pattern to the liver is not visualized in a dog with a confirmed histologic diagnosis of SND, evaluation for a possible pancreatic tumor is necessary. Pancreatic tumors may not be readily visible with an abdominal ultrasound examination, so measurement of plasma glucagon is also recommended. If plasma glucagon concentrations are abnormally increased or a pancreatic mass is visible on ultrasound, the option for exploratory laparotomy and tumor excision can be considered. However, postoperative morbidity and mortality have been high. Plasma amino acids, if measured, should document a characteristic severe hypoaminoacidemia.

74
75

19.4 MANAGEMENT

The most effective symptomatic or palliative therapy for dogs with HS appears to be the administration of intravenous amino acids. A number of amino acid solutions are commercially available. Administration of a total dose of 25 ml/kg of a 10% Aminosyn (Abbot Labs, N.C. and Ill.) solution, administered over 6 to 8 hours and repeated at 7-to 10-day intervals has been recommended. Both Travasol 8.5% without electrolytes (Baxter Healthcare Corp., Clintec Nutrition Company, Deerfield, Ill.) and ProcalAmine 3% amino acids with 3% glycerin and electrolytes (B. Braun Medical Inc., Irvine, Calif.) can also be used for intravenous infusions in treating dogs with SND. These hypertonic amino acid solutions should be administered via a central vein to diminish the chance of thrombophlebitis. Inducing a hyperosmolar state is possible if administration is too aggressive. Dogs should be watched for neurologic signs, and the infusion discontinued if these occur. If compromised hepatic or renal function is present the administration of intravenous amino acids may exacerbate hepatic encephalopathy or augment increases in blood urea nitrogen (BUN). Such dogs warrant close monitoring with serial measurements of ammonia, BUN, and osmolality during intravenous amino acid administration. Some dogs show dramatic improvement in attitude with resolution of skin lesions after receiving amino acid infusions. As yet no defined protocols exist for the

administration of amino acid infusions in these dogs, and repeat infusions are performed bimonthly, monthly, or when clinical signs return.

Oral nutritional support should include a high quality protein diet that can be additionally supplemented with an amino acid powder such as Promod (Ross Laboratories, Columbus, Ohio), at a dose of one scoop per 10 pounds. Unless significant hepatic dysfunction with hyperammonemia has been documented necessitating a low protein diet, most dogs with HS cannot be fed enough protein to overcome the hypoaminoacidemia occurring in this disease. Zinc and essential fatty acid supplementation is often recommended, in part because of the reported initial improvement in some people with NME. Feeding egg yolks (3 to 6 per day) has been reported to result in clinical improvement in some dogs. This provides some additional protein but may also include micronutrients that may have some role in this disease.

Secondary infections should be treated with appropriate antibiotic and antifungal therapy, with careful consideration of those drugs that may be hepatotoxic or require hepatic metabolism. Topical therapy with antibacterial and antiyeast shampoos can also be of benefit in some dogs in helping to manage secondary infections.

Therapy with glucocorticoids is not recommended. Although antiinflammatory therapy for the skin lesions may be of some benefit, the risk of precipitating or exacerbating diabetes mellitus in these dogs makes the use of glucocorticoids contraindicated.

20 CHAPTER • 20 Physique: Obesity: A Disease to Be Recognized and Managed

Rebecca L. Remillard

It is estimated that 24% to 30% of the pet population in the United States seen by veterinarians is overweight or obese. This information, together with an estimated number of pets and veterinarians in the United States, suggests that a single veterinarian may see as many as 840 of these overweight or obese animals per practice. The cause of obesity as a primary disorder is simply that an animal is receiving more calories than it is expending, and body fat mass increases. Obesity may also be a secondary condition in animals with hypothyroidism, hyperadrenocorticism, or insulinomas. Treating these endocrinopathies rarely reduces, so a weight loss program may be necessary. However, the incidence of obesity as a primary disorder exceeds the incidence of the endocrinopathies associated with obesity.

20.1 HEALTH RISKS

Several health risks are associated with obesity as evidenced from long-term studies in cats and dogs. Grossly obese pets have increased prevalence of impaired gaits, traumatic and degenerative orthopedic disorders, and overweight puppies are more likely to develop clinical signs of orthopedic disease. Dogs obese at 1 year of age have a greater risk for developing mammary cancer later in life, and overweight dogs have an increased risk of developing cystic transitional cell carcinoma. Overweight pets have reduced activity, decreased heat tolerance, and they show visible signs of aging earlier than ideal-weight animals. Other health problems commonly noted in obese pets include dyspnea, congestive heart failure, dystocia, and nonallergic dermatologic problems. As we have learned from rodent and canine studies, lean or optimal weight pets may live on average 1 to 2 years longer than overweight pets. Therefore weight control is not only a quality of life issue but also one that may increase longevity. Calorie restriction is the only factor known to increase median life span.

Overweight and obese dogs and cats commonly have primary and secondary health issues. Studies have demonstrated significant weight changes in research dogs and cats using commercially available diets designed for weight loss. These therapeutic weight loss diets are marketed solely to veterinarians.

20.2 RECOGNITION

Body weight alone does not indicate whether that weight is appropriate for the particular patient. Knowing a dog's weight to be 50 lb (23 kg) or a cat to be weighing 12 lbs (5.5 kg) means that animal might be underweight, at optimal weight, or overweight. Writing a body condition score next to the weight puts that weight in perspective, which allows visualization regarding how the weight is carried on that skeletal frame. Scoring body condition is similar to the visual effect of breed (e.g., a 50-lb beagle conjures a very different picture than a 50-lb Newfoundland).

20.2.1 Body Condition Scoring

Body condition scoring (BCS) is a useful tool that estimates an animal's body fat content, taking into account the animal's frame size independent of body weight. Several different numbering systems (using 3-, 5-, or 9-point categories) and wall charts are available. A clinician must learn by experience what visual and palpable characteristics correspond with a given BCS; however, once learned, BCS has been demonstrated to be a reliable indicator for determining body composition. BCS is a useful tool in evaluating weight changes within an individual and as a means of communicating between clinicians.

The 5-or 9-point systems seem to be most commonly used. A 5-point system is most useful to novices using whole numbers (1/5 is emaciated, 3/5 is ideal, 5/5 is grossly obese), but with practice, the scores will be recorded to the nearest half score (e.g., 4.5/5). Experienced clinicians frequently use the 9-point system, in which scores are recorded to the nearest whole number (1/9 is emaciated, 5/9 is ideal, 9/9 is grossly obese). Using the 5-point system scored to the nearest half score actually is the 9-point system.

A pet in optimal body condition has "normal body contours and silhouettes, bony prominences that can be readily palpated but not seen or felt above skin surfaces, and intraabdominal fat insufficient to obscure or interfere with abdominal palpation." Body condition can be defined as the ratio of body fat to nonfat tissues and hence does estimate percent body fat. Fat mass expressed as a percentage of body weight can also be a useful tool in convincing owners their pets are overweight. Body composition studies in dogs and cats suggest that animals assessed to be in optimal body condition have 15% to 25% body fat. Dogs and cats with a BCS of "ideal" will have 15% to 25% body fat, those considered overweight will have 26% to 35% body fat, and those deemed obese will have more than 35% body fat. Some pets may have well more than 40% body fat (e.g., the cat with a 10-lb frame weighing 20 lbs is probably carrying 10 lbs of fat). Therefore it is correct to say that when assigning the maximum BCS, the pet has at least 40% body fat.

Dogs with an ideal BCS of 4 to 5 lived 15% longer than dogs of the same breed, living in the same environment, and eating the same diet but having a BCS of 6 to 7 (using the 9-point system). Hence, weight reduction programs should be discussed and implemented when the BCS is 6/9 or greater because the percent body fat will then be greater than 25%. The benefits derived from controlling body weight and condition are thought to be realized at any time throughout life; hence benefits can be gained by reducing the weight of any pet at any age.

76
77

20.3 MANAGEMENT

Before beginning a weight loss program, it is essential to ensure that the obesity is of primary origin and not the result of an endocrinopathy. Body weight may not naturally correct after such treatments have been instituted. A reduced calorie intake may still be needed after initializing treatment for an underlying endocrinopathy. A complete physical examination, with routine serum, blood, and urine analysis should be done. If necessary, additional diagnostics should be done to further evaluate any abnormal clinical findings of the cardiovascular, gastrointestinal, liver/pancreas, renal/urinary, musculoskeletal, or other organ systems. A dietary history is of limited value because most clients cannot recall the names or amounts of food fed to their pets. The most essential dietary information needed is an estimate of the current amount of calories fed so that appropriate restriction may begin. Most owners of pets with a BCS greater than or equal to 6/9 feed ad libitum, suggesting that a specific feeding amount divided into two meals per day would be an excellent starting point. Some owners requesting a weight loss plan have already begun to limit the pet's calorie intake with no success; hence the first feeding recommendations must be a further restriction of calories. Several different methods can be used to restrict calorie intake.

20.3.1 Short-Term Starvation

Starvation as a method of weight loss cannot be used in cats because of the risk of inducing hepatic lipidosis. Starvation has been used as a form of weight loss in dogs. However, this method creates not only a caloric deficiency but also a deficiency of all other nutrients. Most pronounced would be a protein deficiency (skeletal muscle wasting will occur as a result of the need for synthesis of essential proteins). Body weight lost will then be comprised of fat, muscle, and to a lesser extent bone. Less obvious will be the water-soluble vitamin and trace mineral deficiencies created because little to no body storage of these nutrients takes place, and a daily intake is necessary for ongoing metabolic processes. The goal of weight loss is to reduce the body fat content while

maintaining other body tissues and metabolism. Deficiencies of amino acids, vitamins, and trace minerals are needed to properly and fully catabolize and therefore reduce fat stores. No veterinary protein, vitamin, or mineral supplement exists that will adequately supply 100% of the daily requirement of these essential nutrients. Starvation creates nutritional deficiencies across all metabolic processes and is therefore not an acceptable form of weight reduction from a physiologic perspective. The inhumane aspects of this method are obvious. Additionally, short-term starvation does not teach the owner how to properly feed and manage their pet in the long-term once the proper weight has been achieved.

20.3.2 Feeding Less of Current Food

It is not uncommon to hear a practitioner advocating, “Simply feed less of his regular food,” as a method of weight loss. If the volume of “regular food,” usually an over-the-counter (OTC) pet food product not designed for weight loss, is reduced by 25% or less, there may be little nutritional harm done to a normal healthy overweight adult dog over a short period (weeks), depending on the OTC product used. However, if the volume of regular food has to be reduced by more than 30% to get weight loss, nutritional deficiencies will occur. For example, feeding 30% fewer calories of an OTC adult premium maintenance dog food to a 50-lb overweight dog produces a protein intake 5.6% below current canine feeding recommendations. As the restriction continues, more nutrients become deficient. Therefore when more than a 25% restriction of calories is necessary, changing the pet food product is absolutely necessary. An OTC diet labeled “light,” “lite,” “lean,” “less,” or “reduced calorie or fat” is formulated for weight maintenance, not weight reduction. Some properly formulated OTC “reduced calorie” diets may be fed at 25% less than the recommended feeding; however, unless one is comfortable with the calculations or has some assurance from the manufacturer, it is not advisable as a general rule.

Properly formulated weight loss diets are specifically designed to be low in calories with increased concentrations of all other nonenergy nutrients. In other words, the nonenergy nutrients are in a higher proportion to calories consumed in a weight reduction diet than in the OTC adult maintenance or reduced calorie foods. One only wants to create a caloric deficiency and not other nutrient deficits during weight loss according to Association of American Feed Control Officials (AAFCO) allowances. Feeding fewer or no treats, snacks, or table foods is appropriate because these do not affect the daily nutrient intake balance. Changing treats to high-water (squashes) or fibrous (broccoli) vegetables is also acceptable because they contain no calories to be counted.

20.3.3 Feeding High-Fiber Diets

There has been some debate regarding the effectiveness of diluting dietary calories with dietary fiber, water, and air. Water and air are quickly removed from the gastrointestinal tract and do not contribute substantially to a feeling of gastrointestinal fill; hence they have a minimal sustained effect on decreasing food intake. Dietary fiber has been shown to decrease food intake.

Fibers are complex carbohydrates that cannot be digested by endogenous enzymes within the small bowel but can be fermented to varying degrees in the colon. Fiber is classified by physiochemical and analytic properties. Dietary fiber, including soluble versus insoluble fiber, dilute diet calories, increase satiety, and limit food consumption by increasing digested bulk and prolonged distention of the gastrointestinal tract. The difference between soluble and insoluble fiber is based upon their solubility in water; although the fiber types affect the gastrointestinal rate of transit differently, transit time through the entire gastrointestinal tract is increased approximately the same for both soluble and insoluble fibers. Some dog studies showed no effect on caloric intake when foods contained 12% to 14% of dry matter as soluble or insoluble fibers, but dogs did consume

significantly less of a food containing 21% insoluble fiber. These same dogs also ate less food when offered a second meal 30 to 45 minutes after consuming the high-fiber food. Overall, study results indicate beneficial effects of dietary fiber in foods intended for weight loss. Most commercial weight loss diets contain primarily insoluble fiber at greater than 10% (and sometimes as high as 30%) of the dry matter. Increased fecal bulk is to be expected, and sometimes the increase frequency of defecation is not acceptable to the owner. In this case a lower-fiber diet (10% to 15%) has to be used for weight loss.

20.3.4 Weight Loss Protocol

Several methods can be used to calculate food doses for weight loss. An equation for weight loss must require fewer calories consumed than are currently expended. Different pet food companies offering weight loss products and programs use different methods, and some calculation methods are more successful than others. 77

78

Method 1: The daily caloric intake for weight loss is 50% of the maintenance calories at dog's current weight. This method has not produced a rate of weight loss sufficient to meet owner's expectations or inspire interest in continuing the program in clinical trials.

Method 2: The daily caloric intake for weight loss is a percentage (40% to 60%) of the maintenance energy requirements at the target, desired, or optimal body weight. This method has produced a rate of weight loss acceptable to owners.

Method 3: The daily caloric intake is calculated based upon maintenance energy requirement (MER) at the current weight minus a desired percent body fat loss per day, which could be adjusted depending upon individual animal response. This method has been shown to produce a rate of weight loss acceptable to owners. Several pet food manufacturers have these weight loss calculations available in simple, user-friendly programs that can be run on most personal computers (IBM or Macintosh).

Consistently delivering or feeding fewer calories to the pet is of course the responsibility of the owner. Owner (family) compliance is the single most important aspect in an obese pet losing weight; this is simple to say but very difficult to deal with in the single 20-minute office visit. Approximately 55% of the overweight feline and canine patients are not brought back for a recheck weight loss visit. Pets who returned for three or more recheck visits did successfully lose weight. Recheck visits every 4 to 8 weeks are essential because the caloric intake must be reduced (recalculated) to continue weight loss or the weight will stabilize. Some weight loss packages put together by pet food manufacturers aid owner compliance by providing a well-demarcated feeding cup or cans and printed instructions.

In summary, losing excess body fat has been shown to decrease morbidity and increase longevity in pets. BCS systems and computerized weight loss programs are now available as useful clinical tools. Veterinarians should be regularly discussing weight control with owners and helping those with pets with BCS greater than 5/9 because the majority of pets are now neutered and have less exercise and because pet food companies strive to make their OTC products ever more palatable.

21 CHAPTER • 21 Cachexia

Thomas Schermerhorn

A standard definition for cachexia is difficult to provide. In clinical practice, *cachexia* is the term used to describe the weight loss, loss of muscle, and anorexia that accompany many chronic disease conditions. However, it is important to recognize that cachexia is not simply caused by inadequate nutrient intake and that cachexia and starvation are not equivalent physiologic processes. In humans, two biochemical features distinguish malnutrition caused by cachexia from that caused by starvation. First, unlike starvation, cachexia is associated with a pronounced acute phase inflammatory response, characterized by production of proinflammatory cytokines such as interleukins (IL-1 and IL-6, among others) and tumor necrosis factor alpha (TNF-alpha).

Cytokines stimulate the production of ubiquitin, a protein that binds to other proteins and stimulates their metabolism via the cellular proteasome system. Activation of the ubiquitin-proteasome system does not occur during starvation. Increased resting energy expenditure is the second feature of cachexia that distinguishes it from starvation. Resting energy expenditure increases as a consequence of altered protein, fat, and carbohydrate metabolism.

A diagnosis of cachexia should be considered for any dog or cat with marked weight loss, severe muscle loss, and decreased appetite in the setting of a chronic inflammatory response. By this definition, cachexia is not a specific diagnosis but an indication of a state of disordered metabolism that can be caused by a variety of diseases.

When evaluating an emaciated dog or cat, it is important to determine, from diagnostic and therapeutic standpoints, whether the condition has developed as a result of inadequate nutrient intake (maldigestion, malabsorption, or underfeeding, for example) or represents true cachexia.

21.1 HISTORY

Dogs and cats with cachexia may be brought to veterinarians principally for weight loss or for signs associated with an underlying condition. Careful history taking should include questions about appetite, caloric intake, daily exercise, and environment. Some animals with cachexia have weight loss with preservation of appetite; the loss of body condition may be noted before the onset of anorexia in some cases. Dogs and cats with malnutrition as a result of starvation, malabsorption, or maldigestion typically have a good appetite. However, the level of appetite is variable in animals with cachexia, ranging from normal to complete anorexia. Lethargy, weakness, and exercise intolerance may be marked and in some cases are worse than would be expected if simply the result of poor physical condition. The dietary history should be carefully reviewed and include the type and quantity of food offered (including any dietary supplements provided), the possibility that other pets at home might be competing for food, and the pet's level of appetite. It is important to distinguish those animals that have an appetite but cannot prehend or swallow food from those who have no appetite but can chew and swallow normally. Diagnostic considerations suggested by various patient history findings are presented in Box 21-1.

21.2 PHYSICAL AND LABORATORY FINDINGS

Cachexia has few specific indicators other than the marked loss of body condition that is a characteristic finding; muscle may be lost disproportionately to fat in some animals with cachexia. Similarly, laboratory findings are not specific for cachexia. Serum protein levels are variable even in the presence of a systemic inflammatory response. For example, elevated fibrinogen levels (as a component of the acute phase response) in humans with neoplasia may be offset by reduced albumin synthesis. Increases in hormone concentrations, such as cortisol and insulin, may

be observed in animals with cachexia; these changes may result from or be the cause of cachexia-induced alterations in metabolism. In general, an individual patient's physical and laboratory findings will be representative of the underlying disease rather than specific indicators of cachexia. No compelling reasons exist to perform specific laboratory tests to make a diagnosis of cachexia. Instead, cachexia is largely a clinical diagnosis that is made when appropriate physical findings are present in a dog or cat with a disease associated with a chronic inflammatory response.

21.2.1 Box • 21-1 Diagnostic Considerations for Patients with Marked Weight Loss

21.2.1.1 Dietary History—Inadequate

Starvation

Underfeeding

Poor quality food

21.2.1.2 Dietary History—Adequate

Environmental/housing factors

- Competition for food from other pets
- Limited access to food

Oral and dental disease

Impaired use of nutrients

- Specific nutrient deficiency
- Maldigestion of any cause
- Malabsorption of any cause
- Diabetes mellitus
- Protein-losing disease
  - Nephropathy
  - Gastroenteropathy

Cardiac disease*

Elevated metabolism

Hyperthyroidism

Chronic fever of any cause*

End-stage renal disease*

Neoplasia*

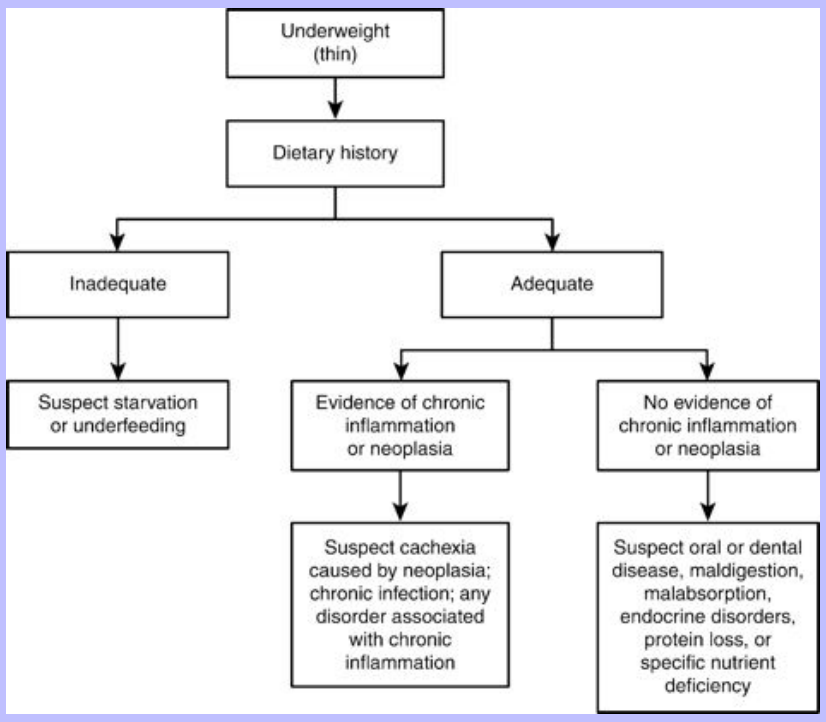
Chronic infection*

Chronic inflammation of any cause (e.g., immunologic disease*)

Note: Patients may present with or without a loss of appetite.

* Diseases typically associated with cachexia in humans and animals.

Figure 21-1 Algorithm for making a diagnosis of cachexia.



21.3 DIAGNOSTIC PLAN

A general algorithm for making a diagnosis of cachexia is shown in Figure 21-1. It is important to recognize cachexia because animals with this condition may not respond as expected to therapeutic interventions and nutritional support.

21.4 THERAPY

Successful therapy of the primary disorder is the most efficacious means of reversing the metabolic abnormalities that underlie the development of cachexia. Nutritional support is the cornerstone of specific therapy for cachexia. Hypercaloric feeding is intended to supply the dog or cat with sufficient calories to meet increased maintenance caloric needs (because of hypermetabolism), prevent additional weight loss, and promote weight gain. Unfortunately, hypercaloric feeding alone may not be sufficient therapy for animals with true cachexia. People with cachexia who receive hypercaloric feeding gain weight, but the increase in body weight is almost exclusively the result of an increase in adipose tissue without change in lean body mass. Thus it appears that simple feeding therapy may not be sufficient in all situations to reverse the abnormal protein catabolism that accompanies cachexia. Additional therapies that have been used for cachexia in humans that may prove useful for the treatment of animals include appetite stimulants, anabolic agents, antiinflammatory drugs, and cytokine inhibitors. Although some of these drugs have been extensively used for other indications in small animals, information is limited about their efficacy when used for cachexia.

22 CHAPTER • 22 Failure to Grow

Sherri L. Ihle

Growth is a complex process that results in an increase in size of an individual. In dogs and cats, growth primarily occurs during the first 6 to 24 months of life. When an animal does not increase in size at the normal rate or to a normal extent, a “failure to grow” is identified. The owner of the affected pet may notice the problem and bring the animal to the veterinarian, or the animal's small size may be first noticed during a routine physical examination. In veterinary medicine, determination of normal growth is sometimes difficult because breed sizes vary and mixed breed pets predominate. Comparing littermates, when possible, can be helpful in making and assessing the individual's growth rate and pattern.

22.1 PATHOPHYSIOLOGY

Genetic, hormonal, metabolic, and nutritional factors influence growth. To meet its full genetic potential, an animal must have growth hormone (somatotropin) to stimulate insulin-like growth factor-I (IGF-I) production, which in turn stimulates skeletal growth, protein synthesis, and cell proliferation. Full IGF-I activity requires the presence of thyroid hormone. The animal must also consume sufficient calories and nutrients; digest, absorb and retain the nutrients; transport the nutrients to the necessary tissues; and be able to use the nutrients for metabolic maintenance and growth. A defect in any of the previously mentioned processes can disrupt, delay, or stop normal growth (Box 22-1; Figure 22-1).

22.1.1 Genetic Abnormalities of Bone Growth

An inherited endochondral ossification defect in chondrodystrophic animals results in angular limb deformities and subnormal height.

22.1.2 Deficient Nutrient Intake

Gastrointestinal parasitism, resulting in a “relative” deficiency in nutrition, is the most common cause of reversible retarded growth in puppies and kittens. If an insufficient amount of food or food of poor quality is consumed, nutrients will not be available to provide substrates and energy for tissue growth. Oral disease may cause pseudoanorexia. Regurgitation or vomiting because of esophageal or gastric disorders results in insufficient food reaching the intestines for digestion and absorption. Maldigestion or malabsorption can result in decreased uptake of nutrients. Renal, hepatic, cardiac, inflammatory, and hypo-adrenal disease can suppress the appetite. Absorption and transport of nutrients from the intestines to other tissues can also be inadequate with cardiac disease.

22.1.2.1 Box • 22-1 Causes of Growth Failure in Dogs and Cats

22.1.2.1.1 Small Stature and Poor Body Condition

Dietary problem

Underfeeding

Poor quality diet

Cardiac disorder

- Congenital anomaly
- Endocarditis

Hepatic dysfunction

- Portosystemic vascular anomaly
- Hepatitis
- Glycogen storage disease

Esophageal disease

- Megaesophagus
- Vascular ring anomaly (e.g., persistent right aortic arch)

Gastrointestinal disease

- Parasites
- Inflammatory bowel disease
- Obstruction (e.g., foreign body, intussusception)
- Histoplasmosis

Exocrine pancreatic insufficiency

Renal disease

Renal failure (congenital or acquired)

- Glomerular disease
- Pyelonephritis

Inflammatory disease

Hormonal disease

- Diabetes mellitus
- Hypoadrenocorticism
- Diabetes insipidus
- Juvenile hyperparathyroidism (dogs)

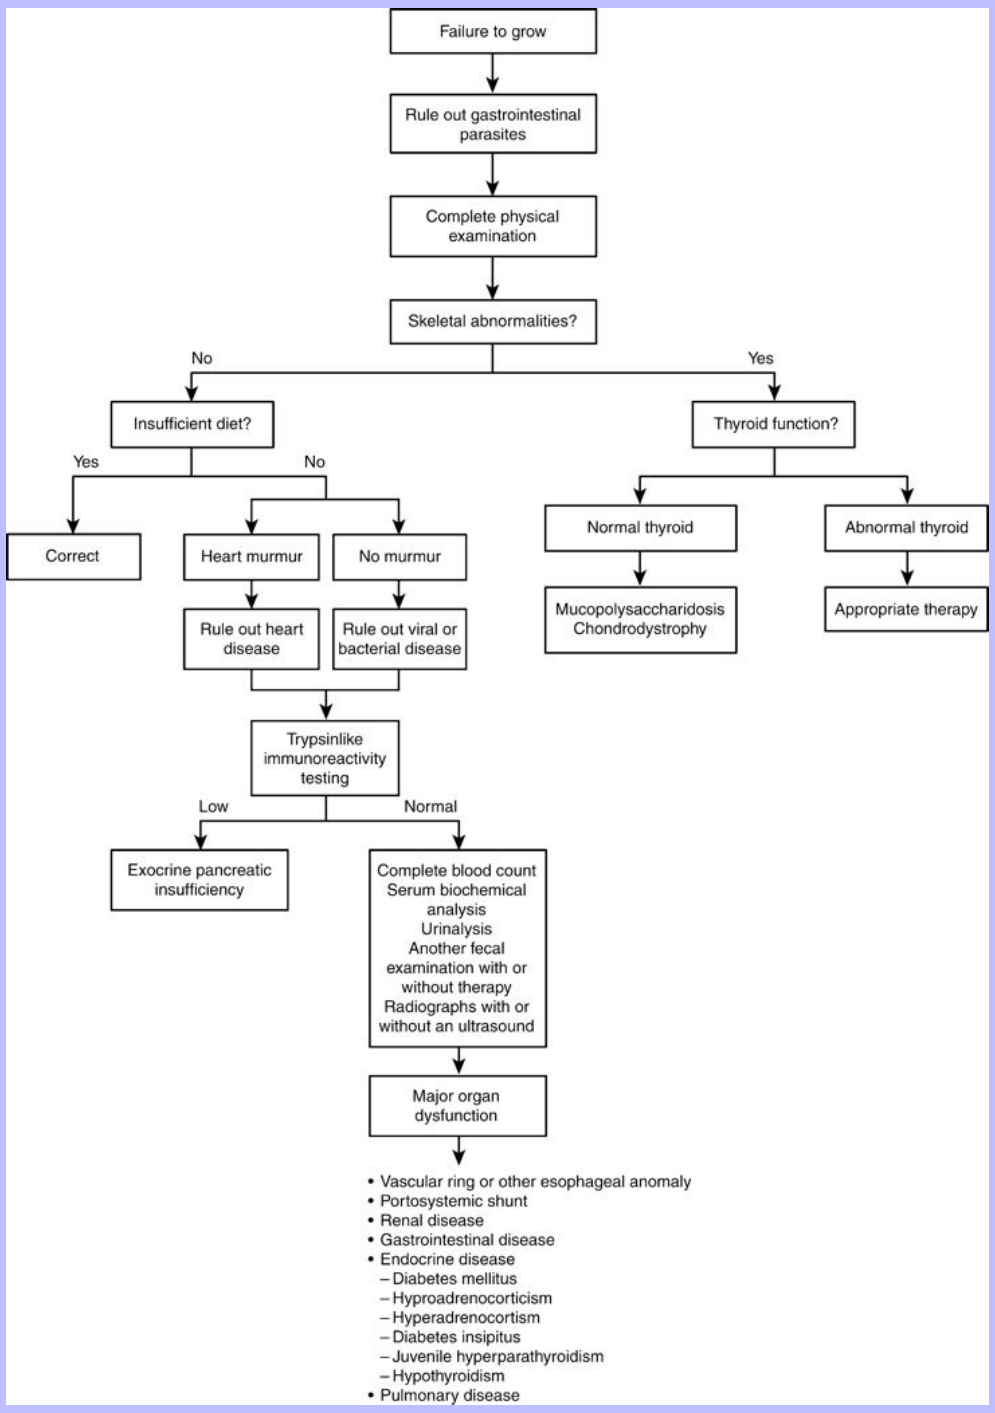
22.1.2.1.2 Small Stature and Good Body Condition

Chondrodystrophy

Hormonal disease

- Congenital hypothyroidism
- Congenital hyposomatotropism (pituitary dwarfism)
- Hyperadrenocorticism

Figure 22-1 Algorithm for diagnostic evaluation of the dog or cat with failure to grow.



22.1.3 Caloric or Nutrient Loss

Fever can result in excess caloric loss as body heat. In diabetes mellitus, glucose is lost in the urine. Protein and salts can also be lost in the urine in animals with glomerular and renal tubular disease, respectively. Several intestinal disorders can result in protein-losing enteropathy. As previously noted, parasitism is the most common cause of “lost” nutrients.

22.1.4 Abnormal Metabolism

Carbohydrate metabolism can be altered in inflammatory disease, renal disease, and hepatic disease. Protein production can also be decreased with hepatic disease. Hypothalamic or pituitary aplasia or neoplasia (e.g., craniopharyngioma) can result in low growth hormone and IGF-I concentrations. Hypothyroidism can decrease the activity of growth hormone. Because insulin has a positive effect on IGF-I production, insulin deficiency caused by diabetes mellitus or malnutrition can slow growth. Cortisol excess, whether endogenous or exogenous in origin, can inhibit the secretion of growth hormone. An extremely rare form of juvenile hyperparathyroidism in German shepherds has also been reported to cause stunted growth.

22.2 HISTORICAL FINDINGS

The animal with subnormal growth may be brought to the veterinarian for that problem or the small body size may be noted during a routine examination. In either case, the owner of the dog or cat should be questioned as to the size of the pet's parents and littermates, if known. If the parents and littermates are also at the lower end of the range of breed size, the small stature of the pet may not be worrisome. However, if the pet is noticeably smaller than its littermates, the problem should be investigated. When the family history is unknown, the pet's size should be compared with others in the breed. For the mixed breed dog, the predominant breed should be determined based on physical characteristics, and that breed's average size should be the standard for comparison.

22.2.1 Duration of the Problem

Determining whether the animal's growth has been slow since birth or whether it was normal and then suddenly seemed to stop can be helpful. In the former case, congenital defects should be strongly considered, whereas in the latter case, acquired disorders must also be considered.

22.2.2 Diet

A detailed nutritional history should be obtained as to type of food, amount of food consumed, appetite, and feeding schedule. A less palatable or poor quality diet may not be eaten well or may be poorly used by the animal. A poor appetite despite the feeding of a palatable, high-quality food suggests the presence of a systemic illness causing inappetence or anorexia. Conversely, if the animal is always hungry and internal parasites have been ruled out or treated, underfeeding (because of inadequate owner knowledge of the pet's nutritional needs), a disorder causing a “relative” lack of calories (e.g., exocrine pancreatic insufficient), or an increased nutrient loss (e.g., diabetes mellitus, renal disease, intestinal disease) should be considered.

22.2.3 Concurrent Clinical Signs

The owner should also be questioned about the presence or absence of other clinical signs, which may help define the cause of the problem. Regurgitation usually indicates a pharyngeal or esophageal problem. Vomiting suggests a gastrointestinal problem or systemic illness (e.g., renal disease, hepatic disease, hypoadrenocorticism). Diarrhea or voluminous stools may be seen with disorders causing maldigestion (e.g., exocrine pancreatic insufficiency) or malabsorption (e.g., severe parasitism, inflammatory bowel disease, histoplasmosis). If polyuria is present, diabetes mellitus, renal disease, hepatic dysfunction, or hypercalcemia (juvenile hyperparathyroidism) should be considered. Seizures, episodic abnormal behavior, vomiting, and diarrhea may be signs of hepatic dysfunction. Exercise intolerance or syncope can suggest a congenital cardiac abnormality. Poor response to housebreaking measures or to obedience training, or a lack of normal puppy play activities can suggest the mental dullness of congenital hypothyroidism, or the encephalopathy of hepatic failure. Poor response to housebreaking measures may also be seen with ectopic ureters or the polyuria of kidney abnormality. Glucocorticoid therapy for an unrelated problem may have slowed the pet's growth. Although the absence of these historical findings does not eliminate these disorders as possible problems, their presence can guide the diagnostic plan.

22.3 PHYSICAL EXAMINATION FINDINGS

Although some animals examined as a result of poor growth will have no other clinical abnormalities, in many animals a thorough physical examination can provide valuable clues as to the organ system or systems responsible for the problem. The animal's general appearance and body condition should be assessed. A short animal with a poor body condition is more likely to have a nutritional, metabolic, or cardiac abnormality, whereas a short animal with a good body condition is likely to have a hormonal problem or be chondrodysplastic (see Box 22-1). Chondrodysplastic animals and many animals with congenital hypothyroidism will also have an abnormal skeletal conformation (e.g., angular limb deformities). Symmetrical truncal alopecia, the prolonged presence of a soft puppy haircoat, or thin scaly skin suggests a thyroid or growth hormone deficiency or cortisol excess. Mental dullness can be seen with hypothyroidism or hepatic encephalopathy. Hepatic failure can also result in cortical blindness.

The head and neck should be examined for pale mucous membranes (anemia of chronic disease), icterus (hepatic disease), oral pain (dysphagia), and lymphadenopathy (inflammatory disease). The thorax should be carefully ausculted for a murmur (congenital cardiac disease, other cardiac dysfunction), bradycardia (hypoadrenocorticism), or abnormal lung sounds (pulmonary disease). On abdominal palpation, enlarged or shrunken kidneys can indicate a renal problem, and hepatomegaly can suggest hepatic disease or dysfunction. Thickened bowel walls may be felt in the presence of inflammatory bowel disease, or a mass lesion may be palpated in the pet with a foreign body or intussusception.

22.4 DIAGNOSTIC PLAN

Decisions concerning the initial diagnostic plan should be based on the animal's body condition and any abnormalities identified from the history and physical examination (see Figure 22-1). Food consumption should always be evaluated (see Historical Findings). If food intake is in question, a brief *feeding trial* can provide information on appetite and caloric consumption in relation to change in body weight. Multiple *fecal examinations* and possible deworming should be performed to eliminate severe parasitism as the cause of malnutrition. If the animal has been given a medication that may have slowed growth, the medication should be discontinued, if possible, and subsequent growth monitored. A *complete blood count* (CBC) should be evaluated for anemia, inflammation, or eosinophilia. Results of a *serum biochemical profile* can suggest renal, hepatic, or gastrointestinal

disease; diabetes mellitus; hypoadrenocorticism; hyperadrenocorticism; hypothyroidism; or hyperparathyroidism. A *urinalysis* may show proteinuria, isosthenuria, hyposthenuria, glucosuria, or inflammatory sediment. *Radiographs* can be used to detect a cardiopulmonary abnormality, organomegaly, a small liver or kidneys, intestinal foreign body, or skeletal abnormalities. *Ultrasonography* may help to further characterize radiographic abnormalities and detect structural abnormalities within an organ. An *electrocardiogram* may be helpful in assessing potential hyperkalemia (in an emergency) and congenital cardiac abnormalities. *Radiographic contrast studies* can be used to characterize congenital cardiac abnormalities, to identify portosystemic vascular anomalies, and to detect partial gastrointestinal obstructions. *Hepatic function tests* can identify the need for further investigation of the liver. *Gastrointestinal function tests* (e.g., serum trypsinlike immunoreactivity, serum cobalamin and folate) can be used to identify occult gastrointestinal disease causing maldigestion or malabsorption. *Biopsy* may be needed if gastrointestinal, hepatic, or renal disease is identified. *Hormonal tests* can be used to detect hypothyroidism, hyperadrenocorticism, hypoadrenocorticism, and hyperparathyroidism; an assay for growth hormone is not currently available on a commercial basis, but an IGF-I assay is available for the dog.

22.5 TREATMENT

Treatment of the animal that exhibits growth failure varies widely based on the underlying pathology. Some disorders can be well managed medically, and others require surgical correction.

23 CHAPTER • 23 Swollen Joints and Lameness

Richard E. Goldstein

Lameness is a common reason for dogs to be taken to a veterinary practitioner. Although lameness has numerous causes, this chapter will address lameness associated with nontraumatic inflammatory disease of the joints. Assessment for swelling or pain of accessible joints should be a routine component of the physical examination of dogs and cats. Arthritis can be categorized based on cause.

Degenerative joint disease is caused by chronic changes to the joint capsule, cartilage, and synovium associated with minimal to no active inflammation. Degenerative joint disease, although painful, is typically not associated with systemic inflammatory signs. Inflammatory joint diseases can be classified as septic or nonseptic (immune mediated). Inflammatory joint disease is typically associated with one or more of the signs consistent with those of systemic disease. These usually include fever, leukocytosis, inappetence, or lethargy. Arthritis can also be classified based on the number of joints involved. Monoarthritis implies involvement of a single joint, whereas polyarthritis involves multiple joints.

23.1 SEPTIC ARTHRITIS

Septic arthritis is defined by presence of bacteria in the synovial or joint fluid, observed on cytologic evaluation or with bacterial culture. Septic arthritis occurs as a result of hematogenous (more common in neonates) spread or external penetrating wounds. It is not always possible to distinguish septic arthritis from immune-mediated arthritis, especially when multiple joints are involved or no obvious penetrating wound is seen. Joint fluid cultures, although worthwhile, are frequently negative even when bacteria are evident on cytologic examination. Neutrophils predominate in the joint fluid of infectious and immune-mediated arthritis. Degenerative changes in neutrophils, however, are more indicative of a septic process. The number and type of joints involved may help the clinician differentiate septic from nonseptic arthritis. Single joint involvement and involvement of proximal joints (hip, shoulder, stifle, and elbow) are usually septic. Multiple, distal joint (carpi, tarsi) involvement, is most commonly seen immune-mediated disease. When a septic process is possible, a period of antimicrobial therapy can be recommended, even if no bacteria are observed on joint fluid cytology and joint fluid cultures are pending or negative.

23.2 IMMUNE-MEDIATED POLYARTHRITIS

Immune-mediated polyarthritis is the most common poly-arthritis in companion dogs and cats. A type III hypersensitivity reaction, in which immune complexes are deposited in the synovial membrane and an inflammatory cascade is initiated, is thought to be the cause. The immune stimulus is frequently unknown, hence the commonly used term “idiopathic polyarthritis.” Immune-mediated polyarthritis can be categorized both radiographically and histologically into the common nonerosive form and the uncommon erosive condition.

23.3 EROSIVE POLYARTHRITIS

Erosive polyarthritis in dogs may have similarities with human rheumatoid arthritis. These similarities include the progressive, severe, deforming course of the disease and the erosive radiographic appearance of affected joints. In humans, specific antibodies, collectively known as *rheumatoid factor* (RF), are commonly identified. An IgM antibody, considered the canine RF, has been identified in some dogs with erosive arthritis. Although the term

rheumatoid arthritis has been used in veterinary medicine, it is preferable to use the descriptive term *erosive arthritis* in dogs. 84

RF is a nonsensitive and nonspecific marker of erosive or immune-mediated arthritis in dogs, making the assay's clinical utility questionable. Radiographic findings commonly seen in dogs with this form of arthritis include erosions involving the articular surface or the loss of trabecular bone density in the epiphyses. The destructive process is progressive. Radiographically, this process appears in the subchondral or juxtaarticular bone as poorly demarcated radiolucent foci. Erosive arthritis has been reported in many breeds but is thought to occur more frequently in small breed dogs, 2 to 6 years of age. A specific form of erosive arthritis has been reported in greyhounds.

Erosive polyarthritis has been reported in cats and has been termed *progressive feline polyarthritis*. This is a disease that occurs more commonly in male cats between 1.5 and 5 years of age. It may be an immune-mediated hypersensitivity type III reaction to chronic viral immune stimulation, secondary to chronic feline syncytium-forming virus infection. Two forms of the disease exist: (1) the deforming type, a severely erosive condition that is similar to canine erosive arthritis, and (2) the more common proliferative form. Both forms can be associated with severe systemic signs of disease, including lymphadenopathy, swollen joints, and muscle wasting.

23.4 NONEROSIVE POLYARTHRITIS

This is the most common form of immune-mediated polyarthritis in dogs and cats. The source of the antigenic stimulation is usually not known. Nonerosive polyarthirtis has been reported to occur secondary to chronic infectious disease, systemic lupus erythematosus (SLE), lymphocytic plasmacytic synovitis, use of certain drugs, and malignancies. It may also be a component of immune-mediated diseases, such as inflammatory bowel disease or chronic hepatitis.

Clinical signs typically include cyclic fever, lethargy, anorexia and varying degrees of pain, lameness and swollen joints. A stiff gait characterized as “walking on egg shells” is frequently observed, but some affected dogs have a normal gait. The distal joints (carpi and tarsi) are most commonly affected. Pain, redness, and swelling range from severe to absent. Some dogs exhibit pain that is difficult to localize. Others have signs of back or neck pain. This could be a result of inflammation of the vertebral articulations or concurrent meningitis. Lymphadenopathy and muscle wasting can be profound. Nonerosive polyarthritis can be seen in any breed at any age but most commonly occurs in young dogs (between 1 and 6 years of age). The condition appears to be overrepresented in German shepherds, Doberman pinschers, collies, spaniels, retrievers, terriers, and poodles. Specific syndromes involving immune-mediated polyarthritis have been identified in certain breeds of dogs, such as swollen hock syndrome in Shar Peis and arthritis in Akitas.

Figure 23-1 A demonstration of the method to grossly assess joint fluid viscosity. A drop is placed on a glass slide. It is gently touched with a fingertip that is then slowly moved away. The reader should note the strand of viscous fluid typical for normal joint fluid viscosity.

Infectious disease can cause a secondary immune-mediated polyarthritis as a result of chronic immune stimulation inducing immune complex deposition in the synovial tissue. Diseases frequently associated with secondary immune-mediated polyarthritis include heartworm disease, rickettsial disease such as ehrlichiosis, Rocky Mountain spotted fever, Lyme disease, and others. Chronic bacterial infections such as discospondylitis, pyelonephritis, prostatitis, and endocarditis can also cause a secondary immune-mediated polyarthritis.

Systemic lupus erythematosus is suspected when polyarthritis is accompanied by immune-mediated hemolytic anemia, thrombocytopenia, glomerulonephritis, or immune-mediated dermatopathies. The value of antinuclear antibody (ANAs) testing is controversial. This syndrome is thought to occur more commonly in females and in German shepherds, collies, Shetland sheepdogs, beagles, and poodles.

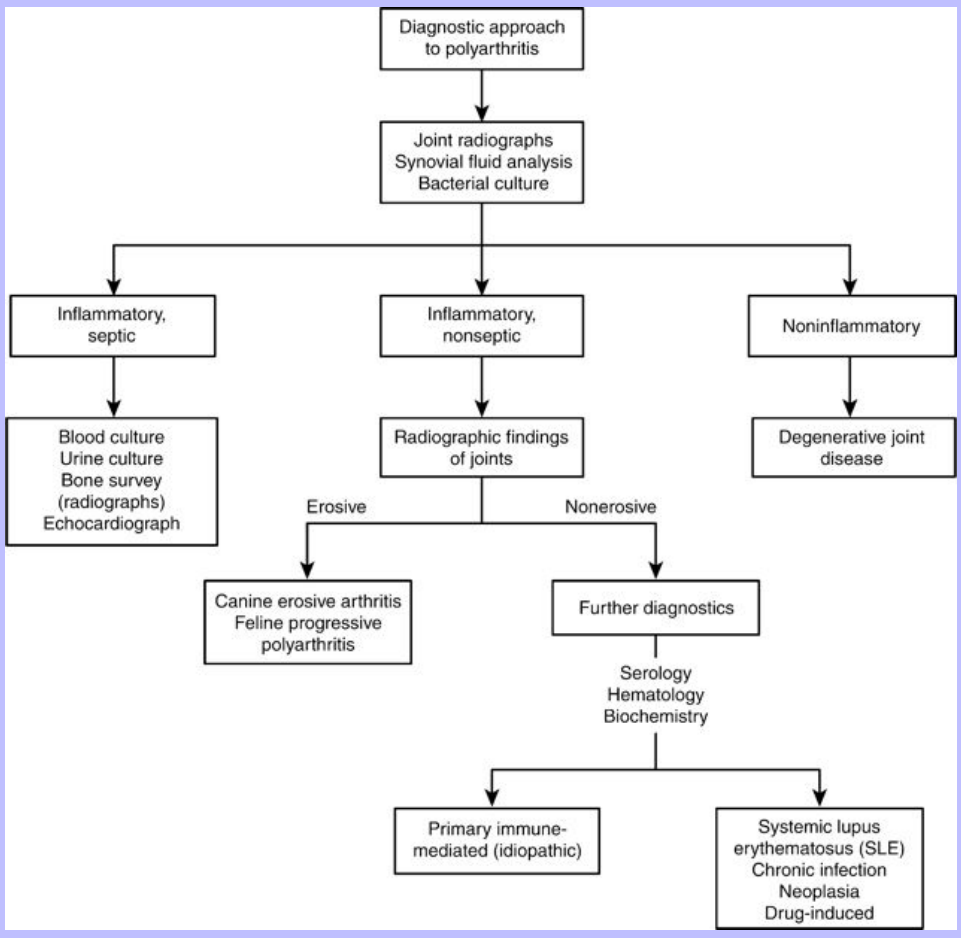
Lymphocytic-plasmacytic synovitis has been reported most commonly in German shepherds and other large-breed dogs. This condition is thought to be associated with degenerative joint disease, such as arthritis in the stifle joint after rupture of the cranial cruciate ligament. The diagnosis can be confirmed with histologic evaluation of the synovium.

Drug-induced immune-mediated polyarthritis appears to be rare. It has been reported to occur as a result of trimethoprim-sulfadiazine therapy in a group of Doberman pinschers. Immune-mediated polyarthritis has been suspected in some cases after vaccinations (e.g., vaccinations for lyme disease).

Inflammatory joint disease (septic or immune mediated) should be suspected in the following instances (Figure 23-2):

- The dog or cat with joint pain, joint swelling, generalized pain, or reluctance to rise.
- Joint pain or swelling that is apparent during the physical examination.
- The dog or cat that has abnormalities that could result from a systemic inflammatory condition: fever or leukocytosis.
- When immune-mediated disease is suspected in other organ systems (i.e., immune-mediated hemolytic anemia, thrombocytopenia, steroid responsive sterile meningitis, glomerulonephritis).

Figure 23-2 Algorithm for diagnostic approach to polyarthritis.



84

23.5 ARTHROCENTESIS AND JOINT FLUID ANALYSIS

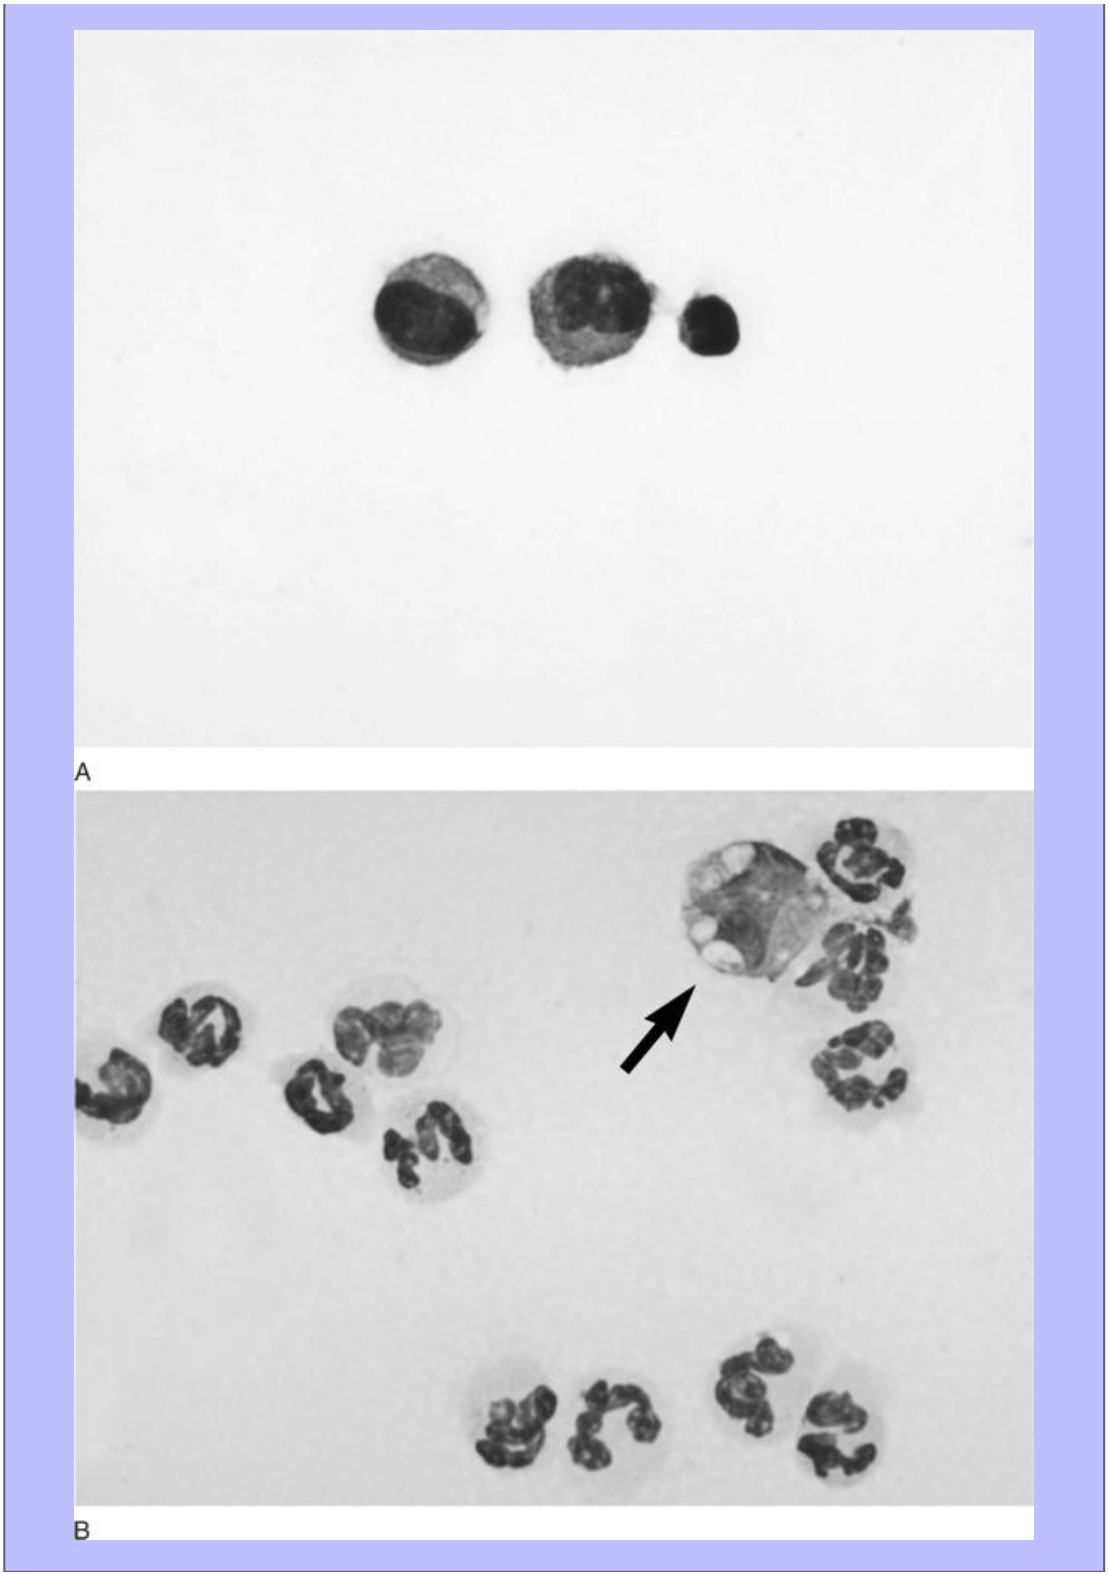
Joint fluid analysis is the single most important test performed in the diagnosis of inflammatory arthritis. Joint taps are usually simple to perform and are associated with minimal morbidity or complications (see Chapter 74). Aspiration of synovial fluid (joint taps) and cytologic analysis are necessary to define the involvement of a joint (Figure 23-3). Affected joints, even severely affected, may not appear swollen or painful. Joint taps should also be performed as part of the diagnostic investigation of a fever or leukocytosis of unknown origin or when other immune-mediated disease is suspected. In a recent study, 20% of dogs with a fever of unknown origin had immune-mediated polyarthritis. Unfortunately, the information clinicians can obtain from joint fluid analysis is limited. Increased numbers of neutrophils appear in joint fluid of both septic and immune-mediated arthritis, making the differentiation between the two difficult, and joint fluid cultures are frequently negative even in the obvious presence of bacteria.

Multiple joints should always be sampled, including those that do not appear to be clinically involved in the disease process. It is recommended that both carpi and both tarsi joints be sampled along with at least one elbow and stifle. Hip and shoulder joints are not commonly tapped unless they appear to be diseased.

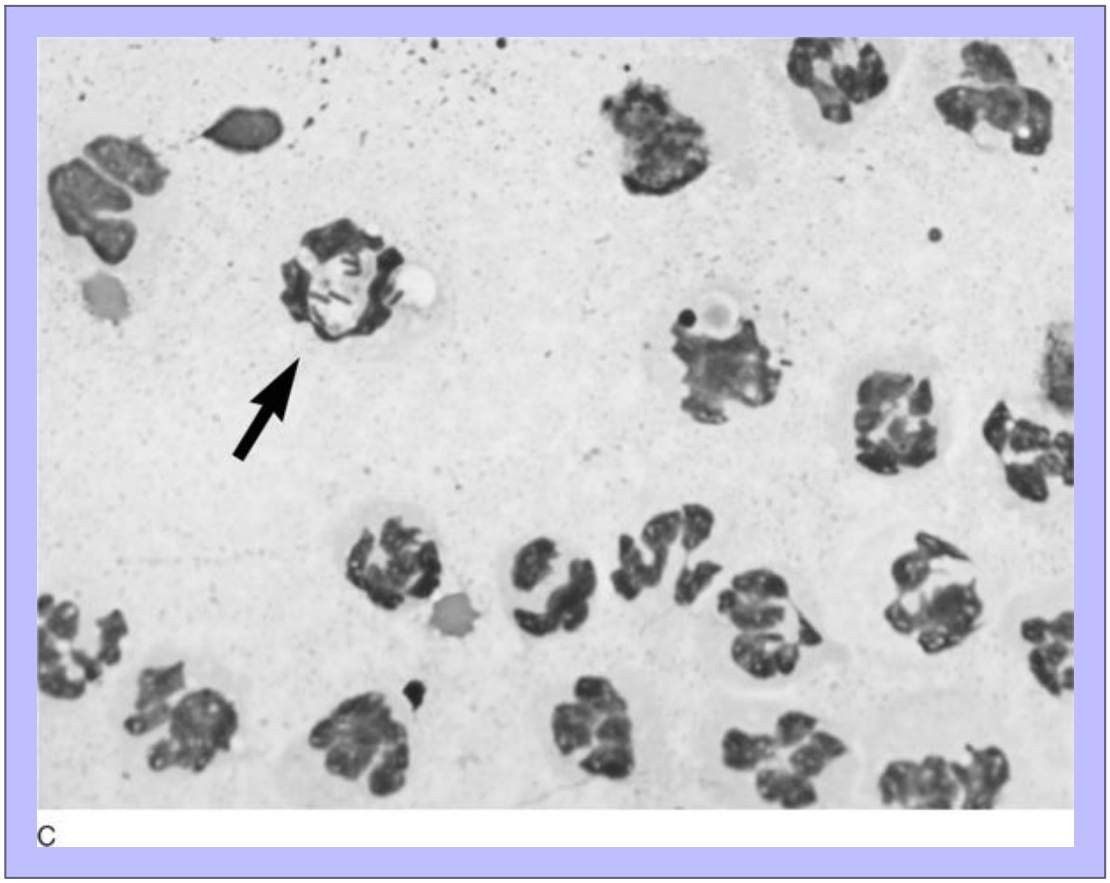
23.6 GROSS EXAMINATION

Fluid from a normal joint is clear, light straw colored and has a sticky viscous feel, forming a strand when a drop is paced between a fingertip and the thumb, which are then slowly pulled apart, or between a glass slide and a fingertip, which is slowly moved away from the slide (Figure 23-1). More than a few drops should not be easily obtained from a normal joint. If the fluid is discolored, turbid, lacks viscosity, or is aspirated in excessive amounts, then joint disease is likely. Blood contamination, only partially mixed in with the joint fluid, may occur.

Figure 23-3 **A,** Normal: Two quiescent mononuclear phagocytes *(larger)* and a small mature lymphocyte are seen in this low-cellularity direct smear of normal canine synovial fluid. These are the predominant cell types in health in all species. **B,** Nonseptic arthritis: Numerous well-preserved neutrophils and a macrophage *(arrow)* are seen in this highly cellular direct smear of synovial fluid from a cat with immune-mediated polyarthritis. Neutrophils typically are less than 10% in health. **C,** Septic arthritis: Numerous neutrophils and a few red blood cells (RBCs) are seen in this highly cellular direct smear of synovial fluid from a dog with septic arthritis. The reader should note cellular debris in the background and several degenerate neutrophils, including one that contains several bacterial rods *(arrow)*. (Courtesy Dr. Tracy W. French, Dip. ACVP, Cornell University.)



A
B



23.7 CYTOLOGIC EVALUATION

Normal joint fluid contains less than 2500 to 3000 white blood cells (WBCs) per milliliter and few red blood cells (RBCs). At least 90% of white cells in normal joints are mononuclear. Inflamed joints (septic or immune mediated) will typically have over 5000 WBCs and over 10% neutrophils. The WBC or neutrophil count can be estimated by multiplying the average number of cells seen in each high-power field by 1000. The presence of bacteria or degenerate changes in the neutrophils is suggestive of septic and not immune-mediated arthritis, as is a positive bacterial culture. WBC counts can be markedly increased with septic or immune-mediated disease processes, approaching 100,000 WBC/ml of joint fluid including over 90% neutrophils.

If sufficient joint fluid is obtained, then additional testing of the fluid is possible, including protein content, glucose concentrations, and a mucin clot test. Clinically these tests are not often performed and are thought to have little additional value if cytology and culture have been performed.

23.8 ADDITIONAL TESTING

A minimum data base, including a complete blood count (CBC), a serum biochemistry profile, and a urinalysis is recommended in any dog or cat with suspected inflammatory arthritis. Radiographs of the joint are indicated if septic or erosive arthritis is suspected. A search for possible sources of bacterial infection should be undertaken if

septic arthritis is suspected and no obvious penetrating wound or source of infection is evident. This search could include blood and urine cultures, thoracic and abdominal radiographs, and spinal radiographs to identify discospondylitis, abdominal ultrasound, and possibly cardiac echocardiogram for bacterial endocarditis.

If immune-mediated polyarthritis is suspected, then a search for the source of chronic immune stimulation and additional manifestations of immune-mediated disease should be undertaken. The chronic immune stimulation could be a primary immune disorder (idiopathic) or a result of chronic infection, inflammation, or neoplasia. Additional diagnostics in this case could include the previously mentioned testing listed for septic arthritis, a Coombs' test, and serology for ANAs and RF. Serology for exposure to rickettsial agents such as *Ehrlichia* species, *Borrelia*, systemic fungal infections, and for occult heartworm infestation may be indicated, depending on the prevalence in the region and a possible travel history. Positive results of any of these tests must be taken as part of the entire clinical picture. Positive Coombs' test, RF, and ANA are all nonspecific findings perhaps strengthening the possibility of more general immune-mediated disease or SLE. Positive titers to the previously mentioned infectious agents are likely indicative of exposure and not necessarily active disease. In the case of Lyme disease, if the pet has been vaccinated, then Western blot analysis can differentiate between antibodies produced as a result of the vaccine and those produced by natural exposure.

24 CHAPTER • 24 Body Odors

Karen A. Moriello

***W**ebster's Dictionary* defines odor as "*That characteristic of a substance which makes it perceptible to the sense of smell whether it be pleasant or unpleasant*." From a clinical perspective, the definition of *odor* would have to be expanded to include whether the odor is *normal* or *abnormal*. Whether clinicians realize it or not, the use of smell is an intricate part of the physical examination process. Depending upon the disease process, it can also be involved in the diagnostic, therapeutic, and monitoring process.

24.1 PEOPLE, PETS, VETERINARIANS, AND THE BODY ODOR ISSUE

Body odor has a biologic purpose. In general, smell and body odor for all species are important in species recognition, social interactions, and mate selection. In the animal phylum, changes in body odor and pheromones are driven by genetics and evolutionary trends. In the human species, one other major driving force exists—changing social trends. For example, body odor in one era may be considered normal or even desirable but in another deemed socially unacceptable. The issue of environmental odors (i.e., room odors) is almost equally important to people. Manipulation of personal and environmental odors (out of the "unpleasant" and into the "neutral or pleasant" spectrum) is an important social trend (and a commercial industry). Further complicating this issue is the increased recognition that body odor may be an early warning sign of health issues (e.g., fruity apple odor of ketoacidosis as the result of diabetes mellitus or starvation) or a human health hazard (e.g., mold). Veterinarians increasingly have to navigate the issue of "the pet's body odor" with clients. This is difficult at times because the current norm is "pleasant odor" or "no odor." The clinician's task is to determine whether the body odor in question is a sign of disease or whether it is within the realm of normal for the pet in question. If the latter is true, then clinicians must find a way to make the pet's odor more acceptable to the owner.

24.2 PATHOPHYSIOLOGY OF BODY ODOR

Body odor in animals varies with species, breed, sex, age, and overall health. In the healthy dog or cat, skin secretions contain insignificant amounts of odorous substances. Skin odor is the result of bacterial decomposition of secretions from sebaceous glands, epidermal lipids, and epitrichial and atrichial sweat glands. Epitrichial glands are present on haired skin just below sebaceous glands and open onto the surface via the piliary canal. These glands are largest and most numerous in mucocutaneous junctions, interdigital spaces, and over the dorsal back and lumbosacral areas. Not surprisingly this is often where odor concentrates in pets. Atrichial glands are located only on footpads. Sweat contains unsaturated fatty acids, ammonia constituents, and their volatile salts. Sebum and epidermal lipids on the skin surface are degraded by lipases of gram-positive bacteria to glycerol and unsaturated fatty acids, which are further metabolized to odorous compounds. It is these by-products that give sebum its antibacterial and antifungal properties. Some of the acids produced by the degradation of these lipids, butyric and caproic acids, are quite volatile and emit a cheesy rancid odor. Oral odor may be associated with systemic illnesses, such as uremia, diabetes mellitus, or periodontal disease. Malodor associated with periodontal disease is due to the production of volatile sulfur components. Oral odors are most often the result of by-products of bacterial metabolism resulting from bacteria colonization of plaque, gingival sulci, and the dorsal surface of the posterior tongue. Oral odors may also be the result of something the pet has ingested (e.g., fecal material).

24.3 CLINICAL APPROACH TO THE PROBLEM OF BODY ODOR

The starting point of any medical visit is the owner's complaint. In general, pets with the problem of body odor fall into one of four broad categories (see the following) as determined by the history and physical examination. In the case of body odor, what the clinician simply sees and smells may accomplish the initial sorting. After this, the clinician can then determine how best to proceed (see Box 24-2). In most cases the veterinarian needs to determine if underlying cause is due to a systemic disease, pure dermatologic disease, external factors, or lack of client education.

"Normal pets" are considered to be malodorous by the client but not by the clinician. In general, the clinician's initial assessment is that the pet's body odor is within the normal range for the *species* (e.g., cat owners first acquiring a dog may not be aware of species differences), *age* (e.g., puppies have a unique odor), *sex* (e.g., intact tom cats are more odorous than neutered male cats), *breed* (e.g., hound dogs' odor versus poodles'), *hair length*, etc. Furthermore, a thorough literal "sniff exam" (nose to tail, dorsum to ventrum, feet, and ears) of the patient reveals no unusual odors. Finally, no evidence of a dermatologic or medical disease exists. The *key sorting aspect* of this group is that the veterinarian considers the animal to smell normal, and no history or physical evidence of illness or skin disease exists. In these situations, client education and suggestions for bathing routines that are tolerable and safe for the pet are indicated.

The clinician should be aware of two subsets in the normal pet group. The first is a subset of normal pets with owners who complain of odors that "come and go." In these situations the cause may be anal sac expression, something the dog ate (e.g., onions, garlic), flatulence, "wet dog" smell, a change in the dog's regular dog food (some specialty diets, especially fish based, cause the dog to "smell fishy"). In warm weather, many dogs will drool excessively, and this will mat the haircoat around the face, chest, and forelegs, leading to an offensive odor. Warm weather often results in increased moisture on the skin, and this can lead to bacterial degradation and odor. In addition, many owners of dogs with allergic skin disease report acute episodes where the skin becomes warm, the dog "literally sweats" and then is very odorous.

88

89

The second subset includes those pets that smell normal to the clinician, but the owner reports that there has been a change in how the dog smells. It is critical to carefully examine these patients for evidence of subtle signs of skin disease because these owners may be reporting a valid finding. A recent study found that 86% of owners that were blindfolded and only allowed to use their sense of smell were consistently able to differentiate their dog's body odor from that of another simply by sniffing a blanket. This finding amazed both owners and investigators. What is pertinent to veterinarians is that owners may very well "know" what their dog smells like when it is normal and when it is not.

24.3.1 Malodorous Pet with an Obvious Cause

These are patients with unmistakable odor from urine, feces, skunk, flatulence, and "I rolled in the compost heap" odors. This group could also include the pets with obvious skin or medical problems, where the source of the odor (infected fracture, ears, seborrheic skin, pyotraumatic dermatitis, and so on) is easily found. Animals with severe halitosis are also included here (Box 24-1). The *key sorting aspect* of this group is that the clinician immediately knows where the odor is coming from, what is causing it, what needs to be done to eliminate it, and whether or not further medical or dermatologic diagnostics are needed. In these situations, client education may be as simple as recommendations on how to remove the odor (e.g., skunk) or more complicated discussions on the need to treat existing infections and perform appropriate diagnostic tests to investigate the underlying cause.

24.3.2 ## Malodorous Pets with Obvious Systemic Illnesses

These are patients that are malodorous, but more importantly are systemically ill. This might be determined by historical or physical examination findings (or both); changes in body odor might have been what prompted the client to finally bring the animal for examination. The *key sorting aspect* of this group is an obvious state of ill health associated with the body odor. In general, cats rarely are presented for the problem of body odor. When they are, it is usually for one of three reasons. First, a strong odor emanates from an ear, mouth, or body region. This should prompt the clinician to look for infections, injuries, neoplasia, myiasis, etc. Second, the cat is soiling itself with urine, feces, or both or not removing it from the haircoat. This could be for any number of reasons, such as physical inability to groom (e.g., obesity, arthritis) or neuromuscular injury. Third, the cat could just be generally odorous to the client. These cats usually have stopped grooming themselves, and their haircoat is matted or greasy. This situation should prompt the clinician to look for a systemic illness (e.g., hyperthyroidism, diabetes mellitus, neoplasia). Dogs with systemic illness may be mildly or severely malodorous. Mild odors are usually caused by concurrent skin infections triggered by debilitation. The skin odor in these patients usually is not noticeable to the clinician until the dog is physically examined. Severely odorous dogs almost always have the odor localized to one area (e.g., mouth odor caused by uremia), a site of injury and infection (open fracture with secondary infection), or excrement on their haircoat because of some cause of immobility. In these situations, client education must focus on a need to aggressively pursue the cause of the illness, whereas the odor issue is addressed as part of the therapy for the health and well-being of the patient (e.g., treatment of urine or fecal soiling).

24.3.2.1 24.3.2.1 Box • 24-1 ***Common Causes of Halitosis in Dogs and Cats***[*]

24.3.2.1.1 ### Oral Diseases

Periodontal disease (gingivitis, periodontitis, abscessation)

Neoplasia (melanoma, fibrosarcoma, squamous cell carcinoma)

Foreign body or trauma (fractures, electrical cord injury)

Pharyngitis

Stomatitis, lymphocytic-plasmacytic feline stomatitis

24.3.2.1.2 ### Respiratory Diseases

Rhinitis and/or sinusitis

Neoplasia

Pneumonia or pulmonary abscess

24.3.2.1.3 ### Dermatologic Diseases

Lip fold pyoderma

Ulcerative mucocutaneous pyoderma

Feline or canine eosinophilic granulomas

Pemphigus complex, bullous pemphigoid, lupus erythematosus

Drug eruptions

Cutaneous lymphoma

Exposure to dimethyl sulfoxide (DMSO)

24.3.2.1.4 Metabolic Diseases

Renal failure/uremia

Diabetic ketoacidosis

24.3.2.1.5 Gastrointestinal Diseases

Megaesophagus

Inflammatory bowel disease

Exocrine pancreatic insufficiency

24.3.2.1.6 Neoplasia

Constipation (cats)

24.3.2.1.7 Dietary

Aromatic foods (onions, garlic)

Fetid foodstuffs (e.g., ingestion of carrion)

Coprophagy

24.3.2.1.8 Grooming Behavior

Anal sacculitis

Vaginitis/balanoposthitis

Lower urinary tract infections

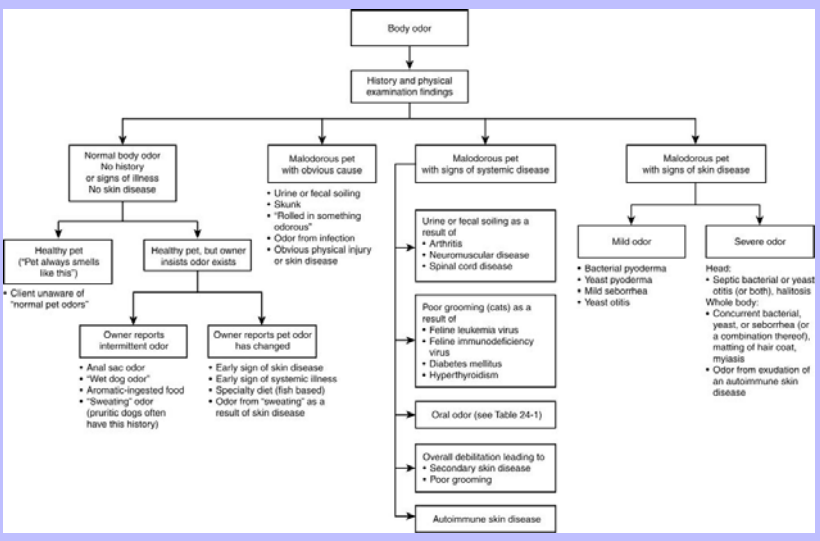
* Adapted from *Veterinary Guide to Odor and Disease, The Oral Cavity and Dermatology*, Veterinary Learning Systems, 1997.

24.3.3 Malodorous Pets with Skin Disease

Without a doubt, most obviously odorous animals will fall into this group. For the vast majority of patients, the *key sorting aspect* of this group is an otherwise healthy pet with a history of skin disease, blatantly obvious skin disease, skin disease found during the examination, or a combination of these factors. When working with these patients, the clinician should remember several key points: 89 91

- The most common causes of body or ear odor is almost always some combination of bacterial pyoderma, *Malassezia* pyoderma, and seborrhea (usually oily).
- Many of these patients are severely pruritic. The pruritus is most likely caused by a combination of the microbial infections, inflammatory degradation products of oily seborrhea, the presence of an underlying pruritic disease (e.g., atopy), or a combination of these factors.
- The duration of the skin problem, presence or absence of underlying primary seborrhea, and severity of the skin infections (superficial or deep) mostly determine the severity of the odor. Other factors such as length of the haircoat, presence or absence of hair mats, and exposure to moisture can also affect the severity of the odor.
- The odor will most likely resolve with appropriate systemic and topical treatment of the superficial microbial infections and seborrhea; it may or may not return. This depends on whether the underlying trigger of microbial infections is still present, whether the patient has a previously undiagnosed primary disorder of keratinization, and whether the pruritus has resolved. If not, the return of the body odor is almost guaranteed because it will trigger secondary microbial infections and seborrhea.
- Recurrent otic or skin odor always means an underlying skin disease is present. Whether or not diagnostics beyond skin scrapings, flea combing, skin and ear cytology, and possibly a fungal culture are indicated in malodorous pets with skin disease depends on the patient's history and physical examination.

Figure 24-1 Algorithm for presenting complaint of body odor.



24.3.3.1

Box • 24-2 General Recommendations for Control of Odor

24.3.3.1.1

Normal Pets without Skin Disease

- Client education for the owner.
- Keep the haircoat short; no feathering haircuts.
- Clip hair from inner pinnae.
- Avoid cloth dog collars that can become impregnated with the pet's body odor.
- Bathe pet in a veterinary hypoallergenic shampoo only as often as to keep odor free.
- Dry pet after exposure to rain or after swimming to avoid wet-dog smell.
- Use veterinary coat deodorizers only.

24.3.3.1.2

Skunk Odor

- Liberal application of “Skunk Off”
- Keep pet dry to prevent reemergence of skunk odor (it may take several weeks for the odor to dissipate completely).

24.3.3.1.3

Urine, Fecal Matter, and Odors Associated with “Rolled in Something Dead”

- Clip any mats from haircoat.
- Bathe pet in grooming or flea shampoo first to remove gross debris, and rinse well.
- Bathe a second time in a degreasing shampoo such as benzoyl peroxide; odors are often held in skin and hair lipids.

24.3.3.1.4

Pets with Odor and Skin Disease

- Complete appropriate diagnostics, and begin appropriate systemic therapy.
- Administer appropriate sedation, analgesia, or anesthesia, if needed.
- Clean or flush ears as needed.
- Grooming recommendations:
  - Clip haircoat from inner ear pinnae and around ears, if necessary.
  - Clip hair mats and areas of lip fold pyoderma.
  - Clip haircoat of medium-or long-haired dogs.

- Bathing recommendations:
  - Always prebathe pet with grooming or flea shampoo to remove gross debris before using a medicated shampoo; rinse well (this step facilitates efficacy of medicated-shampoo product).
- Bathe pet in antimicrobials or antiseborrheic shampoo (it may work best if the client alternates between two shampoos).
- Severely odorous pets should be bathed daily until client deems pet acceptable.
- Most pets require two to three baths per week during medical treatment.
- Warnings:
  - Some shampoos are irritating; do not use if pet seems uncomfortable after use.
  - If haircoat becomes excessively dry, decrease frequency of bathing.
  - Dogs with primary seborrhea will require aggressive bathing for life to control disease and odor.

Note: A subgroup of malodorous pets exists with skin disease and signs of systemic illness (e.g., anorexia, persistent or waxing and waning fevers, depression, reluctance to walk, weight loss, dehydration). This triad (odor, skin disease, illness) should alert the clinician to the possibility that the patient has a severe life-threatening condition such as deep pyoderma with or without demodicosis, drug reactions, immune-mediated diseases, deep fungal infections with cutaneous manifestations, or toxic epidermal necrolysis. An immediate aggressive dermatologic evaluation is needed: skin scrapings, bacterial cultures, impression smears of exudate, and skin biopsy, in addition to appropriate medical diagnostics and supportive care pending diagnosis.

25 CHAPTER • 25 Ocular Manifestations of Systemic Disease

David J. Maggs

Clinicians tend to consider the eye and adnexa as unique structures that are dissimilar to nonocular tissues. This can lead to omission of the ophthalmic examination in patients with systemic disease or omission of the general physical examination in patients presented with ophthalmic disease. In fact, the eye is a complex aggregate of tissues with marked anatomical and functional similarities to tissues found in most other organ systems. Viewed in this manner, the eyes provide a unique opportunity for direct observation of tissue types that are otherwise not visible without invasive techniques or special instrumentation.

The major correlations between ocular and nonocular tissues are summarized in Table 25-1. This table identifies ocular tissues that should be examined carefully in animals with systemic disease and nonocular tissues that should be examined in those with ocular disease. For example, in a dog or cat with generalized lymphadenopathy, the conjunctiva, third eyelid gland, and uveal tract should be closely examined because they are also composed of lymphoid tissue. Likewise, a thorough general physical examination of the pet with retinal disease may reveal more widespread vascular, neurologic, or hematologic disease.

The following is a description of specific ocular conditions, arranged by affected ocular tissue, often associated with systemic disease. This chapter highlights the correlation between ocular and systemic tissues. It does not provide an exhaustive description of the diagnostic approach or therapies.

25.1 SURFACE OCULAR DISEASE

The eyelids, conjunctiva, cornea, and sclera are intimately related, physiologically and anatomically. They provide a protective surface for the eye, and all three tissues are susceptible to the same insults that cause surface (dermatologic) disease elsewhere. Therefore a thorough dermatologic history and a complete dermatologic examination may be helpful in animals with surface ocular disease. The diagnostic approach to lesions involving eyelids, conjunctiva, or cornea is identical to that used for skin. It includes incisional or excisional biopsy, scrapings, and viral, fungal, chlamydial, and mycoplasmal or bacterial culture.

Table • 25-1 Correlations between Ocular and Nonocular Tissues

Tissue Type	Visible Ocular Correlates
Mucous membrane	Conjunctiva
Vascular tissue	Conjunctiva, uvea, retina
Neural tissue	Retina, optic nerve
Lymphoid tissue	Uvea, conjunctiva, third eyelid
Glandular tissue	Meibomian glands, conjunctival goblet cells, third eyelid gland
Connective tissue	Sclera, cornea
Smooth muscle	Iris, upper eyelid third eyelid
Interstitial space	Anterior chamber, subretinal space, vitreous
Hematologic	Conjunctiva, uvea, retina

Ocular surface tissues may also be affected as “innocent bystanders” in more serious orbital disease or intraocular conditions such as uveitis or glaucoma. Retropulsion of the globe and thorough intraocular exam with measurement of intraocular pressure (IOP) will identify such animals.

25.1.1 Eyelids

Although blepharitis may represent more widespread dermatitis, special consideration should be given to unique palpebral anatomy. Meibomian glands are specialized sebaceous glands that can be primarily infected; particularly with *Staphylococcus* and *Demodex* spp. Altered immune responses can exacerbate clinical signs at this site. Immunodeficiency may encourage colonization by organisms such as dermatophytes or *Demodex* spp., whereas an exuberant immunologic response such as hypersensitivity to *Staphylococcus* spp. may cause more severe inflammation. Eyelid margins represent a clearly visible mucocutaneous junction that could be involved in primary immune-mediated dermatitis such as the pemphigoid diseases or systemic lupus erythematosus (SLE). Other immune-mediated diseases such as vasculitis or uveodermatologic syndrome (also known as Vogt-Koyanagi-Harada [VKH] or VKH-like syndrome) may also be more obvious or more severe in periocular skin.

Altered lid position, with or without altered pupil size or globe deviation can also represent central, peripheral, or disseminated neurologic disease, specifically dysfunction of cranial nerve (CN) III or VII or decreased sympathetic tone (Horner's syndrome). Clinical localization of the lesion or lesions is important, particularly for Horner's syndrome—the triad of enophthalmos (with protrusion of the third eyelid), ptosis, and miosis. Because of the circuitous, three-neuron route by which sympathetic neurons course from the hypothalamus to the eye, Horner's syndrome can result from disease involving the brain, spinal cord, brachial plexus, thorax and mediastinum, neck, temporal bone and tympanic bulla, or orbit. Diagnostic procedures should be directed at each specific area to eliminate definitive causes. However, even with intensive diagnostic testing, approximately 50% of cases of Horner's syndrome are idiopathic and usually resolve within 2 months.

25.1.2 Conjunctiva

Conjunctival disease is seen alone, with blepharitis or keratitis, or may reflect inflammation of deeper structures such as the sclera, meibomian glands, orbital contents, third eyelid gland, or intraocular tissues. The rich vascularity of conjunctiva and its almost transparent epithelium also make it an excellent site for detection of hematologic (cyanosis, anemia, icterus) or vascular disease. 92 93

Feline herpesvirus (FHV-1) and *Chlamydophila felis* (formerly *Chlamydia psittaci*) are primary conjunctival pathogens of cats. Although cats undergoing primary FHV-1 exposure generally demonstrate concurrent signs of upper-respiratory infection, cats infected with *C. felis* and those undergoing a recrudescent FHV-1 episode may demonstrate few or mild nonocular clinical signs. Despite an apparent lack of systemic signs, recent evidence confirms that cats harbor and shed *C. felis* from nonocular sites. Studies also suggest that systemic therapy is more effective than topical therapy at decreasing clinical signs and shedding of *C. felis*.

Conjunctivitis in dogs is usually not associated with systemic disease. Ligneous conjunctivitis is an uncommon but important exception. This is a chronic, membranous conjunctivitis in which gross thickening of conjunctiva occurs bilaterally. Younger, female Doberman pinschers may be predisposed. Other mucous membranes may also be involved, and the majority of affected dogs also have evidence of upper-respiratory or urinary tract disease. Histology reveals a characteristic amorphous, eosinophilic hyaline material throughout the subconjunctiva.

25.1.3 Cornea and Sclera

Corneal clarity is important for normal vision. Attentive owners may often note early or subtle corneal pathologic changes. Although altered corneal appearance may represent primary keratitis or intraocular disease (particularly uveitis or glaucoma), corneal opacification that begins at or is most notable at the limbus is often an indicator of systemic disease. For example, lymphosarcoma (LSA) tends to cause a homogenous, creamy-pink discoloration of the peripheral corneal stroma. Corneal lipidosis is an important differential diagnosis in these cases and may occur secondary to any disease causing systemic hyperlipidemia. Hypothyroidism is one of the most common causes; however, hyperadrenocorticism, diabetes mellitus, and familial hypertriglyceridemia should also be considered. Serum triglycerides and cholesterol should both be assessed in animals with corneal lipidosis. Rarely, corneal opacification in dogs or cats will be caused by mucopolysaccharidosis.

Although hyperadrenocorticism and diabetes mellitus are associated with prolonged corneal wound healing, dogs with diabetes mellitus have also recently been shown to have significantly decreased corneal sensitivity relative to normal dogs. This may represent a manifestation of diabetic neuropathy, making dogs less likely to blink and produce reflex tears to protect their corneas. In addition, multiple growth factors are transferred to the cornea by sensory nerves, and these are likely to be reduced in such dogs. This likely contributes to the poor wound healing observed in these pets. Therefore therapy and monitoring of corneal disease, especially ulceration, should be more intense in diabetic dogs.

25.1.4 Keratoconjunctivitis Sicca

Decreased aqueous tear production with subsequent keratoconjunctivitis sicca (KCS) is common in dogs but uncommon in cats. In dogs it is usually caused by idiopathic lymphocytic-plasmacytic dacryoadenitis. Rarely, cats or dogs with KCS have immune-mediated destruction of the salivary glands and associated xerostomia (Sjögren's-like syndrome), sometimes clinically apparent as dysphagia. KCS in association with xeromycteria (dry nose) should prompt investigation of neurogenic KCS caused by damage to afferent or efferent pathways of lacrimal innervation. Lacrimal stimuli are transmitted by CN V, and efferent (parasympathetic) fibers are carried first by CN VII and peripherally by CN V. Because these same neural pathways are involved in the production of moisture for the nasal mucosa, ipsilateral xeromycteria evidenced by a dry crusty nostril may be seen. Diagnostic efforts should be directed at disease processes along the paths of CN V and VII, particularly in the region of the tympanic bullae.

KCS may also occur as a result of drug therapy. Drugs incriminated in decreased tear production include systemically or topically administered atropine, systemically administered sulfa drugs, etodolac, and general anesthesia within the preceding 2 days. Dogs with marginal tear production before administration of these drugs, and those weighing less than 12 kg (in the case of trimethoprim sulfa), appear to be at increased risk of developing KCS. Dose and duration of therapy are less relevant. Restoration of tear production and corneoconjunctival health does not always occur upon discontinuation of the offending drug; therefore Schirmer tear test (STT) results should be monitored before and during therapy.

Finally, KCS may occur as a component of systemic disease but may be overlooked unless a STT test is performed. Systemic infection with canine distemper virus (CDV) or FHV-1 is associated with usually transient KCS. Dysautonomia (Key-Gaskell syndrome) can cause bilateral reduced aqueous tear secretion, nonresponsive dilated pupils, and protrusion of the third eyelids. Associated systemic signs of autonomic dysfunction including urinary and fecal incontinence, bradycardia, hypotension, dysphagia, and dry nose are usually more noticeable

than the ocular signs; however, ocular signs may help to confirm the diagnosis. Association between hypothyroidism and KCS has not been substantiated by recent studies.

25.2 UVEAL TRACT

Uveal pathology is commonly seen with systemic disease. The uveal tract includes the iris, ciliary body and choroid and is the major vascular supply for the avascular components of the eye (cornea, lens, outer retina). It is composed of a large network of arterioles, venules, and fine capillaries and therefore is a sensitive indicator of vascular or hematologic conditions, such as vasculitis, hypertension, anemia, and hyperviscosity (see Fundus). Loss of vascular integrity may be apparent in the anterior chamber as breakdown of the blood-aqueous barrier. This appears differently, based on the extent of breakdown and the presence or absence of inflammatory mediators within the anterior chamber and surrounding tissues. With minimal breakdown, albumin and other small serum proteins are detectable in the anterior chamber as aqueous flare. The aqueous humor may be thought of as a directly visible area of interstitial space, and if serum contents are seen within this space, the possibility of similar plasma “leakage” in other less visible nonocular interstices should also be considered.

Detection of aqueous flare requires that a beam of light emanating from a bright and focal source be viewed transversely, preferably with some magnification, as it traverses the anterior chamber. This examination should be done with dim ambient light. A slit lamp biomicroscope provides the optimum combination of these conditions; however, a direct ophthalmoscope turned to the smallest spot of light and held within 1 cm of the corneal surface provides a focal light source and can be used in general practice to detect flare. By definition, albumin, and therefore aqueous flare, will be approximately evenly distributed throughout the anterior chamber. Cellular debris (hyphema, dispersed white blood cells [WBCs], or hypopyon) or larger proteins, particularly fibrin in the anterior chamber suggests more major vascular compromise or potent, cytokine-mediated extravasation of cells. These blood constituents are more likely to settle into the ventral anterior chamber. Depressing the pet's nose so that the eyes are elevated within the orbits will often assist in seeing this region.

93

94

Fine uveal capillary beds can act as a biologic “filter” that traps organisms, particularly fungi, or metastatic neoplastic cells. It is frequently involved in systemic infectious disease or as a site of metastatic neoplasia. The uvea also contains the major intraocular lymphoid tissue and is therefore a common site for LSA. It is also frequently involved in specific or nonspecific ocular inflammatory responses (uveitis) that may reflect broader immunopathology such as infectious or neoplastic disease. The list of organisms that have been associated with uveitis is expanding and is somewhat species specific. In cats, feline infectious peritonitis (FIP), feline immunodeficiency virus (FIV) (principally a retinochoroiditis), feline leukemia virus (FeLV) (principally via LSA), *Toxoplasma gondii,* Mycobacteria, and the systemic mycoses (principally a chorioretinitis) have traditionally been associated with uveitis. More recently, intraocular detection of other organisms such as FHV-1, *Bartonella* spp., and some *Ehrlichia* spp. has led to suggestions that these organisms also warrant consideration as causative agents in feline uveitis. Despite this expanding list of differential diagnoses and thorough diagnostic testing (sometimes including enucleation and histopathology), a definitive cause of uveitis is not identified in 50% to 70% of affected cats.

The list of infectious organisms causing uveitis in dogs includes fungal organisms, *Leishmania donovani*, *Ehrlichia platys* or *canis*, *Rickettsia rickettsii*, *Brucella canis*, *Toxoplasma gondii*, Canine adenovirus, and *Leptospira* spp. In addition, dogs appear to be more susceptible to immune-mediated uveitis than cats. One example is lens-induced uveitis, in which lens proteins leak from a cataractous or ruptured lens and overwhelm normal immune tolerance of these proteins. Another example is uveodermatologic (VKH-like) syndrome in which the immunopathology is directed at melanocytes throughout the body. Because of the preponderance and visibility of melanin-containing cells in the uveal tract and skin, clinical manifestations of disease in these two tissues are most dramatic.

It is incorrect to suggest that the clinical appearance of uveitis can be used to determine a definitive cause. However, noting whether the uveal inflammation appears more cellular or granulomatous, blood tinged, or proteinaceous may help prioritize diagnostic efforts (Figure 25-1).

Finally, the iris (anterior uvea) forms the pupil and therefore often provides clinical evidence of neurologic disease. Pupillary abnormalities suggestive of systemic disease include feline "spastic pupil syndrome" in which intermittent periods of anisocoria are seen without obvious iridal or afferent neurologic defects. Most cats are FeLV positive or become so soon after diagnosis but may not have other systemic signs of infection when pupil abnormalities are noted. A virally induced neuropathy of CN III is suspected. Pupilomotor abnormalities with normal vision and without ocular inflammation are also seen with dysautonomia (mydriasis) and Horner's syndrome (miosis).

25.3 LENS

The two most common conditions affecting the lens are cataract and lens dislocation (subluxation or luxation). Lens dislocation usually occurs secondary to severe intraocular disease, particularly uveitis, which may be a sign of systemic disease. Although lens dislocation may also occur as a primary event in predisposed dog breeds such as terriers, these pets do not have evidence of the generalized connective tissue disorders seen in some humans.

Although the majority of canine cataracts are hereditary in origin, almost all dogs with diabetes mellitus will develop cataracts within 12 months of diagnosis. By contrast, the most common cause of feline cataracts is uveitis. Cats with diabetes rarely develop cataracts. Other systemic causes of cataracts include altered nutrition (especially orphan animals raised on milk replacement products), hypocalcemia with or without hyperphosphatemia (as seen with hypoparathyroidism), electric shock, lightning strike, and senility.

25.4 FUNDUS

The ocular fundus is not a single structure. Rather, it is a collective term describing all structures in the posterior portion of the globe that can be viewed with the ophthalmoscope. Visible structures will vary but may include retinal pigment epithelium (if pigmented), neurosensory retina, optic nerve head, retinal vasculature, sclera, tapetum, or choroid. The fundic examination therefore provides a unique opportunity to directly visualize a large cranial nerve (optic nerve), sensitive neural tissue (retina), large venules and arterioles (retinal vessels), and a massive capillary bed (choroid). For this reason, a fundic examination should be performed in all animals with systemic disease.

The choroid is perhaps the fundic tissue most commonly affected in animals with systemic disease. Because of its position immediately subjacent to the retina and its critical role in retinal nutrition and function, signs of choroidal disease are frequently first noted once they affect the retina. The classic example is retinal detachment, which may be caused by primary retinal disease but frequently reflects choroidal effusion. As a result of these close anatomic and physiological relationships, the terms *chorioretinitis* and *retinochoroiditis* are used to reflect inflammation of these two tissues. The difference between these two terms is subtle, with the intent that the first-mentioned tissue is the one believed to be primarily involved. For example, the systemic mycoses have a predilection for the choroid and so cause a marked chorioetinitis. By contrast, CDV targets neurologic tissue in general and, within the eye, retinal tissue specifically. Insults to the subjacent choroid usually also occur, and the disease is typically referred to as a *retinochoroiditis*.

25.4.1 Optic Nerve and Retina

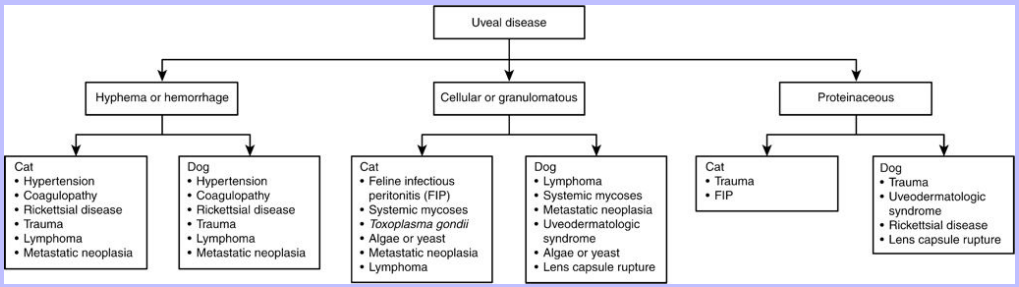
Although primary dysfunction of the optic nerve or retina occurs, altered appearance of these tissues often represents disease of the adjacent central nervous system (CNS) or subjacent choroid (see Uveal Tract). Optic neuritis and retinitis may therefore reflect more widespread meningoencephalitis or uveitis. Causes include infectious agents (CDV, systemic mycoses, or *Toxoplasma gondii*), immune-mediated diseases such as granulomatous meningoencephalitis, or neoplasia involving the CNS, meninges, orbit, or choroid. Diagnosis frequently involves cerebrospinal fluid (CSF) analysis and advanced imaging. Optic nerve edema without hemorrhage, exudates, or blindness is termed *papilledema* and is seen in association with increased intracranial pressure. Therefore fundic examination is recommended in all animals suspected of having CNS disease, especially when a CSF tap is planned.

Taurine deficiency in cats has been associated with retinal degeneration that begins as a focal rhomboid area of subtle increased granularity of the area centralis, progresses to involve retina on both sides of the optic papilla, and ultimately affects the whole retina. Affected cats should also be screened for dilated cardiomyopathy. This syndrome is sometimes called *feline central retinal degeneration* (FCRD) because abnormal dietary or tissue taurine concentration is not always established.

Sudden acquired retinal degeneration (SARD) describes a rapid onset of complete blindness in middle-aged to older dogs with initially normal fundic examination findings. Generalized retinal degeneration becomes clinically evident within 4 to 6 weeks of blindness. Complete and irreversible loss of photoreceptor function takes place without any clinically or histologically detectable inflammation. Female dogs appear overrepresented and many are moderately overweight. Many have a history suggestive of hyperadrenocorticism and some may have clinical signs, blood work, or both that support the diagnosis. The cause of the apparent hyperadrenocorticism is unknown, but unlike the vision loss, systemic signs typically resolve without treatment. This disease must be differentiated from blindness as the result of optic nerve or CNS disease (particularly a functional pituitary tumor with blindness secondary to pressure effects at the optic chiasm). This can be accomplished with advanced imaging under general anesthesia; however, it is completed more simply, safely, and inexpensively by demonstrating an extinguished electroretinogram in the dog with SARD. Sight is never regained; however, owners should be reassured that this is a nonpainful disease that does not involve other ocular tissues.

94
96

Figure 25-1 The nature of the exudates in patients with uveitis can be used to prioritize differential diagnoses.



25.4.2 Vascular and Hematologic Disease

Direct visualization of retinal (and sometimes choroidal) blood vessels permits assessment of many hematologic abnormalities, including anemia (where obvious attenuation or paleness of vessels exists), hyperlipidemia (where retinal vessels take on a creamy orange hue), and hyperviscosity (where increased vessel tortuosity sometimes is noted). Anemia, hyperviscosity, and systemic hypertension also alter tissue perfusion and vessel wall viability and can be associated with segmental vascular constriction and sacculations of retinal vessels (so-called "box-carring"), "sludging," and extravasation of blood or plasma into the choroid, retina, and subretinal space. This is clinically apparent as intraretinal or subretinal edema or hemorrhage or as retinal detachment. Some hypertensive cats also have iridal aneurysms and hyphema. A recent retrospective study of hypertensive cats established that concurrent chronic renal failure, hyperthyroidism, diabetes mellitus, hyperaldosteronism, and cardiac or neurologic abnormalities were common; however, the majority of cats with systemic hypertension are brought to veterinarians after owners observe apparent vision loss.

26 CHAPTER • 26 Acute Vision Loss in Small Animals

Teresa R. Tucci-Prošek

Vision loss is seldom truly acute; more commonly it is a sudden recognition of blindness in a pet by the owner. Multiple lesions in the visual system and central nervous system (CNS) can result in bilateral blindness. Acute vision loss is more apparent to the owner compared with progressive vision loss. Gradual vision loss enables the dog or cat to acclimate and memorize its surroundings. Many times the owner may not realize their pet is blind until an abrupt change takes place in the pet's environment, such as rearranging the furniture or moving the pet to another location. The goal of this chapter is to provide the proper guidelines for a comprehensive ophthalmologic examination, which enables the veterinarian to accurately assess acute vision loss in a dog or cat. (Please see Figure 26-1 in the e-dition.)

26.1 ABNORMALITIES RESULTING IN BLINDNESS

Blindness is a bilateral functional complete loss of vision to which attributing causes are numerous. Three categories are listed in the initial approach to locate a lesion that has caused blindness:

1. Lesions interfering with formation of an image onto the retina
2. Lesions preventing transmission of an image (peripheral → central)
3. Lesions inhibiting image interpretation (central)

Lesions limiting the formation of the image onto the retina are caused by the absence of a normally clear ocular media (cornea, aqueous humor, lens, and vitreous humor). Disruption of this media results in varying degrees of blindness (Boxes 26-1 and 26-2). Lesions affecting the retina and its ability to transmit images to the brain or visual pathway (optic nerve, optic chiasm, optic tract, lateral geniculate nuclei [LGN] and optic radiations) are listed (Box 26-3). Central blindness, also known as *cortical blindness*, results when interpretation of an image is absent (Box 26-4).

26.1.1 Box • 26-1 Ocular Media Abnormalities Causing Blindness

26.1.1.1 Cornea

- Edema (glaucoma, endothelial dystrophy, immune-mediated keratitis such as keratouveitis caused by cainine adenovirus-1, neurotropic keratitis, trauma, persistent papillary membranes)
- Cellular infiltrate (bacterial, fungal, viral)
- Vascular invasion (exposure keratitis)
- Fibrosis (scar formation)
- Dystrophies (lipid, genetic)

26.1.1.2 Aqueous Humor

- Fivrin (anterior uveitis—numerous causes)

- Hyphema (trauma, neoplasia, blood-clotting deficiencies)

26.1.1.3 Lens

- Cataracts (genetic, nutritional, metabolic/diabetic, toxic, traumatic)

26.1.1.4 Vitreal Humor

- Hemorrhage (trauma, systemic hypertension, retinal detachment, neoplasia, clotting deficiency)
- Hyalitis (numerous infectious diseases such as feline infectious peritonitis [FIP], penetrating injury causing cellular infiltrate)

26.1.2 Box • 26-2 Retinal Lesions Causing Blindness

26.1.2.1 Retinopathies

- Glaucoma
- Sudden acquired retinal degeneration syndrome (SARD)
- Progressive retinal atrophy (rod-cone dysplasia, rod dysplasia, progressive rod-cone degeneration)
- Central progressive retinal atrophy
- Feline central retinal degeneration
- Toxicity (fluoroquinolone administration in cats)

26.1.2.2 Retinal Detachment Syndromes

- Exudative/transudative retinal detachment (systemic hypertension, mycoses, viral, bacterial, rickettsial)
- Neoplasia
- Retinal dysplasia
- Hereditary/congenital (collie eye anomaly)

26.2 VISUAL ASSESSMENT

Obtaining a complete and proper history is an essential component of completing an ophthalmologic examination. Discerning information, such as previous developmental, hereditary, traumatic, or systemic disease problems, should assist in accurate diagnosis of the dog or cat's acute blindness. In addition, a history of prior neurologic disturbances or drug usage will many times confuse lesion localization of visual deficits. A unique feature of the eye is that its structures can be directly observed and interpreted without clinical pathology or invasive tests. Orderly sequence of examination is essential for a thorough, detailed analysis of the ocular structures and is

typically performed by examining the superficial structures and then proceeding to deeper structures. Characterization of blindness will assist in lesion localization. For example, day blindness with good night vision (hemeralopia) could be an indication of the pet having cataracts. In dim light the pupil dilates, allowing sight around the cataract. Good day vision with poor night vision (nyctalopia) may be an indication of progressive retinal atrophy (PRA). Blindness with no cause (amaurosis) or mechanical blindness (exophthalmia, facial nerve paralysis, elevated third eyelid [Horner's syndrome]) will give the examiner an area of focus when deciphering the clinical findings.

26.2.1 Box • 26-3 Abnormalities Resulting in Failure to Transmit the Visual Message

26.2.1.1 Viral Diseases

- Canine distemper
- Feline infectious peritonitis (FIP)

26.2.1.2 Systemic and Ocular Mycoses

- Blastomycosis, cryptococcosis, histoplasmosis, and coccidiodmycosis
- Neoplasia
- Tramautic avulsion of optic nerves
- Granulomatous meningoencephalitis (GME)
- Hydrocephalus
- Optic nerve hypoplaysia
- Immune-mediated optic neuritis

26.2.2 Box • 26-4 Abnormalities Resulting in Failure to Interpret the Visual Message

- Viral (canine distemper virus and feline infectious peritonitis [FIP])
- Canine distemper virus and FIP
- Granulomatous meningoencephalitis (GME)
- Systemic mycoses
- Trauma
- Heatstroke
- Hypoxia
- Hydrocephalus

- Hepatoencephalopathy
- Neoplasia
- Storage diseases
- Postictal
- Meningitis

26.2.3 Motion Detection

Evaluation of motion detection in animals is done by tossing an object (cotton balls) across the animal's field of view and monitoring the response, such as a head or eye movement following the object. The presence of tactile hairs, especially in cats, makes it important not to touch or create air currents or sound if stimulation of these hairs would create a similar response.

26.2.4 Obstacle Course

Creating an obstacle course in an exam room will allow the examiner to determine if the dog or cat is able to navigate an unknown environment. Any large solid object can be used (chairs, wastebasket, or cones). It is important to perform this test in both bright and dim light and to perform several trials. Neurologic deficits or animals who are unwilling to walk are not good candidates for this test. The animal should be able to walk through the course and avoid walking into the obstacles. If the dog or cat is unable to visualize objects and hesitates or bumps into them, that animal is likely blind.

26.2.5 Menace Response

Before testing the menace response, a palpebral reflex should be elicited to assess if the dog or cat is capable of blinking (intact facial nerve CN VII and eyelid function). Severe buphthalmia, exophthalmia, or blepharospasm will prevent blinking and obtund the menace testing. A menace response is elicited by waving a hand or an object toward the animal's head and eyes. The normal response is an avoidance motion, such as moving the head away from the object or blinking the eyes. The response is “learned” and therefore not typically present in dogs or cats less than 12 weeks of age. An intact menace response requires an intact visual cortex, whereas a dazzle reflex and corneal reflex are strictly subcortical responses. Dazzle reflex is mediated by reflex centers in the rostral colliculi and can evaluate optic nerve function while not stimulating the trigeminal nerve.

97
98

26.2.6 Visual Placing and Postural Reactions

This test is performed by holding the animal cradled in a horizontal position with its front legs free to move and then moving toward the edge of a tabletop. A visual animal will respond by lifting the legs before touching the table. A blind animal will move the legs after they touch the table. Stairs can be used to perform this test on dogs too large to hold.

26.2.7 Pupillary Light Reflex

Pupillary light reflex (PLR) is not a test of vision but rather a starting point in lesion localization. No special equipment is needed for this test. Using a focal light source in a dimly lit room, the examiner can adequately assess the PLR in a dog or cat. Brachycephalic patients such as Boston terriers and pugs can sometimes be more difficult to examine because of their lateral globe position. A nervous animal may require a few minutes for the sympathetic nervous system (SNS) response to lessen. Stimulation of the SNS causes mydriasis, giving the examiner the illusion of absent or diminished PLR. Before testing the PLR, the examiner should ensure that the pupils are equal size in both dim and ambient light. Unequal pupil size (anisocoria) is usually pathologic in small animals.

The PLR pathway requires normal optic nerve function, optic chiasm, optic tracts, pretectal and accessory oculomotor nuclei (Edinger-Westphal), oculomotor nerves (parasympathetic portion), and functional iridal muscles (iridal sphincter mm). The retinas are also required for the PLR pathway, although there can be marked retinal pathology and a PLR may still be present. Iris atrophy, synechia, and opacification of the cornea or anterior chamber are additional complications that can diminish the PLR or prevent observation of the pupil. In this situation the lesion may or may not be localized in the globe.

26.3 SPECIAL DIAGNOSTIC TESTS

Electroretinography (ERG) is a highly sensitive test interpreted by specialists to evaluate the function of the photoreceptors (rods and cones) using light stimulation. The ERG is beneficial in dogs and cats with acute vision loss when ophthalmoscopic examination proves normal because of its ability to differentiate between photoreceptor disease verses optic nerve or CNS lesions.

Ocular ultrasonography is a useful tool in diagnosis of intraocular or retrobulbar lesions when opacification of the ocular media such as corneal edema, cataracts, or severe enophthalmos is present.

Computed tomography (CT) and magnetic resonance imaging (MRI) scans are excellent diagnostic imaging tools used to localize lesions in animals with acute vision loss. When other tests are unremarkable, they suggest a retrobulbar, optic nerve, or central lesion.

27 CHAPTER • 27 Urogenital: Vaginal-Vulvar and Preputial Discharge

Claudia J. Baldwin

27.1 VAGINAL-VULVAR DISCHARGE

When veterinarians examine a female animal with genital discharge, it is usually a vulvar discharge, composed of fluid, cells, and/or tissue, that originates from the uterus, vagina, urinary tract, vestibule, or vulva. Such discharges may occur in both intact and neutered females. Other sources or causes that need to be considered, because their manifestations may present as a vaginal-vulvar discharge, are sex hormone-producing ovarian disorders (neoplasia or remnant), generalized mucosal disease, exudative perivulvar dermatitis, and bleeding diathesis arising from disorders of blood coagulation.

Normal physiologic vaginal-vulvar discharges, which originate from the uterus, are expected in the intact bitch and queen during the reproductive cycle. During proestrus, the bitch produces a serosanguineous discharge of varying volume. During estrus, the discharge becomes less bloody and usually is straw colored. During early diestrus, the discharge is scant and, if present, is mucoid to dark red. The queen does not normally exhibit appreciable discharge. During late gestation, both the queen and the bitch may display a mucoid discharge. At parturition, both produce a clear to green-black discharge that signifies amniotic fluid and separation of placentas, respectively. Normal lochia is red/green/brown; it diminishes to undetectable levels by 3 weeks post gestation in the bitch but may not be appreciable in the queen. The etiology of a *pathologic vaginal-vulvar discharge* (Table 27-1) can be considered using the DAMNITT diagnostic method. This broad scheme allows the clinician to consider the origin and potential causes of discharge in both intact and ovariohysterectomized (OHE) females. (*D* stands for degenerative or developmental, *A* stands for allergic or autoimmune, *M* for metabolic, *N* for neoplastic or nutritional, *I* for iatrogenic, idiopathic, or inflammatory [infectious or immune related], *T* for toxic or traumatic.)

Table • 27-1 Source and Etiology of Pathologic Vaginal-Vulvar Discharges

	SOURCE		ETIOLOGY	
ORGAN OR DISORDER	**DEVELOPMENTAL/DEGENERATIVE ORIGIN**	**NEOPLASTIC**	**INFLAMMATORY/INFECTIOUS OR IATROGENIC**	**TRAUMATIC/TOXIC**
Uterus/stump	Healing failure post-OHE, SIPS	Various	CEH/pyometra, metritis,	Parturient
Vagina	Vaginal bands/septa	Various	Primary and secondary	Breeding, postpartum, FB
Urinary tract	Ectopic ureter, sphincter laxity Vaginal abnormality	TCC	Cystitis/urethritis Iatrogenic	Calculi
Vestibule	Vulvovestibular stricture	Various	Primary or secondary	Breeding, postpartum, FB
Vulva	Ventral displacement/agenesis Infantile/intersex	Various	Clitoral enlargement	FB
Generalized mucosal disease			Immune mediated Infectious	Irritant
Ovarian disorders	Cystic disease/remnant	E2-secreting tumor	Ovarian remnant	
Perivulvar dermatitis			Pyoderma	Irritant
Bleeding diathesis	Inherited deficiency		Iatrogenic platelet dysfunction	Vit K antagonism

OHE, Ovariohysterectomy; *CEH,* cystic endometrial hyperplasia; *SIPS,* subinvolution of placental sites (etiology is nondegeneration of trophoblastic cells); *FB,* foreign body; *TCC,* transitional cell carcinoma; *E2,* estradiol; *Vit,* vitamin.

27.1.1 History

The history is important in determining the age, breed, and reproductive status of the female. Information on the date of the OHE or the last estrus, pregnancy, or parturition may assist the clinician in choosing diagnostics. When there is a question as to whether an OHE has been performed, the clinician should inspect the skin for a surgical incision line.

The history may include a continuous or intermittent discharge, licking, and scooting. Developmental or inherited conditions likely would manifest in a younger female, whereas neoplastic disease would be more common in an older female. Clinical signs of systemic illness (e.g., fever, anorexia) would be expected with inflammatory, infectious, disseminated neoplastic, traumatic, or toxic disorders. A drug administration history is important.

27.1.2 Physical Examination

A complete physical examination should be performed, including abdominal palpation to detect organomegaly (uterine or bladder) or discomfort. Inspection of the vulva and perineal region may reveal edema, often associated with estradiol influence, inflammation, or trauma; primary or secondary dermatitis; or anatomic abnormalities (e.g., enlarged clitoris, infantile vulva, or ventral vulvar displacement). A rectal examination in bitches allows palpation of the cranial vestibule, the urethra, and a variable portion of the vagina.

27.1.3 Cytology

Further reproductive evaluation should include collection of discharge from the vestibule with a cotton swab (or in a container if copious). Cytologic evaluation is important to characterize the discharge further. Typically, large amounts of *clear* discharge are relatively acellular and most often of urinary bladder origin. Analysis of fluid to determine compatibility with urine (chemical and microscopic) is indicated, as is comparison of results with those from a voided sample or one obtained by cystocentesis. A *mucoid* discharge displays few cells cytologically, usually healthy appearing neutrophils. With *mucopurulent to purulent* discharges, neutrophil numbers have increased and an increasing number of cells have degenerated. *Serosanguineous to sanguinous* discharges contain red blood cells with either healthy appearing neutrophils or degenerate neutrophils, indicating inflammation. Discharges that are *greenish-black or a mixture of red, green, and brown* derive this coloration from red blood cell breakdown pigment and tissue particles when associated with abortion.

27.1.4 Vaginal-Vulvar Examination

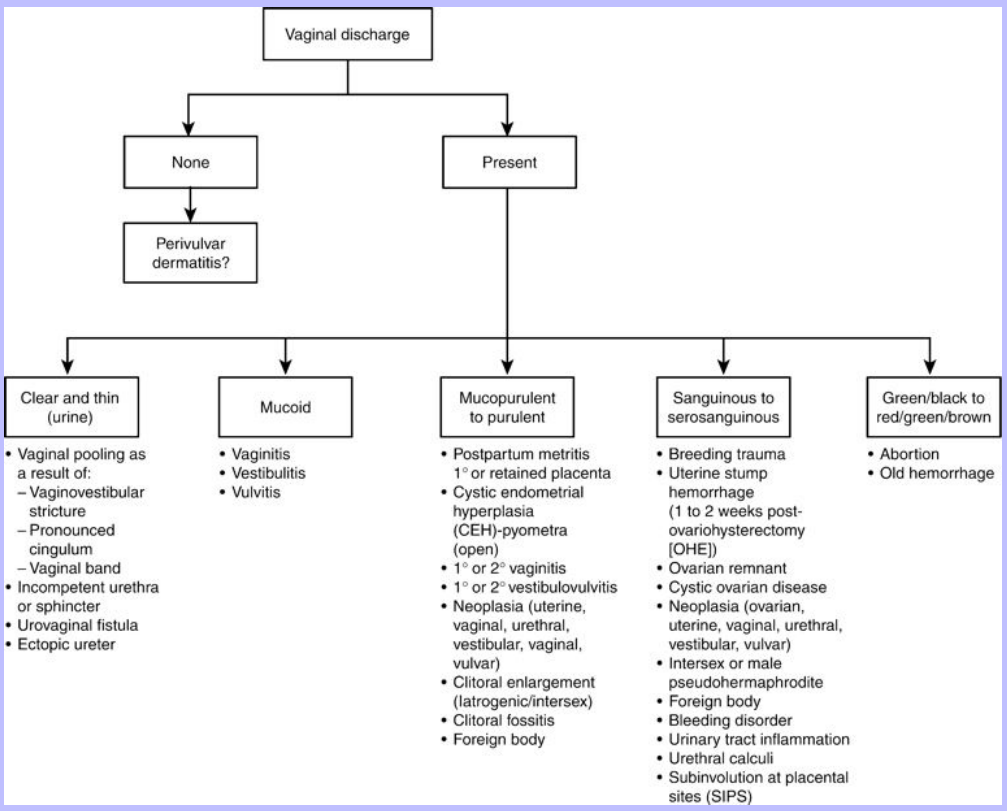
Once fluid has been collected, a *digital vaginal examination* is indicated. Examination may not be possible without sedation in a juvenile small breed dog or in a cat or if pain or discomfort is present. The digital examination should be performed before vaginoscopy, because structural abnormalities can easily be "passed by" if the clinician is relying only on what is seen.

Digital examination allows evaluation of the vulva, vestibule, urethral papilla, vaginovestibular region, and possibly the vagina. Normal anestrous or OHE females have narrowing at the vulvovestibular junction and also at the vaginovestibular junction (the *cingulum*). Abnormal findings such as circumferential strictures or vaginal septa or bands (commonly at the cingulum) or narrowing of the lumen and altered mucosal texture should be noted, as should straining or discomfort. Digital examination may elucidate the cause of the discharge.

Vaginoscopy can be performed in many dogs without sedation. A rigid pediatric proctoscope can be used in medium to large dogs. Other instruments (e.g., a rigid endoscope) allow visualization in cats and smaller dogs. Insufflation and adequate lighting are essential. Shorter instruments with a light source can be used to examine the vestibule, clitoris, and fossa.

99
100

Figure 27-1 Algorithm for assessment of pathologic vaginal-vulvar discharge based on character of discharge and digital examination.



With the information gained from these examinations, the clinician may approach the problem with more clarity (Figure 27-1). (See Artificial Insemination and Vaginoscopy and Vaginal Disorders for further detail on these procedures.)

Other diagnostic testing may be indicated. If the dog or cat has signs of systemic illness, a *complete blood count (CBC), serum biochemistry,* and *urinalysis* should be performed. If the abdomen is painful, the uterus enlarged, and/or the discharge is characterized as purulent, a pyometra should be considered and cystocentesis should be avoided to prevent contamination of the abdomen. *Bacterial culture* of the discharge (collected with a guarded or sheathed culturette to avoid contamination) is indicated for a systemically ill animal or if an infectious process is suspected. Susceptibility testing of the cultured organisms is indicated to determine the appropriate therapy. *Imaging of the abdomen and urogenital system* by means of plain and contrast radiology (i.e., vaginogram, vagino-urethrogram), as well as ultrasound, may be indicated.

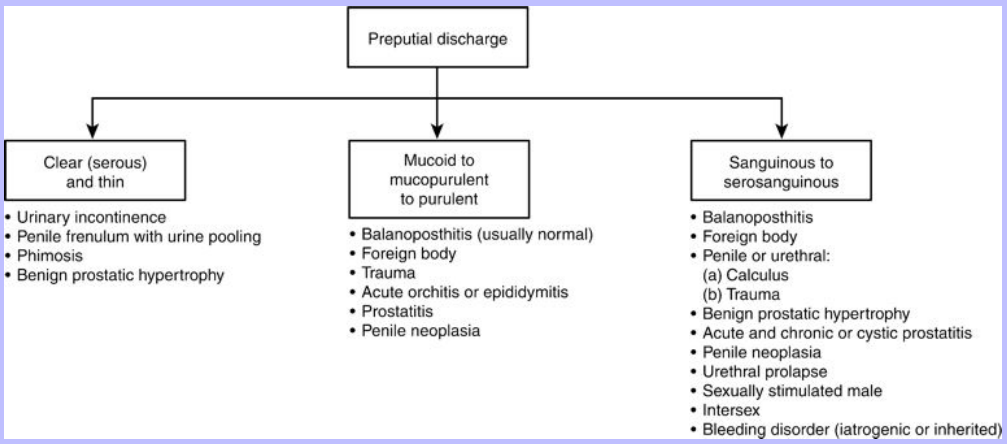
Assessment of *reproductive hormonal status* is important when evaluating both intact and OHE females. Increased estradiol concentrations and vaginal cytology suggestive of estradiol influence (keratinization of vaginal cells) is consistent with normal proestrus or estrus, follicular cysts, ovarian secreting neoplasia, or ovarian remnant, although estradiol concentrations may fluctuate. *Stimulation tests* using human chorionic gonadotropin or gonadotropin-releasing hormone, which induce ovulation with resultant increases in the progesterone concentration, may be diagnostic for follicular cysts or ovarian remnant (see the section on Ovarian and Estrous Cycle Abnormalities). Measurement of serum progesterone for evidence of the luteal phase of the reproductive cycle may also be helpful with suspected cystic endometrial hyperplasia (CEH)/pyometra in both intact and OHE females, because the majority of females with this disorder have an elevated progesterone concentration or have received exogenous progestational therapy (see the section on Cystic Endometrial Hyperplasia and Pyometra).

Histology of masses found in the reproductive tract can further characterize them and allow prognostication. *Coagulation system testing* should be considered in a female with a serosanguineous to sanguinous discharge. Mucosal hemorrhage is characteristic of a primary system (platelet and vascular) defect but may also be associated with a coagulation factor abnormality. Iatrogenic, inherited, and acquired disorders should be considered.

100

101

Figure 27-2 Algorithm for assessment of pathologic preputial discharge based on character of discharge and examination.



At times no cause may be apparent for a vaginal-vulvar discharge. Common causes of chronic vaginitis include morphologic abnormalities of the reproductive or urinary tract, resulting in urinary incontinence or pooling. Juvenile vaginitis, seen in the prepubertal bitch, is almost always self-limiting. Vaginitis in the queen is unusual. (See Vaginal Disorders.)

27.2 PREPUTIAL DISCHARGE

Preputial discharges are composed of fluid and cells that originate from the urinary bladder, prostate gland, testes and epididymis, urethra, and mucosa of the penis and penile sheath. Discharges may be present in both intact and neutered males, and they are much more common in the dog than in the cat. Other causes that should be

considered are sex hormone–induced conditions (e.g., hermaphroditism), generalized mucosal disease, or bleeding diathesis caused by disorders of blood coagulation.

Normal discharge in the male is typified as a small amount of grayish-white to yellow material that may be seen at the preputial orifice as moist or dried exudate. It may be difficult to determine, upon inspection of the preputial orifice and surrounding skin and haircoat, whether the volume present is normal. Careful examination of the genitalia is indicated. *Abnormal discharge* in the male may be investigated by means of the source of origin and the gross appearance of the discharge. Abnormal discharge may be characterized grossly as clear or serous, mucoid to mucopurulent to purulent, and sanguinous or serosanguineous (see the section Cytology, above, for the cytologic characteristics).

27.2.1 History

It is important to determine the age, breed, and reproductive status of the animal. It also should be ascertained whether the male has been castrated and if so, whether one or both testes were removed. Reproductive activity may be important. The duration and historical character of the discharge should also be noted. The presence of systemic signs that precede or are associated with discharge would be expected with inflammatory or infectious disease, neoplasia, and traumatic or toxic causes.

27.2.2 Physical Examination

A complete physical examination should be performed, with particular attention given to the scrotum, testes (if present), and prepuce. Edema of the scrotum or enlargement or asymmetry of testicular or epididymal tissues is important. The prostate gland can be evaluated by simultaneous abdominal and rectal palpation for size, symmetry, and pain. The size of the urinary bladder can also be evaluated by abdominal palpation. The prepuce and penis should be palpated, and the prepuce then should be retracted, caudal to the bulbus glandis, to allow visual inspection of the entire penis. Digital and visual inspection of the preputial space (using a blunt instrument) may be indicated.

27.2.3 Other Diagnostic Testing

Based on the appearance of the discharge, the historical information, and the physical examination findings, a list of differential diagnoses can be generated (Figure 27-2). Further evaluation might include a *CBC, serum biochemical profile,* and *urinalysis,* as well as *imaging* of the testicles, prostate, or urinary bladder by means of ultrasound or radiology. Evaluation of testicular or prostatic secretions may be possible through *semen collection* or *prostatic massage*. Additional diagnostics may include *bacterial culture with susceptibility determination, fine needle aspiration, or biopsy*. (See Cystocentesis; Bladder, Urethral, Vaginal, Prostatic Mass Aspiration/Biopsy; and Urethral Catheterization and Cystoscopy.) *Coagulation system testing* should be considered for a male with a serosanguineous to sanguinous discharge. Mucosal hemorrhage is characteristic of a primary system defect but may also be associated with a coagulation factor abnormality; iatrogenic, inherited, and acquired disorders should be considered.

The above evaluation may well lead to a definitive diagnosis. In the absence of definite findings, the male should be re-evaluated at a later date. Comparison of subsequent findings with the original data may lead to a definitive diagnosis or management plan.

28 CHAPTER • 28 Polyuria and Polydipsia

Edward C. Feldman

Concerns about a pet's atypical or unusual urination habits are a common reason for owners to seek veterinary assistance. For example, a dog or cat may urinate excessive volumes, urinate more frequently than “normal,” appear to be incontinent, urinate for an unusually long time, or urinate in atypical or unacceptable locations. Some owners seek veterinary care because they think their pet is drinking too much water, but this is a less common concern than those previously mentioned.

28.1 PHYSIOLOGY OF WATER METABOLISM

Water consumption and urine production are controlled by complex interactions between plasma osmolality, fluid volume in the vascular compartment, the thirst center, the kidneys, the pituitary gland, and the hypothalamus. Dysfunction in any of these can result in the clinical signs of polyuria (PU) and polydipsia (PD). Vasopressin (antidiuretic hormone [ADH]) plays a key role in the control of renal water resorption, urine production, urine concentration, and water balance. In the presence of ADH and dehydration, the average healthy dog or cat has the capacity to produce urine with an osmolality well above 2000 mOsm/kg. If a dog or cat is chronically deficient in ADH or is chronically unable to respond to ADH at the renal tubular level, the urine may be as dilute as 20 mOsm/kg.

Plasma osmolality and its principal determinant, the plasma sodium concentration, normally are maintained within remarkably narrow ranges. This stability is achieved through the adjustment of total body water concentrations to maintain balance with the plasma sodium concentration. Water balance is controlled by an integrated system that involves precise regulation of water intake via thirst mechanisms and control of renal water loss via ADH secretion and action. Water is continuously lost through the urine, respiratory tract, and feces. Lost water is replaced by that consumed. The urine concentrating capacity can reduce but not eliminate water loss.

ADH, a nonapeptide, is synthesized in the hypothalamus and secreted from the posterior pituitary gland. The primary sites of ADH activity are epithelial cells in the renal distal tubules and collecting ducts. Here, ADH acts to increase the hydro-osmotic permeability of these cells. The fluid in the tubular lumen normally is dilute, and the fluid in the interstitial space, through which the tubules traverse, is concentrated. Therefore, if water is allowed to diffuse passively along concentration gradients, it flows from the lumen of the nephron in which the fluid is dilute into the hypertonic milieu that normally exists in the interstitial space of the renal medulla. If ADH is present, the volume of fluid in the nephron decreases, the osmolality of that fluid increases, and water is conserved. Thus the “normal” animal has the capacity to secrete ADH in response to appropriate stimuli (increasing plasma osmolality, decreasing plasma volume) and the ability to respond to ADH at the level of the renal tubules and collecting ducts. In the absence of ADH (central diabetes insipidus) or if renal tubular cells are resistant to the action of ADH (nephrogenic diabetes insipidus), the cells lining this portion of the nephron are resistant to diffusion of both water and solutes. Hence, the hypotonic filtrate formed in the more proximal portion of the nephron passes unmodified through the distal tubule and collecting duct. This *water diuresis* is associated with large volumes of urine that has a low osmolality.

It should be noted that 85% to 90% of the fluid filtered by the glomerulus is reabsorbed isosmotically with sodium and glucose in the proximal portion of the nephron. Sodium then is selectively reabsorbed from the remaining fluid, making the fluid in the distal nephron hypotonic. However, if a poorly reabsorbed solute, such as urea or glucose, is present in excess in the glomerular filtrate, fluid resorption from the proximal tubule is impaired.

Because of this physiologic process, an abnormally increased volume of fluid reaches the distal nephron and can overwhelm its capacity to reabsorb water. Consequently, urine volume increases despite the presence of ADH. This type of polyuria is called *solute diuresis*.

28.2 DIAGNOSTIC APPROACH TO POLYURIA, POLYDIPSIA, AND OTHER ABNORMALITIES IN URINATION

28.2.1 The First Step: Collecting the Urine

It may be difficult for a veterinary hospital staff member to distinguish “inappropriate” urination (frequency with or without straining or hematuria) from polyuria at the time an owner phones the hospital to make an appointment. Therefore, it is strongly recommended that all cat and dog owners with any “chief complaint” that resembles those mentioned here, be encouraged to catch a urine sample from their pet (Figure 28-1). That urine (even if only a few drops) should be collected in a clean container with a lid and brought with the pet at the time of initial evaluation. Owners of medium-to-large breed dogs rarely have difficulty collecting urine in a small relatively flat container if they approach their pet slowly and discreetly. Owners of small dogs, especially female dogs, may find success in collecting urine if the container lid is used for collection. Owners of cats can try placing plastic wrap on top of their cats' litter and collecting urine after the cat uses the litter box. Alternatively, owners can replace absorbable litter with non-absorbable litter (using any type of gravel, such as that used in an aquarium). In this situation, the urine can simply be poured into a container.

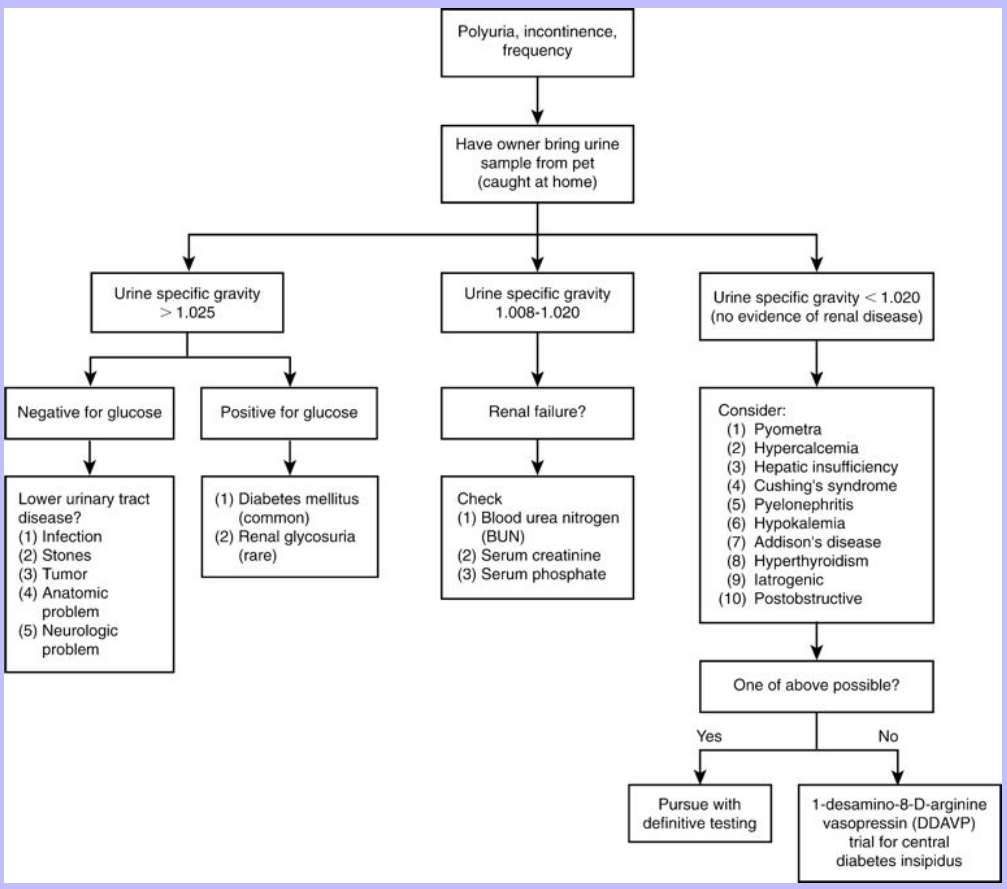
28.2.2 The Next Step: Evaluating the Urine

When the owner arrives at the veterinary hospital, the urine they collected can be evaluated prior to their pet being examined. The urine specific gravity should be noted and a “dip stick” test completed. Urine is usually considered normally “concentrated” if the specific gravity is 1.025 to 1.035 or greater. Since the owner has collected the urine sample from the pet while that animal was in its home environment, problems in interpretation associated with water being withheld prior to an automobile trip or a pet not consuming typical amounts of water due to nervousness or fear are not encountered. The truly polyuric dog or cat will almost always have dilute urine (specific gravity <1.012), “relatively” dilute urine (specific gravity >1.012 but <1.022), or it will have glucose in the urine.

102

103

Figure 28-1 Algorithm for polyuria, incontinence and frequency.



28.2.3 Concentrated Urine without Glucose

If the urine bought to the hospital by the owners is concentrated (specific gravity >1.025 to >1.035) and it has no glucose, it is likely that the animal has a lower urinary tract condition. In this situation the veterinarian must consider the possibility of urinary tract infection, bladder calculi, bladder mass, anatomic or neurologic problems that may explain the owner's observations. Appropriate testing for these conditions (culture, abdominal imaging, etc.) can be recommended if the history and physical examination support such an approach.

28.2.4 Concentrated Urine with Glucose

Most dogs and cats with diabetes mellitus are first examined after an owner has observed polyuria. These animals frequently also have polydipsia, polyphagia, and weight loss. Less commonly, a diabetic dog is brought in for veterinary examination after an owner notes that it has become acutely blind due to cataract formation. A dog or cat also may be brought in for treatment of vomiting, diarrhea, anorexia, listlessness, or other systemic

signs secondary to developing diabetic ketoacidosis. Regardless, almost all diabetic dogs and cats have a urine specific gravity of 1.025 to 1.045 and glycosuria. The diagnosis of diabetes mellitus can be strongly suspected simply by noting a positive reaction in the glucose reagent portion of the urine test strip within seconds of removing the strip from the urine. Thus diabetes mellitus can be diagnosed in dogs and cats before the pet is ever examined by the veterinarian. This diagnosis can be confirmed by the finding of hyperglycemia. In cats, stress may result in glycosuria; also, two uncommon causes of hyperglycemia and glycosuria are Cushing's syndrome and acromegaly. In the rare case in which the blood glucose concentration is within reference limits, the veterinarian should consider the possibility of renal glycosuria, a congenital renal tubular defect in the basenji and Norwegian elkhound. Renal glycosuria, however, can occur in any dog or cat.

103

104

28.2.5 Isosthenuric Urine (Urine Specific Gravity of 1.008 to 1.012): Chronic Renal Failure

The term *isosthenuria* usually implies that the urine specific gravity or osmolality is the same as that of serum or plasma. Using this criterion, urine with a specific gravity of 1.008 to 1.012 is *isosthenuric*. However, for clinical purposes, it is important to remember that a dehydrated animal typically has a plasma osmolality greater than normal due to loss of water and abnormal retention of solutes (e.g., urea). In this setting, urine with a specific gravity of 1.013 to 1.020 may be “isosthenuric” despite being greater than the classic 1.008 to 1.012. In other words, what happens if a cat or dog is examined and is thought to be 3% to 10% dehydrated? If the animal has a normal hypothalamus, pituitary, and kidneys, it should have responded to this degree of water loss by secreting maximum amounts of ADH (it has been demonstrated repeatedly that a 3% to 5% decrease in body weight due to water loss is associated with this response). The urine of such an animal, therefore, should reflect maximum release of ADH, and the specific gravity should be well in excess of 1.035. If the dog or cat has a urine specific gravity of 1.018, for example, it should not be considered to have responded appropriately to the dehydration.

The primary concern a veterinarian should have when an animal has polyuria and a urine specific gravity within the isosthenuric range is renal insufficiency or failure. In chronic renal failure, the number of functioning nephrons progressively decreases. A compensatory increase in the glomerular filtration rate by surviving nephrons occurs, and a commensurate increase in fluid volume is presented to the distal renal tubules. The increase in the tubular flow rate causes less urea and sodium to be reabsorbed. The result is an osmotic diuresis, which may be exaggerated by a reduction in the renal medullary concentration gradient. For an animal with this type of urine specific gravity, a serum chemistry evaluation is the first step toward determining the presence or absence of renal disease as the cause of the polyuria. Specifically, the blood urea nitrogen (BUN), serum creatinine, and serum phosphate concentrations should indicate whether the pet has renal disease.

28.2.6 Urine Specific Gravity < 1.020: Pyometra

It has been stated that any ill, intact female dog or cat should be considered a candidate for having pyometra until proven otherwise. This is an appropriate approach because of the serious nature of uterine infection. Animals with pyometra can quickly deteriorate as a result of overwhelming sepsis. Dogs and cats that may have pyometra typically have a history of being in estrus 2 to 10 weeks previously, and most have a purulent vaginal discharge. For any animal in which pyometra is suspected, a complete blood count (CBC) should be done to assess for evidence of systemic infection; abdominal radiographs or ultrasound scans also should be obtained and examined for uterine enlargement. Dogs and cats with pyometra may develop polyuria and dilute urine because of the effects of endotoxin from *Escherichia coli,* the bacteria most commonly associated with pyometra. Because this endotoxin interferes with the action of ADH at the level of the renal tubules, these animals have a reversible form of nephrogenic diabetes insipidus.

28.2.7 Urine Specific Gravity < 1.020: Hypercalcemia

Hypercalcemia has several common causes. Some, but not all, of the conditions associated with this biochemical abnormality are lymphosarcoma, chronic renal failure, hypoadrenocorticism, primary hyperparathyroidism, vitamin D toxicosis, granulomatous disease (histoplasmosis, blastomycosis), multiple myeloma, and apocrine gland carcinomas of the anal sac. Therefore, if a dog or cat has a urine specific gravity of less than 1.020, it would be appropriate to obtain a serum biochemistry profile to assess the serum calcium concentration. If the serum calcium concentration is abnormally increased, tests needed to rule in or rule out the various causes of hypercalcemia can be considered. An increased serum calcium concentration may interfere with the action of ADH at the renal tubular level, causing a reversible form of acquired nephrogenic diabetes insipidus. This is the most likely explanation for the polyuria and secondary polydipsia noted in hypercalcemic animals. Other possible explanations for this polyuria are damage to ADH receptors in the renal tubules, inactivation of adenyl cyclase, or decreased transport of sodium and chloride into the renal medullary interstitium.

28.2.8 Urine Specific Gravity < 1.020: Hepatic Insufficiency

Although the condition is not extremely common, some dogs with severe hepatic insufficiency also have an inability to concentrate their urine. One possible owner concern, therefore, would be polyuria. In these dogs, a decrease in one or more of the following “liver function” tests usually is seen on routine serum biochemical profiles: albumin, BUN, cholesterol, or glucose. In addition, an afflicted dog may have microhepatica or a liver that appears otherwise abnormal on radiography or ultrasonography. A dog with some or many of these abnormalities could be further assessed with pre-and post-prandial bile acid, a radio-labeled liver scan, or hepatic biopsy. There are several explanations for the polyuria and dilute urine. Although not well understood, one plausible explanation is loss of renal medullary hypertonicity secondary to impaired BUN production. BUN is an important component of the renal medullary concentration gradient. Decreases in this gradient result in polyuria with compensatory polydipsia. Other potential explanations are hypokalemia and impaired metabolism of cortisol.

28.2.9 Urine Specific Gravity < 1.020: Canine Cushing's Syndrome

Polyuria is an extremely common clinical sign in dogs with canine Cushing's syndrome (CCS) (excess cortisol concentrations do not commonly cause polyuria in cats). The urine specific gravity in at least 75% of dogs with iatrogenic or naturally occurring CCS is less than 1.020 and can be as low as 1.001. The cause of this polyuria remains obscure, although most of these dogs appear to have secondary and reversible ADH deficiency (central diabetes insipidus). Dogs with CCS typically have additional clinical signs, such as polydipsia, polyphagia, panting, muscle weakness, alopecia, pot belly, and thin skin. Routine laboratory abnormalities commonly include increases in serum alkaline phosphatase and alanine amino transferase activities, increased serum cholesterol concentration, and a decreased or low-normal BUN. Confirmation requires appropriate pituitary-adrenocortical function tests.

28.2.10 Urine Specific Gravity < 1.020: Pyelonephritis

Infection and inflammation of the renal pelvis can destroy the countercurrent mechanism in the renal medulla. This results in isosthenuria, polyuria, secondary polydipsia and, eventually, renal failure. A dog or cat with bacterial pyelonephritis may have nonspecific signs of lethargy, anorexia, and fever. Neutrophilic leukocytosis

may be noted on the CBC. Urinalysis may reveal white blood cells, casts, bacteria, and red cells. Recurrent urinary tract infection may increase suspicion of pyelonephritis. Urine cultures should be performed on cystocentesis samples, but these may or may not be positive for bacteria. Abdominal ultrasonography or urography usually is required to confirm this diagnosis.

28.2.11 Urine Specific Gravity < 1.020: Hypokalemia

Hypokalemia is thought to interfere with the action of ADH in the renal tubules, creating a reversible form of nephrogenic diabetes insipidus. This electrolyte disturbance is more common in cats than in dogs, more commonly causes muscle weakness than polyuria, and usually occurs secondary to other disorders (see Chapter 65).

104

105

28.2.12 Urine Specific Gravity < 1.020: Hypoadrenocorticism (Addison's Disease)

Most dogs with Addison's disease are young to middle-aged females. Despite normal kidney function and severe hypovolemia, animals in an Addisonian crisis frequently have a urine specific gravity of less than 1.030 due to the hyponatremia caused by mineralocorticoid deficiency. Hyponatremia reduces the renal medullary concentration gradient, impairing the ability to produce concentrated urine. Although “relatively” dilute urine is typical of addisonian dogs and cats, signs of polyuria or polydipsia are quickly overshadowed by the more worrisome and obvious signs of vomiting, diarrhea, listlessness, weakness, anorexia and weight loss. The combination of signalment and findings of hyperkalemia and hyponatremia should raise suspicion of Addison's disease. Confirmation requires a finding of an abnormally suppressed plasma cortisol concentration after administration of ACTH.

28.2.13 Urine Specific Gravity < 1.020: Hyperthyroidism

Polyuria and polydipsia are common in hyperthyroid cats and dogs. Although the exact mechanism of the polyuria is unclear, it is likely that increases in renal blood flow cause a decrease in renal medullary concentration. This impairs water resorption from the distal nephron. Concurrent renal insufficiency may also contribute to these signs. The tentative diagnosis of hyperthyroidism is based on palpation of a thyroid nodule or mass. Confirmation requires a finding of abnormally increased serum total or free thyroxine concentrations.

28.2.14 Urine Specific Gravity < 1.020: Iatrogenic

Several drugs may cause polydipsia and polyuria, including some that are commonly used, such as glucocorticoids, diuretics, and anticonvulsants.

28.2.15 Urine Specific Gravity < 1.020: Postobstructive Diuresis

Postobstructive diuresis is most often encountered after a urethral obstruction has been relieved in cats, but it may occur in dogs. These animals often show dramatic increases in BUN secondary to the obstruction, which accounts for a marked osmotic diuresis after the obstruction has been relieved.

28.3 CENTRAL DIABETES INSIPIDUS, NEPHROGENIC DIABETES INSIPIDUS, AND PSYCHOGENIC (PRIMARY) POLYDIPSIA

It should be emphasized that most dogs and cats with polyuria and polydipsia have one of the conditions described in the previous sections of this chapter. Most causes of polydipsia and polyuria can be identified from the signalment, history, physical examination, urinalysis (especially if the urine is caught by the owner before leaving the home environment), CBC, and serum biochemistry profile. *Primary nephrogenic diabetes insipidus (NDI)* is an extremely rare condition. However, secondary and often reversible NDI accounts for the polyuria in many of the conditions previously discussed. Both *central diabetes insipidus (CDI)* and *psychogenic (primary) polydipsia (PP)* are quite uncommon (although CDI is much more common than PP). If an animal has dilute urine and does not appear to have any of the previously discussed conditions, it is appropriate to assume that the animal does not have primary NDI, but it may have CDI or PP.

The veterinarian then can ask the following question: Does this animal drink a lot because it urinates a lot (CDI), or does it urinate a lot because it drinks a lot (PP)? If CDI is present, the serum osmolality should be high-normal or increased. If PP is present, the serum osmolality should be low-normal or decreased. Thus the serum osmolality becomes a reasonable, cost-effective, and simple test to run. Because the veterinarian has reached a point where it is likely that one of these two conditions may exist and because CDI is much more common than PP, trial therapy at home is recommended using oral DDAVP (synthetic ADH, which is commercially available as 0.1 or 0.2 mg tablets). The dose is empirical. It is recommended that a 20 kg dog be given 0.1 mg three times a day for about 7 days and that a 40 kg dog be given 0.2 mg three times a day for about 7 days. The dosage for dogs and cats weighing more or less than this can be so-adjusted. The response in dogs or cats with CDI is quick and obvious. Owners can collect urine on a daily basis during the trial to substantiate their clinical impressions regarding response. If the pet responds, CDI (Cushing's syndrome remains a possibility) is diagnosed, and dose of DDAVP can be slowly tapered to determine the minimum required for long-term treatment. The use of nasal drops placed in the eyes is no longer recommended. The water deprivation test is considered dangerous and is never warranted.

29 CHAPTER • 29 Micturition Disorders

Mary Anna Labato

Micturition is a two-stage process involving the passive storage and the active voiding of urine. Processes that interfere with the storage and voiding of urine are termed *micturition disorders*. Micturition disorders may lead to unresponsive urinary tract infection, resulting in an ascending pyelonephritis and ultimately renal disease. Neurogenic disorders, typically functional obstructions, include lower motor neuron disorder, or atonic bladder, with overflow incontinence; upper motor neuron disorder, or automatic bladder; detrusor-urethral dyssynergia, and dysautonomia. Non-neurogenic disorders, typically mechanical obstructions, include such processes as infection, inflammation, calculi, and neoplasia.

29.1 ANATOMY AND PHYSIOLOGY OF THE URINARY BLADDER

The body of the bladder is composed of smooth muscle, which is referred to as the *detrusor*. The *outlet conduit* consists of the trigone and proximal urethra. The smooth muscle fibers of the detrusor continue into the proximal urethra, forming a functional internal urethral sphincter. The distal urethra is composed of striated skeletal muscle and functions as an external sphincter. During the storage phase of micturition, the bladder functions as a low-resistance, high-capacity vessel. The urethra functions as a high-resistance barrier. The reverse is true during the voiding phase, at which time the bladder acts as a muscular pump and the urethra as a low-resistance vessel.

29.2 NERVOUS CONTROL OF MICTURITION

Nervous control of the bladder and urethra is a combination of autonomic and somatic interactions. Parasympathetic innervation is supplied to the detrusor by the pelvic nerve, which arises from sacral spinal cord segments S1 to S3. Sympathetic innervation is supplied via the hypogastric nerve, which is composed of preganglionic fibers that exit the lumbar spinal cord (L1 to L4 in dogs and L2 to L5 in cats) and synapses in the caudal mesenteric ganglion. Sympathetic innervation, which is supplied both to the detrusor and the urethral smooth muscles, characterizes the storage phase of micturition. Alpha-adrenergic fibers synapse in smooth muscles in both the trigone and proximal urethra. Stimulation results in contraction of these muscles and forms a functional internal urethral sphincter. Beta-adrenergic fibers synapse in the detrusor muscle; stimulation results in relaxation. Somatic innervation is supplied via the pudendal nerve, which arises from sacral spinal cord segments S1 to S3 and provides stimulation to the striated urethral musculature. For voluntary control of micturition to occur, the actions of the cerebral cortex, pons, and reticulospinal tract must be integrated. A second pathway, from the cerebral cortex to the sacral nuclei, coordinates voluntary sphincter control.

29.3 HISTORY AND DIAGNOSIS

When an animal is presented for a urine retention problem, it is of utmost importance to obtain a complete history, including reproductive status; age at neutering; age at the onset of the problem; previous medical problems, especially those involving the urogenital system; previous history of trauma; and an accurate description of the abnormality (Figure 29-1). If the animal is having difficulty urinating, two other questions are important: How frequent is urination? Is there stranguria, and if so, is any urine being passed?

A *complete physical and neurologic examination* should be performed, with particular attention paid to the urogenital system. The bladder should be palpated carefully before and immediately after voiding to evaluate the extent of distension, tone, and the ease with which the bladder may be expressed manually. Lower motor neuron

lesions generally are associated with easy manual expression and reduced sphincter tone. Upper motor neuron lesions generally are associated with difficult manual expression and increased sphincter tone. In the neurologic examination, the innervation of the urogenital system should be evaluated. The perineal reflex evaluates the pudendal nerve. Pricking or pinching the skin of the perineum results in contraction of the anal sphincter. The bulbospongiosus reflex evaluates the integrity of both the pudendal nerve and the sacral spinal segments. Squeezing the distal portion of the penis or the edges of the vulva causes the anal sphincter to contract.

A *rectal examination* should be done to evaluate the prostate gland, pelvic diaphragm, and anal tone. The veterinarian should try to observe the animal urinating to verify the micturition abnormality. Also, the residual urine volume should be measured. The animal is allowed to void until urine is no longer passed, the bladder is catheterized, and the volume of any remaining urine is measured. In a normal animal, the residual volume should not exceed 0.4 mL/kg. Catheterization of the bladder also assesses the patency of the urethra.

The *minimum database* should include a *complete blood count (CBC), serum biochemical profile,* and *urinalysis and culture*. In most cases the CBC and chemistry profile are within normal limits, unless a post renal azotemia has developed from an obstructive process. The urinalysis may reflect evidence of infection, inflammation, or neoplasia or a combination of these.

Survey and *specialized radiographic studies* may be useful. Survey radiographs should be checked for any obvious abnormalities in the bladder, urethra, pelvis, or spine. Contrast radiographic studies (intravenous urography, retrograde urethrocystography, vaginourethrography) are evaluated for bladder wall thickening, calculi, prostatic enlargement, urethral strictures, and skeletal abnormalities in the pelvis. An abdominal ultrasound examination may be useful for evaluating bladder wall thickness, the prostate, and the sublumbar lymph nodes and for checking for calculi or masses. A myelogram may be indicated to evaluate for spinal cord compression, as with cauda equina syndrome, or intervertebral disk disease. Magnetic resonance imaging may be indicated to evaluate for diseases of the spinal cord and vertebrae.

Urodynamic studies to evaluate micturition disorders routinely consist of a cystometrogram and urethral pressure profile; electromyography also may be a part of the study. The cystometrogram is a pressure-volume recording that measures bladder tone and volume, threshold volume and pressure, maximum contraction pressure, and the detrusor reflex. The urethral pressure profile measures intraurethral resistance and identifies and localizes areas of increased or decreased resistance. Electromyography can evaluate coordination of muscular activity between the detrusor and the urethral sphincter. Electromyography usually is performed on the anal sphincter; however, with specialized catheters that incorporate electrodes, it also can be performed directly on the urethral sphincter.

29.4 CAUSES OF MICTURITION DISORDERS

Micturition disorders have a number of causes, which may be categorized as *neurogenic* or *non-neurogenic*.

29.4.1 Neurogenic Causes

The four types of neurogenic disorders are lower motor neuron disorder, upper motor neuron disorder, detrusor-urethral dyssynergia, and dysautonomia.

29.4.1.1 Lower Motor Neuron Disorder (Detrusor Areflexia with Sphincter Areflexia)

Lower motor neuron disorder, or *atonic bladder,* results from lesions involving the sacral spinal cord segments or pelvic nerve, including intervertebral disk disease, cauda equina syndrome, sacroiliac luxations,

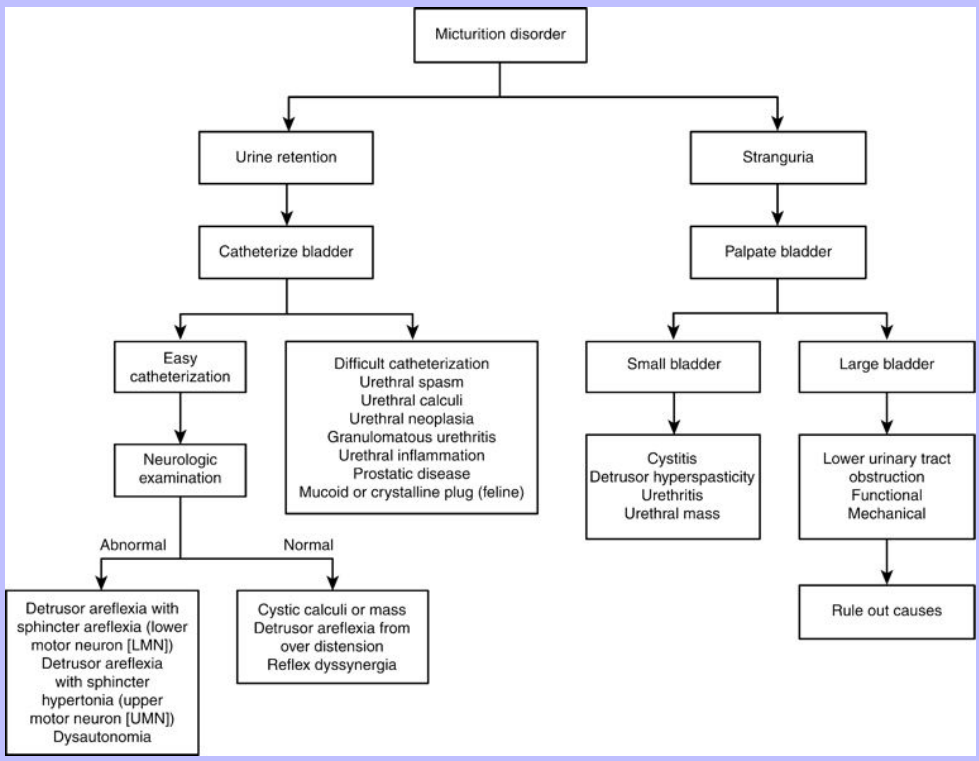
sacrococcygeal fracture/separation, and tumors (e.g., spinal lymphoma). This type of disorder causes both detrusor and sphincter areflexia. Dribbling of urine with the bladder remaining full often is referred to as *overflow incontinence*. The bladder typically is large, distended, and easily expressed. The incontinence is continuous, and a loss of perineal, bulbospongiosus, and detrusor reflexes is noted.

Treatment involves manual expression of the bladder three or four times daily. Long-term therapy for this disorder has not been successful. Complications include urine scalding, decubital ulcers, and recurrent urinary tract infections. Bethanechol, a parasympathomimetic, may be administered to increase detrusor contractions.

106

107

Figure 29-1 Algorithm for diagnostic approach to micturition disorders. *LMN,* Lower motor neuron; *UMN,* upper motor neuron.



29.4.1.2

Upper Motor Neuron Disorder (Detrusor Areflexia with Sphincter Hypertonus)

Upper motor neuron disorder, or *automatic bladder,* results from a lesion involving the spinal cord above the sacral spinal cord segments, such as intervertebral disk disease, tumor, or trauma. This disorder causes incomplete reflex detrusor contraction and spasticity of the urethral sphincter, the result being incomplete emptying of the bladder. The bladder is large, turgid, and initially extremely difficult to express. The animal has a history of inability to urinate, and concomitant hindquarter paresis or paralysis frequently is seen.

Voluntary control is lost, and manual expression is difficult if not impossible. After a period of days to weeks, the spinal reflexes resume. Involuntary micturition is initiated when the threshold capacity of the

bladder is reached (automatic bladder). Initially it is difficult to express the bladder manually. Because of the risk of bladder rupture, this maneuver should not be attempted until manual evacuation of the bladder is tolerable. Instead, the patient should be catheterized aseptically at least three times daily to empty the bladder completely. An indwelling catheter should not be used because of the risk of urinary tract infection. Frequent urinalyses with culture and sensitivity should be performed.

Concurrent administration of antibacterial agents may be indicated, especially with long-term intermittent catheterization. Baclofen, a skeletal muscle relaxant, decreases muscle tone by exerting a depressive effect on the central nervous system. It inhibits medullary interneurons and spinal reflexes, and it decreases spasticity by reducing the activity of gamma efferent neurons.

29.4.1.3 Detrusor-Urethral Dyssynergia

In detrusor-urethral dyssynergia, initiation of the detrusor reflex that results in voiding is followed by involuntary contraction of the urethral sphincter. The term *detrusor-urethral dyssynergia* refers to involuntary contraction of the external urethral sphincter in the distal urethra (detrusor-striated sphincter dyssynergia) or contraction of smooth muscle in the bladder neck and proximal urethra (detrusor-smooth sphincter dyssynergia) during detrusor contraction. The condition is caused by lesions or partial lesions (masses, degeneration) of the reticulospinal tract. Increased sympathetic activity of both the smooth and striated urethral musculatures may arise from a lesion cranial to or involving the caudal mesenteric ganglion. Treatment involves decreasing sympathetic tone or the use of muscle relaxants (Table 29-1.

108

Table • 29-1 Pharmacologic Agents Used in the Treatment of Micturition Disorders

AGENT	ACTION	DOSAGE	ADVERSE EFFECTS	CONTRAINDICATIONS
Baclofen	Skeletal muscle relaxant	*Dog:* 1–2 mg/kg PO q8h *Cat:* Not recommended	Weakness, pruritus, GI upset	
Bethanechol	Parasympathomimetic effect	*Dog:* 5–25 mg PO q8h *Cat*: 2.5–10 mg PO q8h	Vomiting, anorexia, cramping, ptyalism	Urethral obstruction, GI disease, hyperthyroidism
Dantrolene	Skeletal muscle relaxant	*Dog:* 1–5 mg/kg PO q8-12h *Cat:* 0.5–2 mg/kg PO q8h	Weakness, GI upset, sedation, hepatotoxicity	Cardiopulmonary disease
Diazepam	A benzodiazepine; skeletal muscle relaxant	*Dog:* 2–10 mg/dog PO q8h *Cat:* 1–2.5 mg/cat PO q8h	Sedation, polyphagia, paradoxic excitement, hepatotoxicity	Hepatic disease, pregnancy
Phenoxybenzamine	An alpha antagonist; urethral smooth muscle relaxant	*Dog:* 0.25 mg/kg PO q12-24h *or* 2.5–20 mg/dog PO q12-24h *Cat:* 1.25–7.5 mg/cat PO q12-24h	Hypotension, GI upset, tachycardia	Cardiac disease, glaucoma, diabetes mellitus, renal failure
Prazosin	Same as phenoxybenzamine	*Dog:* 1 mg/15 kg PO q8h *Cat:* 0.5 mg/cat PO q12-24h	As for phenoxybenzamine	As for phenoxybenzamine
Terazosin	Same as phenoxybenzamine	*Dog:* 0.5–5 mg/dog PO q12-24h *Cat:* Not established	As for phenoxybenzamine	As for phenoxybenzamine

GI, Gastrointestinal.

108

109

Alpha-adrenergic blocking agents (e.g., phenoxybenzamine, prazosin, and terazosin) can be used to decrease internal sphincter resistance. In addition to its alpha-1 antagonism in urethral smooth muscle, prazosin can cause a centrally mediated decrease in somatic input to the external urethral sphincter. Skeletal muscle relaxants (e.g., baclofen, diazepam, and dantrolene) can be used to decrease external sphincter resistance.

29.4.1.4

Dysautonomia

Dysautonomia is a result of dysfunction of the autonomous nervous system. The cause is unknown. It is a rare disease seen mostly in cats in Great Britain, but it has been recognized in dogs and cats worldwide. The clinical signs are acute in onset and involve many autonomic abnormalities. Urine dribbl-ing and dysuria often are presenting clinical signs due to an atonic bladder. Treatment options include administration of bethanechol and frequent bladder emptying by means of catheterization or manual expression.

29.4.2 Non-Neurogenic Causes of Micturition Disorders

As mentioned previously, non-neurogenic disorders, which typically involve mechanical obstructions, include such processes as infection, inflammation, calculi, and neoplasia.

29.4.2.1 Detrusor Atony from Overdistention

Detrusor atony from overdistention results from a mechanical or functional outflow obstruction that causes the tight junctions of the detrusor muscle to separate. Subsequent contractions of the detrusor muscle are weak and ineffectual. A functional outflow obstruction may have a neurogenic component. It usually is the result of excessive sympathetic stimulation to the urethra, which effects an increase in urethral tone. Common examples of mechanical obstruction are urethral obstruction (especially in cats from mucoid or crystalline plugs), cystic and urethral calculi, neoplasia of the trigone or urethra, severe urethritis, stricture of the urethra, and prostatic disease.

As a result of a functional or mechanical obstruction, urine volume increases until the intravesicular pressure can overcome the urethral resistance. Once the urethral pressure has been overcome, dribbling of urine occurs because of ineffectual detrusor contractions.

With detrusor atony from overdistention, the animal has a history of continuous incontinence and urine outflow obstruction. Abdominal palpation reveals a large, flaccid bladder. Neurologic examination reveals intact perineal and bulbospongiosus reflexes, yet the detrusor reflex is weak or absent. There is a large residual urine volume. Urodynamic studies may help rule out a neurogenic component.

Detrusor atony from overdistention is the one disorder in which indwelling urinary catheterization for up to 7 to 14 days is indicated, because the bladder must be kept as small as possible to re-establish tight junction connections in the detrusor muscle. It is imperative that the obstruction be removed or the primary cause resolved. Occasionally anti-inflammatory therapy is indicated. Frequent urinalyses should be performed, and the appropriate antibiotics, based on susceptibility results, should be given. The cholinergic drug bethanechol has been used successfully to stimulate detrusor contractions in both neurogenic and non-neurogenic atonic bladders. It also is effective for postobstructive atony; however, care must be taken to ensure urethral patency. When the overdistention is caused by increased urethral resistance, an alpha-adrenergic blocker is given before the administration of bethanechol.

29.5 OUTCOME

The prognosis for return to normal function depends on the underlying cause of the micturition disorder. The prognosis is good for acute mechanical obstruction associated with resolving obstructive or irritative disease, acute reversible neurologic lesions, and detrusor atony from overdistention. The prognosis is less favorable for chronic detrusor atony or idiopathic functional obstructive disorders. A complete return to normal voiding may not occur, and long-term treatment may be necessary.

30 CHAPTER • 30 Urinary Incontinence

S. Dru Forrester

***U**rinary incontinence* is the inability to voluntarily control the passage of urine through the urethra. *Enuresis* is urinary incontinence that occurs during sleep; it is a common finding in dogs with urethral incompetence. Dogs and cats with urinary incontinence may also have *nocturia* (excessive urination at night), although this probably is more likely in pets with *polyuria* (increased urine volume). *Dysuria* (painful or difficult urination) most often is characterized by *pollakiuria* (increased frequency of urination attempts) or *stranguria* (straining to urinate); however, it may be associated with incontinence caused by increased urgency to urinate.

30.1 PHYSIOLOGY OF MICTURITION

Control of micturition is centered in the lumbosacral spinal cord and is modified by higher neurologic structures. Sympathetic input originates from lumbar spinal cord segments and projects to beta-adrenergic receptors in the urinary bladder and alpha-adrenergic receptors in the urinary bladder neck and internal urethral sphincter. Parasympathetic input is derived from sacral spinal cord segments and travels through the pelvic nerve to cholinergic receptors in the urinary bladder. The pudendal nerve originates from sacral spinal cord sements and provides somatic input to the external urethral sphincter.

Urine storage is maintained primarily by sympathetic activity, whereas voiding is initiated and maintained by parasympathetic input. Sympathetic input stimulates beta-adrenergic receptors in the urinary bladder, causing detrusor relaxation. Sympathetic input also stimulates alpha-adrenergic receptors in the urethra, causing contraction of the internal urethral sphincter. Voluntary contraction of the external urethral sphincter contributes to increased outlet resistance, which helps maintain continence. Filling of the urinary bladder stimulates stretch receptors, which send impulses through the pelvic nerve and spinal pathways to the brain stem and cerebral cortex. Parasympathetic impulses are transmitted from the micturition center through spinal pathways and the pelvic nerve to stimulate cholinergic receptors and initiate detrusor contraction. During detrusor contraction, concomitant inhibition of sympathetic and somatic input to the urethra allows urethral opening. In normal animals, complete voiding occurs, and the urinary bladder returns to a relaxed state.

30.2 CAUSES OF URINARY INCONTINENCE

30.2.1 Neurogenic Disorders

Any neurologic lesion that affects the micturition reflex may cause abnormal micturition. Incontinence is most likely to occur with lower motor neuron disorders (i.e., S1 to S3 segments or peripheral nerves), such as congenital malformation of the sacrum in Manx cats, sacral fractures, trauma affecting the pelvic nerve, and lumbosacral disease (e.g., rupture of an intervertebral disk, neoplasia, and stenosis). Upper motor neuron disorders (e.g., lesions cranial to S1) usually are characterized by urinary retention; however, if the urinary bladder is overdistended, urine may leak through the urethra once intravesicular pressure exceeds outlet resistance, causing overflow incontinence.

30.2.2 Non-Neurogenic Disorders

Incontinence may be associated with functional or anatomic disorders of the urethra or urinary bladder. Urethral incompetence is a functional disorder associated with incontinence; it occurs most often in neutered dogs but has also been observed in dogs with ectopic ureters and cats with feline leukemia virus infection. A less common functional cause of incontinence is detrusor instability, a disorder characterized by failure of the urinary bladder to relax during the storage phase. Anatomic abnormalities such as ectopic ureters, patent urachus, and vaginal stricture also may cause incontinence. Lower urinary tract disorders (e.g., urinary tract infection, urolithiasis) most often cause pollakiuria; however, incontinence may occur secondary to an increased urge to urinate. Animals with partial urinary outlet obstruction (e.g., small uroliths) may have incomplete voiding and a distended urinary bladder, but they also may have periods of paradoxical incontinence as urine escapes past the obstructive lesion.

30.3 DIAGNOSTIC EVALUATION

In the evaluation of dogs and cats with abnormal micturition, it is helpful to determine whether failure of urine storage or of voiding (or both) is present. Urinary incontinence is the hallmark of urine storage disorders; however, some animals with primary urine retention may also have incontinence. In addition to the information gained from the signalment, history, and physical examination, it is helpful to determine whether neurologic deficits, which may be a cause of incontinence, are a factor (Figure 30-1). Additional diagnostic tests (e.g., imaging studies) may be needed to identify the underlying cause and to help determine the appropriate treatment.

30.3.1 Signalment

Congenital disorders (e.g., ectopic ureters) are more common in younger animals, whereas acquired diseases (e.g., hormone-responsive incontinence) are more likely in older dogs and cats. Ectopic ureters occur most frequently in female, large breed dogs. Hormone-responsive incontinence is most common in neutered female dogs that weigh more than 20 kg.

30.3.2 History

Owners should be asked about previous urogenital tract problems in their pets, including trauma or surgery. Dogs and cats with ectopic ureters usually have incontinence from birth, whereas hormone-responsive incontinence often occurs in dogs several months to years after neutering. Animals with urethral incompetence often dribble urine while sleeping or lying down. If polyuria exists, it may worsen clinical signs in dogs predisposed to incontinence. It should be determined whether the incontinence is intermittent or continuous. Continuous incontinence occurs with bilateral ectopic ureters and severe urethral incompetence; intermittent incontinence may be observed with mild to moderate urethral incompetence, unilateral ectopic ureters, and disorders that cause paradoxical incontinence. The presence of dysuria, stranguria, or pollakiuria suggests lower urinary tract disorders (e.g., urinary tract infection, urolithiasis), which may cause urge incontinence.

A description of the pet's urination should be obtained from the owner; if this is not possible, the veterinarian should observe the animal urinate. The ability to voluntarily initiate and maintain urination until voiding is complete indicates normal detrusor reflex activity. Absence of this ability occurs with neurogenic diseases. Animals with urethral incompetence and those with anatomic abnormalities (e.g., ectopic ureters) can initiate and maintain urination.

30.3.3 Physical Examination

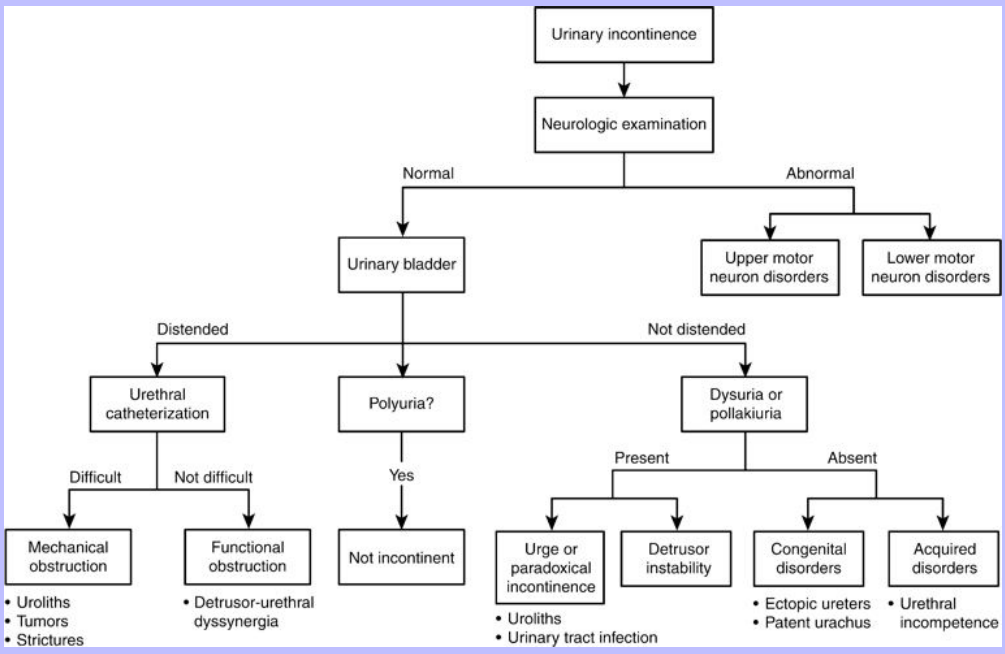
A thorough physical examination should be completed before the urogenital tract is examined. The urinary bladder should be palpated to detect masses and to determine whether it is full or empty, spastic or flaccid, and easy or difficult to express. Upper motor neuron disorders are associated with a firm, distended urinary bladder that is difficult to express. However, if urinary retention is prolonged, the urinary bladder may become overdistended and flaccid. Lower motor neuron diseases result in a flaccid, distended urinary bladder that is easily expressed. After the animal has voided, the bladder should be palpated again to allow estimation of the residual urine volume, which should be less than 0.4 mL/kg in normal animals. A rectal examination is indicated for evaluation of the caudal urinary bladder, urethra, and prostate gland. Vaginal palpation should be done in female dogs to detect strictures and urethral masses. The perineal area should be inspected for anatomic abnormalities and evidence of urine staining or scalding, which may occur with incontinence.

30.3.4 Neurologic Examination

A neurologic examination should be completed to detect deficits caused by neurogenic disorders. A decrease in or the absence of anal tone, perineal sensation, and the bulbospongiosus reflex are consistent with lower motor neuron disease. Pain on palpation over the lumbosacral area or when the tail is lifted and decreased tail tone occur in patients with lumbosacral disease. Animals with intervertebral disk disease may have ataxia, proprioceptive deficits in the rear limbs, and/or pain on palpation of the vertebral column. 110

111

Figure 30-1 Algorithm for diagnosis and treatment of urinary incontinence.



30.3.5 Laboratory Tests

A urinalysis should be done and urine should be collected for culture in all animals with incontinence; other tests, such as serum chemistries, are indicated when systemic signs of illness are present (e.g., inappetence, vomiting, polyuria, polydipsia). Cystocentesis is the preferred method of collecting urine. The presence of pyuria is consistent with urinary tract inflammation, which may cause urge incontinence. Hematuria may be the predominant finding in feline lower urinary tract disease and in animals with urinary tract neoplasia. Bacteriuria found in urine collected by cystocentesis is highly suggestive of urinary tract infection. Although urinary tract infection may cause urge incontinence, it also may occur secondary to abnormal host defenses in animals with incontinence.

30.3.6 Diagnostic Imaging

Radiography and ultrasonography are helpful when anatomic or structural abnormalities are suspected to be the cause of incontinence. Abdominal radiographs provide information about the size and location of the urinary bladder and also help identify radiopaque uroliths and prostatomegaly. Ultrasonography is helpful for identifying structural abnormalities of the urogenital tract. If the results of noninvasive imaging are normal, contrast studies should be considered. Cystourethrography and vaginography are indicated for identifying abnormalities of the lower urinary tract and vagina, respectively. Excretory urography may be helpful for detecting ectopic ureters. In animals with neurogenic disorders, additional imaging studies (e.g., spinal films, myelography, computed tomography) may be indicated.

30.3.7 Endoscopy

Endoscopy of the lower urogenital tract may be helpful in female dogs suspected of having congenital or anatomic abnormalities. Vaginal strictures should be identified through digital examination of the vaginal vault, and urethral masses can be identified by vaginoscopy. Cystoscopy may be used to evaluate the flow of urine through the ureteral openings into the urinary bladder in normal dogs; the absence of urine flow through one or both ureteral openings is consistent with ectopic ureters.

30.3.8 Urodynamic Tests

Urodynamic studies measure pressure, volume, and flow in the urinary bladder and urethra. Because specialized equipment is needed, these tests generally are available at referral centers. In most cases, urodynamic testing is not needed; however, it may be helpful when the diagnosis is uncertain or when the response to treatment is inadequate.

30.4 OUTCOME

The outcome depends in part on the underlying cause of the urinary incontinence. The outcome in dogs and cats with structural abnormalities that can be corrected is good to excellent. Surgical correction of ectopic ureters may be successful; however, incontinence may persist due to concomitant urethral incompetence in these animals. Dogs with hormone-responsive incontinence respond well to treatment but may have periods of worsening signs that require adjustments in dosage.

31 CHAPTER • 31 Discolored Urine

Joseph W. Bartges

31.1 NORMAL URINE

Normal urine is typically transparent and yellow or amber upon visual inspection. Two pigments impart the yellow coloration: urochrome and urobilin. Urochrome is a sulfur-containing oxidation product of the colorless urochromogen. Urobilin is a degradation product of hemoglobin. Because the 24-hour urinary excretion of urochrome is relatively constant, highly concentrated urine is amber, whereas dilute urine may be transparent or light yellow. The intensity of the color is partly related to the volume of urine collected and the concentration of urine produced; therefore color should be evaluated in the context of the urine specific gravity. Care must be taken not to overinterpret the significance of urine color as part of a complete urinalysis. Significant disease may exist when urine is normal in color. Abnormal urine color may be caused by the presence of several endogenous or exogenous pigments. Although the abnormal color indicates a problem, it provides relatively nonspecific information. Causes of abnormal coloration should be investigated with appropriate laboratory tests and examination of urine sediment. Detection of abnormal urine color should prompt questions related to diet, administration of medication, environment, and collection technique. A knowledge of urine color may also be important in interpreting colorimetric test results, because the color may induce interference with the test.

Table • 31-1 Potential Causes of Discolored Urine

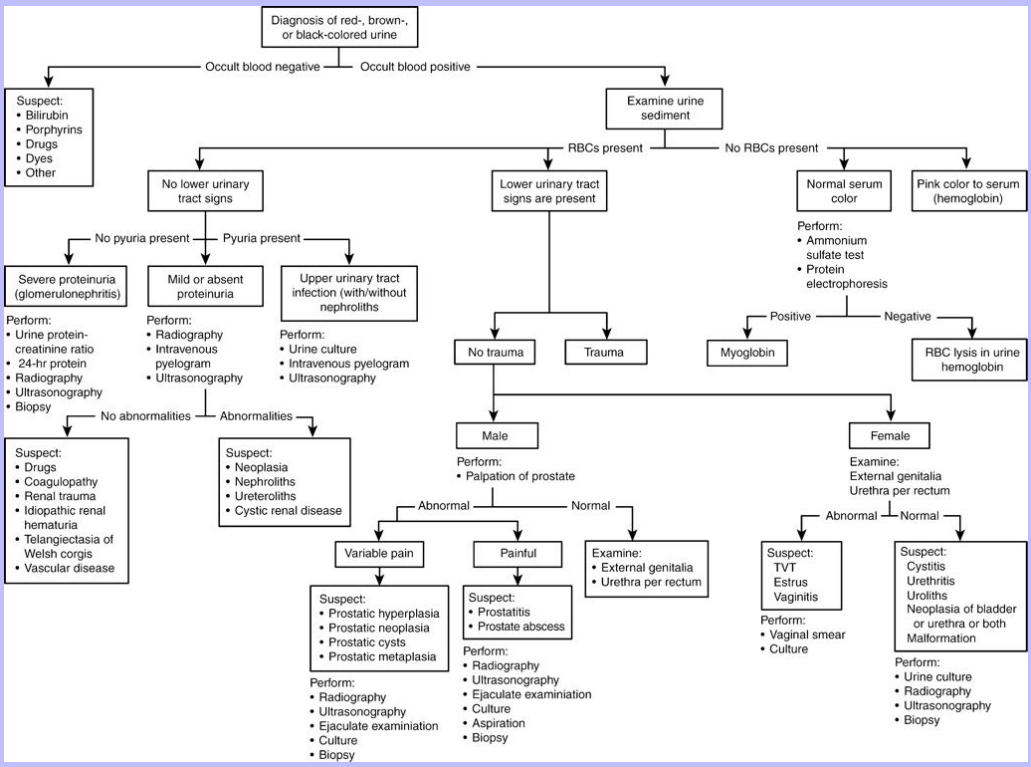
URINE COLOR	CAUSES
Yellow or amber	Urochromes, urobilin
Deep yellow	Highly concentrated urine, quinacrine,* nitrofurantoin,* phenacetin,* riboflavin (large quantities),* phenolsulfonphthalein (acidic urine)*
Blue	Methylene blue, indigo carmine and indigo blue dye,* indicans,* *Pseudomonas* infection,* water-soluble chlorophyll,* rhubarb,* toluidine blue,* triamterene,* amitriptyline,* anthraquinone,* blue food dye*
Green	Methylene blue, dithiazanine, urate crystalluria, indigo blue,** bilirubin, biliverdin, riboflavin,* thymol,* phenol,* triamterene,* amitriptyline,* anthraquinone,* green food dye*
Red, pink, red-brown, red-orange, or orange	Hematuria, hemoglobinuria, myoglobinuria, porphyrinuria, Congo red, phenolsulfonphthalein (after alkalinization), neoprontosil, warfarin (orange),* food pigments (rhubarb, beets, blackberries),* carbon tetrachloride,* phenazopyridine, phenothiazine,* diphenylhydantoin,* bromsulphalein (after alkalinization), chronic heavy metal poisoning (lead, mercury),* rifampin,* emodin,* phenindione,* eosin,* rifabutin,* acetazolamide,* red food dye*
Orange-yellow	Highly concentrated urine, excess urobilin, bilirubin, phenazopyridine, sulfasalazine,* fluorescein sodium,* flutamide,* quinacrine,* phenacetin,* 2,4-d,* acetazolamide,* orange food dye*
Yellow-brown or green-brown	Bile pigments
Brown to black (brown or red-brown when viewed in bright light in a thin layer)	Melanin, methemoglobin, myoglobin, bile pigments, thymol,* phenolic compounds,* nitrofurantoin,* nitrites,* naphthalene,* chlorinated hydrocarbons,* aniline dyes,* homogentisic acid*
Brown	Methemoglobin, melanin, sulfasalazine,* nitrofurantoin,* phenacetin,* naphthalene,* sulfonamides,* bismuth,* mercury,* feces (rectal-urinary fistula), fava beans,* rhubarb,* sorbitol,* metronidazole,* methocarbamol,* anthracin cathartics,* clofazimine,* primaquine,* chloroquine,* furazolidone,* copper toxicity
Colorless	Very dilute urine (diuretics, diabetes mellitus, diabetes insipidus, glucocorticoid excess, fluid therapy, overhydration)
Milky white	Lipid, pyuria, crystals

* Only observed in human beings.

31.2 DISCOLORED URINE

Urine color that is anything other than yellow or amber is abnormal. Discolored urine has many potential causes (Table 31-1). The most common abnormal urine color in dogs and cats is red, brown, or black, which may be caused by hematuria, hemoglobinuria, myoglobinuria, and bilirubinuria (Figure 31-1). 112 114

Figure 31-1 Algorithm for diagnosis of red, brown, or black colored urine.



31.2.1 Pale Yellow Urine

Urine that is pale yellow or clear may be normal or indicative of a polyuric state. Urine may be appropriately dilute if associated with recent consumption or administration of fluids, consumption of a diet containing low amounts of protein or high amounts of sodium chloride, glucocorticoid excess, or administration of diuretics. Urine concentration would be considered inappropriate if it were dilute in the presence of dehydration. Diseases that may be associated with persistently dilute urine include renal failure, diabetes insipidus, hyperadrenocorticism, hypoadrenocorticism, hypercalcemia, diabetes mellitus, and hyperthyroidism. If the urine is pale yellow or clear, the urine specific gravity often is less than 1.015. A simple test of whether polyuria is persistent is to determine the urine specific gravity of a sample collected in the morning. Other tests should include serum biochemical analysis and a complete urinalysis. Additional testing may include measurement of the serum thyroxine concentration, adrenal function testing, or monitoring of the urine specific gravity after several days of vasopressin administration.

31.2.2 Red, Brown, or Black Urine

Urine that is red, brown, or black suggests the presence of blood, hemoglobin, myoglobin, or bilirubin (see Figure 31-1). A positive occult blood reaction is obtained when urine contains any of these substances. Discoloration of urine may also result in false-positive reactions on other urine dipstick test pads. Analysis of

urine sediment reveals the presence of red blood cells if the discoloration is due to hematuria. If no red blood cells are present on microscopic examination of the urine sediment, hemoglobin, myoglobin, or bilirubin should be suspected. Examination of plasma color may help differentiate these. If the discoloration of the urine is due to myoglobin, the plasma is clear, because myoglobin in plasma is not bound significantly to a carrying protein and the result is filtration and excretion of myoglobin. Pink coloration of the plasma is suggestive of hemoglobin. A yellow plasma color is suggestive of bilirubin; the serum bilirubin concentration should also be increased. Myoglobinuria is indicative of muscle damage, and serum creatine kinase activity often is increased in this setting. Hemoglobinemia is indicative of intravascular hemolysis resulting from immune-mediated, parasite-mediated, or drug-mediated destruction of red blood cells. Hyperbilirubinemia may result from liver disease, posthepatic obstruction, or hemolysis.

31.2.3 Milky White Urine

A milky white color may be due to the presence of white blood cells (pyuria), lipid, or crystals in the urine. The more concentrated the urine sample is, the more opaque it may appear. The presence of pyuria secondary to a bacterial urinary tract infection is the most common cause of milky white urine; however, pyuria may occur as a result of inflammation and may not be associated with an infection. Lipiduria may be observed in healthy animals but is frequently observed in cats with hepatic lipidosis. Crystalluria, if heavy and present in a concentrated urine sample, may also result in milky white urine. Microscopic examination of the urine sediment aids differentiation of these causes.

32 CHAPTER • 32 Proteinuria

Gregory F. Grauer

Normal canine and feline urine contains only a small amount of protein. The permselectivity of the glomerular capillary wall hinders filtration of most plasma proteins, primarily on the basis of weight and, to a lesser extent, charge. Proteins with a molecular weight greater than 60,000 to 65,000 daltons are not usually filtered because of their size. Negatively charged proteins of glomerular capillary walls further restrict the filtration of other negatively charged proteins, such as albumin. Smaller molecular weight proteins, as well as the positively charged proteins that are filtered, are largely resorbed from the glomerular filtrate by proximal tubular epithelial cells. Resorbed proteins may be catabolized by the epithelial cells or returned to the circulation. Protein resorption by tubular epithelial cells has a transport maximum and, if that maximum is exceeded, proteinuria may result.

Another source of urine protein is the secretion of enzymes, mucoproteins, and immunoglobulins by renal tubular and lower urinary and genital tract epithelial cells. These secreted proteins may account for as much as 50% of the protein typically present in urine.

When examining a dog or cat with proteinuria, it is important that the veterinarian try to identify the source of the urine protein. Proteinuria may be caused by physiologic or pathologic conditions (Table 32-1). Physiologic or benign proteinuria often is transient and abates when the underlying cause is corrected. Strenuous exercise, seizures, fever, exposure to extreme heat or cold, and stress are examples of conditions that may cause physiologic proteinuria. The process by which physiologic proteinuria occurs is not completely understood; however, relative renal vasoconstriction, ischemia, and congestion likely are involved. Decreased physical activity may also influence urine protein excretion in dogs; one study demonstrated that dogs confined to cages had a higher urine protein loss than dogs with a normal level of activity.

Pathologic proteinuria may be caused by urinary or non-urinary abnormalities. “Nonurinary” disorders associated with proteinuria often involve excessive production of small molecular weight proteins, which are freely filtered by the glomerulus and which subsequently overwhelm the resorptive capacity of the proximal tubule. Examples of this excessive production include the production of immunoglobulin light chains (Bence-Jones proteins) by neoplastic plasma cells or the release of hemoglobin and myoglobin from damaged red blood cells and muscle tissue. Hemoglobin and myoglobin in plasma are bound by haptoglobulin, and glomerular filtration of these proteins does not occur until the binding capacity of haptoglobulins has been exceeded. Renal vascular congestion secondary to heart failure may also result in pathologic nonurinary proteinuria, as can genital tract inflammation (e.g., prostatitis or metritis).

Table • 32-1 Diagnostic Criteria for Different Types of Proteinuria

TYPE AND POSSIBLE CAUSES OF PROTEINURIA	DIAGNOSTIC TESTS/SIGNS
Physiologic/Benign Proteinuria	
Change in exercise level, seizure activity, fever, exposure to temperature extremes, stress	• UP/C usually <0.5 • Compatible history • Intermittent/transient proteinuria
Pathologic Proteinuria	
Nonurinary	• UP/C not indicated
Congestive heart failure	• History/PE/thoracic radiographs/echocardiogram
Hemoglobinuria/myoglobinuria	• Urine remains red after centrifugation
Paraproteinuria	• Serum/urine electrophoresis
Genital tract inflammation/hemorrhage	• PE/imaging/urine sediment changes
Urinary—nonrenal	
Lower urinary tract inflammation (e.g., bacterial cystitis, cystoliths, polyps, neoplasia)	• UP/C not indicated • History/PE • Urine sediment changes • Imaging • Urine culture
Urinary—renal	
Renal parenchymal inflammation (e.g., pyelonephritis, renoliths, neoplasia)	• UP/C not indicated • Urine sediment changes • Imaging
Tubular proteinuria	• UP/C usually 0.5–1.0 • Can be associated with normoglycemic glucosuria and excessive urinary loss of electrolytes
Glomerular proteinuria	• Persistent UP/C ≥ 1.0 • Inactive urine sediment except for possible hyaline casts

PE, Physical examination; *UP/C*, urine protein/creatinine ratio.

"Urinary" proteinuria may arise from renal or nonrenal sources. Nonrenal proteinuria most frequently is associated with lower urinary tract inflammation or hemorrhage. Changes in the urine sediment often suggest the underlying cause (e.g., urolithiasis, neoplasia, trauma, or bacterial cystitis). Glomerular lesions are the most common causes ofrenal proteinuria. Glomerulonephritis and amyloidosis alter the selective permeability of the glomerular capillaries and frequently result in proteinuria greater than 40 mg/kg/24 hours or urine protein/creatinine ratios greater than 2.0. Persistent proteinuria of this magnitude with a normal urine sediment or a urine sediment that contains hyaline casts is suggestive of glomerular disease. In addition to glomerular disease, renal proteinuria may be caused by inflammatory or infiltrative disorders of the kidney (e.g., neoplasia or pyelonephritis) or by tubular abnormalities that result in decreased resorption of filtered protein (e.g., Fanconi syndrome) (see Table 32-1).

Proteinuria is routinely detected by semiquantitative methods, including the dipstick colorimetric test and the sulfosalicylic turbidimetric test. The dipstick test is inexpensive and easy to use; amino groups of proteins bind to the indicator incorporated in the filter paper on the dipstick and cause a color change. The color change is graded by subjective comparison to a standard. The dipstick test is most sensitive to albumin, inasmuch as albumin has more free amino groups compared with globulins or Bence-Jones proteins. False-positive results are common and may be seen with alkaline urine or urine that has been contaminated with quaternary ammonium compounds, or with excessive urine contact time, which causes the citrate buffer to leach out of the filter paper pad. False-negative results may occur with Bence-Jones proteinuria or dilute or acidic urine. The sensitivity of the dipstick test is approximately ≥30 mg/dL.

The sulfosalicylic acid test can be performed by mixing equal amounts of urine and 5% sulfosalicylic acid. The turbidity that results from the acid precipitation of protein is graded on a scale of 0 to 4+. The advantages of this test, compared with the dipstick test, are increased sensitivity and the ability to detect proteins other than albumin (e.g., Bence-Jones proteins). False-positive results are rare but may be obtained if urine contains radiographic contrast agents, penicillin, cephalothin, cephalodine, sulfisoxazole, or thymol preservatives. The protein content may be overestimated with the sulfosalicylic acid test if uncentrifuged urine or turbid urine is analyzed. False-negative results may be obtained with highly alkaline or dilute urine. Similar to the dipstick test, the varying degrees of turbidity are not standardized, and variability in results may be seen among laboratories. The sensitivity for this test is approximately ≥5 mg/dL.

115

116

Proteinuria detected by these semiquantitative methods should always be interpreted in light of the urine specific gravity (USG) and urine sediment findings. Significant proteinuria may be overlooked if the urine is dilute and voluminous. Conversely, a protein reaction of trace or 1+ may be normal in concentrated urine. For example, a 2+ proteinuria with a 1.010 USG suggests much greater urine protein loss on a 24-hour basis than does a 2+ proteinuria with a 1.040 USG. In addition, the urine protein concentration is frequently increased in dogs or cats with urinary tract inflammation and/or hemorrhage. Proteinuria, therefore, should also be assessed in relation to changes in the urine sediment that are compatible with inflammation or hemorrhage (e.g., bacteria and increased numbers of white and red blood cells and epithelial cells in the urine sediment).

Recently an enzyme-linked immunosorbent assay (ELISA) for detecting low levels of albumin in canine and feline urine *(microalbuminuria)* has become commercially available (E.R.D.-Screen, Heska Corp., Fort Collins, CO). Microalbuminuria usually is defined as a urine albumin concentration between 1.0 and 30 mg/dL. These concentrations are too small to be detected routinely by standard dipstick screening tests. It is interesting to note that microalbuminuria has been shown to be an accurate predictor of subsequent renal disease in human beings secondary both to systemic hypertension and to diabetes mellitus and that it has also been observed in human beings with systemic diseases associated with glomerulopathy. Studies in dogs have shown the prevalence of microalbuminuria in apparently healthy dogs to be 19% and in dogs brought to veterinarians because of illness to be 36%. In addition, high prevalence rates of microalbuminuria have been reported in soft-coated wheaten terriers (SCWT) and SCWT/crosses (76%); in dogs experimentally infected with heartworm disease (100%); and male dogs with X-linked hereditary nephropathy (97%). Each of these models is associated with glomerulopathy, and in all three studies microalbuminuria, when it occurred, appeared to be progressive and preceded the onset of overt proteinuria. These results suggest the utility and importance of microalbuminuria as an early marker of renal disease in the dog.

Prerenal (physiologic and pathologic-nonurinary), postrenal (pathologic urinary-nonrenal), and inflammatory renal proteinuria usually can be identified on the basis of the history, physical examination, and urine sediment changes (see Table 32-1). Renal proteinuria caused by abnormal tubular resorption may be accompanied by glucosuria and excessive urinary loss of electrolytes, which helps differentiate tubular proteinuria from glomerular proteinuria. Identification of the source of the proteinuria is important, because quantitation of glomerular proteinuria can be a helpful prognostic tool, although it is not useful in patients with prerenal or postrenal proteinuria.

When glomerular proteinuria is suspected, urine protein excretion should be quantitated. Quantitation of renal proteinuria aids evaluation of the severity of renal lesions, as well as the response to treatment or the progression of disease. The trichloroacetic acid-N-Ponceau S, Coomassie brilliant blue, or benzethonium chloride tests are the methods most commonly used to quantify urine protein and are available at referral centers and reference laboratories. Collection of urine for 24 hours and measurement of urine protein excretion in milligrams per kilogram per 24 hours has been the time-honored method of quantitating proteinuria, because errors caused by variation in urine volume are minimized by 24-hour collection. However, such collections require the use of a metabolism cage, an indwelling urinary catheter, or repeated urinary catheterization, all of which make the procedure cumbersome and

expensive. In addition, incomplete collection of all urine produced over the 24-hour period results in errors. Alternatively, the urine protein concentration (in milligrams per deciliter [mg/dL]) in a single, random urine sample may be divided by the urine creatinine concentration (also in mg/dL). This ratio negates the effect of urine volume on the urine protein concentration.

Calculation of the urine protein/creatinine ratio from canine and feline urine samples has been shown to accurately reflect the amount of protein excreted in the urine over a 24-hour period. This test has greatly facilitated the diagnosis of glomerulonephritis in small animals. Most studies suggest that normal urine protein excretion in dogs and cats is less than 10 to 20 mg/kg/24 hours. A regression line equation allows the urine protein/creatinine ratio, when multiplied by approximately 20, to be converted to milligrams of protein per kilogram per 24 hours. A urine protein/creatinine ratio of less than 0.5 to 1.0 is usually considered normal in dogs and cats. A complete urinalysis should always be obtained before or along with the urine protein/creatinine ratio, because hematuria or pyuria may indicate significant nonglomerular proteinuria. If evidence of inflammation is present (e.g., pyuria, bacteriuria), the protein determination should be repeated after successful treatment of the inflammatory disorder. The urine protein/creatinine ratio cannot be used to differentiate glomerular proteinuria from proteinuria associated with lower urinary tract inflammation or hemorrhage.

Urine and serum protein electrophoresis may be helpful both in identifying the source of the proteinuria and in establishing a prognosis. Proteinuria associated with hemorrhage into the urinary tract has an electrophoretic pattern similar to that of the serum. Early glomerular damage usually results principally in albuminuria; however, with progression of the glomerular disease, an increasing amount of globulin may be lost as well. Marked hypoalbuminemia and increased concentrations of larger molecular weight proteins in the serum suggest severe glomerular proteinuria and are often associated with nephrotic syndrome.

The consequences of glomerular proteinuria may include loss of plasma oncotic pressure, sodium retention, formationof edema and/or ascites, hypercoagulability, muscle wasting, and weight loss. With progressive renal disease and nephronloss, proteinuria tends to diminish as the number of affected glomeruli decrease. However, the remaining viable nephrons that have undergone compensatory hypertrophy exhibit intraglomerular hypertension and hyperfiltration. Protein loss remains increased in these individual nephrons. Evidenceis accumulating in many species, including the dog and cat, that proteinuria can contribute to progressive nephron loss through tubulointerstitial damage and exacerbation of glomerular lesions.

33 CHAPTER • 33 Gastrointestinal: Anorexia

John P. Hoover

William E. Monroe

In general, a good appetite for food is associated with health, whereas *anorexia,* or loss of appetite, is associated with illness. Reduced food consumption is a common manifestation of disease. When accompanied by observable weight loss, anorexia often prompts pet owners to seek veterinary attention. Anorexia may be the result of decreased appetite (true anorexia) or may occur secondary to other factors that do not affect appetite *(pseudoanorexia)*. Anorexia can range from partial to complete and can reflect the severity or cause of disease.

33.1 PATHOPHYSIOLOGY

Appetite was once simplistically thought to be controlled by a "hunger" or "feeding center" in the lateral (hypothalamic) nuclei (LHN) as modulated or inhibited by a "satiety center" in the ventromedial nuclei (VMN) of the hypothalamus. Chemical mediators produced by vagal or sympathetic stimulation of central and peripheral receptors provide LHN and VMN input that alters appetite. *Satiety* is associated with the absence of hunger during the absorptive phase after food ingestion, when metabolic fuels are supplied by nutrients assimilated from the gastrointestinal tract. *Hunger* is associated with the postabsorptive phase before food ingestion when energy must be derived from mobilization of stored nutrients such as glycogen, triglycerides, and proteins to provide glucose, fatty acids, and amino acids. Current evidence suggests that in addition to the LHN and VMN, the amygdala, the solitary nuclei, arcuate nuclei, paraventricular nuclei (PVN), and suprachiasmic nuclei, the anterior piriform cortex, and the telencephalon play important roles in facilitating or inhibiting appetite by means of a plethora of peripheral and central neurochemical mediators or transmitters.

33.2 HISTORICAL FINDINGS

Environmental or psychologic factors that an owner may not perceive as significant (e.g., fear, dominance) may lead to pseudoanorexia. The addition of animals that are threatening or aggressive may interfere with eating. A new baby or other individuals who make an animal feel threatened or ignored, or a change of housing, may also affect appetite. Changing the diet to one that is less palatable may lead to anorexia or a reduced appetite.

Animals that lack a sense of smell *(anosmia)* may have difficulty finding their food, and animals with severe nasal disease, especially cats, may find food unpalatable. Pets with lingual, pharyngeal, or esophageal dysfunction or those with neurologic disorders that affect swallowing (e.g., trigeminal neuritis) may show interest in food but may drop it and be unable to eat. Others with painful retrobulbar abscesses, masticatory myositis, mandibular fractures, temporomandibular joint disease, maxillary or nasal fractures or masses, severe periodontal or dental disease, or oral foreign bodies may attempt to eat only to stop, cry out, and drop food. Some may show no interest in eating. There may be a history of trauma, feeding of bones, or chewing on sticks or other potential sources of self-trauma. Animals with respiratory disease and marked dyspnea or orthopnea may be unable or unwilling to eat or drink due to compromise in breathing during prehension and deglutition.

The historical findings in animals that do not eat because of systemic disease are variable and depend on the disease present. In general, animals that are anorectic because of systemic disease have no interest in food. Pain, lameness, motor dysfunction, urination abnormalities, vomiting, diarrhea, coughing, and dyspnea all may be signs

of disease that leads to anorexia. Animals with neurologic disease that results in decreased eating because of reduced cerebral arousal may have a history of behavioral changes or stupor.

Medications also may cause partial or complete anorexia through direct effects on appetite centers. Chemotherapeutic agents may inhibit appetite by inducing nausea. Opioid peptides inhibit the orexigenic network and suppress appetite. Supplying glucose, fatty acids, and amino acids by intravenous infusion may promote satiety and decrease hunger similar to that seen after eating, in the absorptive state.

33.3 PHYSICAL FINDINGS

Animals that are anorectic because of psychologic causes, such as environmental stress or unpalatable diet, usually are normal on physical examination. Bite or fight wounds may be present in pets that are not eating because of the presence of another dominant animal or excessive competition. The veterinarian can determine if an animal is having trouble finding food because of a poor sense of smell by blindfolding the pet and placing aromatic food near its nose. If the animal shows no sniffing behavior, it may not be able to smell. Observing the animal walk around the examination room where other animals have been may also reveal whether it has a sense of smell, because most pets exhibit sniffing behavior in these circumstances.

An animal that is unable to eat because of pain or dysfunction of the oral area may resist or cry out when the mouth is opened for examination. Skull fractures, soft tissue trauma, neoplasia, craniomandibular arthritis or osteoarthropathy, masticatory myositides, and retrobulbar masses all may be associated with pain when attempts are made to open the mouth. Asymmetry of the face, mandible, nose, mouth, or skull may be apparent. Evidence of dental disease may be noted, such as severe calculus, loose or broken teeth, pain, or exudation when applying pressure to or tapping on the teeth. Ulcers, wounds, stomatitis, gingivitis, masses, or foreign bodies such as sticks, rocks, or bones may be noted when the mouth and pharynx are examined. If nasal disease is the cause of poor appetite, nasal swelling, epistaxis, mucopurulent discharge, masses, or ulceration of the mucocutaneous junctions of the nares may be seen. Exophthalmos often is noted with retrobulbar abscesses or tumors and masticatory myositides. Trigeminal neuritis or trauma to the jaw may be associated with a dropped jaw and inability to eat.

117 118

Physical examination abnormalities associated with systemic diseases that cause anorexia are as varied as the potential causes of disease. Fever, pallor, jaundice, ocular abnormalities, abdominal pain, abnormally small or large organ size, abdominal distention from fluid accumulation, spinal or limb pain, masses or swellings, cardiac murmurs, dyspnea with muffled heart and lung sounds, and adventitial breath sounds all are signs of diseases that can lead to anorexia.

33.4 DIAGNOSTIC PLAN

A thorough history is the essential diagnostic tool for psychologic or iatrogenic causes of anorexia. A thorough physical examination, in conjunction with the history, is essential to help determine physiologic causes of anorexia (Figure 33-1). Pets that are anorectic, particularly those that seem interested in food but are unable or refuse to eat, should receive a thorough oral, dental, and cranial examination. If the dog or cat is uncooperative, sedation or anesthesia may be necessary. In addition to the more routine physical examination procedures, the spine should be carefully palpated for pain (e.g., discospondylitis), and a careful rectal examination should be performed in all dogs to determine prostate size (in males), to detect pelvic masses, or to assess for unsuspected abnormalities, such as hematochezia or perineal hernias. When respiratory distress due to pleural space disease is present, thoracocentesis can provide symptomatic relief, and fluid analysis may prove diagnostic. A fundic examination after pupil dilatation should be included in the examination, because systemic diseases such as feline infectious

peritonitis, lymphoma, deep mycoses, toxoplasmosis, and rickettsial infections may have characteristic ocular changes.

For pets without a history that supports a psychologic cause for anorexia and that also have no physical examination abnormalities to indicate a physiologic cause, a minimum data base should be compiled that includes a complete blood count, serum chemistry profile, urinalysis with microscopic examination of the sediment, a heartworm test in dogs, and feline leukemia virus and immunodeficiency virus serology in cats. These tests may suggest inflammatory, degenerative, endocrine, metabolic, neoplastic, or toxic disorders that can lead to anorexia. If systemic disease appears to be the probable cause of anorexia, further diagnostic testing should be directed toward abnormalities identified by the history, physical examination, and minimum data base. For cases in which no historical, physical, or data base abnormalities can be found, thoracic and abdominal radiographs or ultrasonography may reveal evidence of occult disorders, such as thoracic masses, gastrointestinal foreign bodies or masses, or pericardial, pleural, or abdominal fluid. When these procedures reveal no abnormalities, gastrointestinal endoscopy, contrast radiographic studies, or a computed tomography (CT) scan may be indicated to rule out the possibility of neoplasia or other infiltrative diseases. Multiple joint centesis may also be indicated to rule out the possibility of polyarthritis.

33.5 GOALS OF TREATMENT

The first goal of therapy for anorexia should be to correct any underlying causes, such as oropharyngeal or systemic inflammatory disease. Although definitive treatment requires a definitive diagnosis, animals that have been anorectic for longer than 3 to 5 days should receive nutritional support through enteral or parenteral feeding (see Chapters 92 and 161) until the definitive diagnosis can be made.

Appetite stimulation by drug therapy focuses on agents that affect central nervous system serotonin and dopamine receptors. Benzodiazepines and the serotonin antagonist cyproheptadine induce hunger and inhibit physiologic sati-ety. Megestrol acetate may stimulate appetite by centralinhibition of anorexigenic hormones, such as corticotrophin-releasing hormone, as in human cancer patients. The efficacy of gastrokinetic agents in stimulating appetite in anorecticanimals hasn't been established, but metoclopramide, cisapride, and the peripheral dopamine D2 receptor antagonist domperidone have yielded positive results in some human beings.

34 CHAPTER • 34 Polyphagia

Ellen N. Behrend

***P**olyphagia* is the consumption of food in excess of normal caloric intake. Hunger and satiety and, consequently, feeding behavior are primarily controlled by certain regions in the central nervous system (CNS), but many factors affect the function of these areas. Thus polyphagia can be classified as *primary* (i.e., a CNS abnormality) or *secondary* (i.e., a systemic problem affecting the CNS). Secondary polyphagia is by far more common and usually is accompanied by clinical signs of the underlying disease. Determining whether weight gain or loss has occurred should be the first step in formulating a list of differential diagnoses and a diagnostic plan.

34.1 PHYSIOLOGY

Food intake is controlled by a variety of factors, including gastrointestinal, environmental, and CNS phenomena. The CNS, mainly the hypothalamus, controls eating behavior. The lateral hypothalamic nuclei represent the "feeding center"; their stimulation causes an animal to eat, and their destruction results in severe, fatal anorexia. Conversely, the ventromedial nuclei are the "satiety center," because their stimulation causes a refusal to eat even highly appetizing food, and their ablation leads to polyphagia and obesity. The feeding center is constantly active unless inhibited by the satiety center (e.g., postprandially). Lesions of the amygdala or paraventricular nuclei also can increase feeding behavior.

Gastrointestinal components that affect feeding include gastric distention, the rate of gastric emptying, the release of gastric hormones, and absorption of nutrients, such as fatty acids, glucose, and amino acids. The gut hormones can act locally on the gastrointestinal tract and centrally on the CNS. Insulin, glucagon, and cholecystokinin secreted in response to a meal decrease feeding signals from the CNS. Leptin, a polypeptide released from adipose tissue, may also help to create a sense of satiety. Decreased serum concentrations of glucose, amino acids, or lipid metabolites cause hunger by stimulating neural centers so as to re-establish normal levels. Feeding behavior also can be incited by increased nutrient utilization (i.e., an elevated metabolic rate).

Normal control of feeding, therefore, is complex and works to maintain energy stores and body weight through an interplay of central and peripheral inputs. Pathologic conditions that affect the CNS can increase feeding behavior even in the presence of normal energy stores *(primary polyphagia)*. *Secondary polyphagia* exists when feeding behavior is stimulated by non-neural factors and can be caused by an increased metabolic rate or decreased nutrient supply (Box 34-1). An augmented metabolic rate can be physiologic (e.g., pregnancy) or pathologic (e.g., hyperthyroidism) in origin. Diabetes mellitus is an unusual case of decreased nutrient supply. Due to an inability to respond to or a lack of insulin, the body does not recognize glucose and reacts to a perceived hypoglycemia. Certain diseases (e.g., hyperadrenocorticism and liver disease) lead to polyphagia by unknown mechanisms. Secondary polyphagia can also be caused by certain drugs.

34.2 HISTORY

Any change in body weight is an important differentiating feature of the various causes of polyphagia (Figure 34-1). Primary or drug-induced polyphagia typically results in weight gain, because nutrients are adequate and feeding is inappropriately increased. Pathologic secondary polyphagia is more commonly associated with weight loss, because the nutrient supply usually does not meet physiologic demands. However, some causes, such as acromegaly, hypoglycemia caused by an insulinoma, sudden acquired retinal degeneration syndrome (SARDS), and hyperadrenocorticism (HAC), lead to weight gain. Physiologic polyphagia can result in weight gain (e.g.,

pregnancy, growth) or maintenance of weight (e.g., lactation, cold environment, increased exercise). An animal with HAC or in the early stages of any of these states, however, may show no weight change.

Certain causes of polyphagia may be diagnosed on the basis of the history. The possibility of exposure to a cold environment, increased exercise and, for intact females, pregnancy and lactation should be ascertained. Polyphagia is commonly associated with anticonvulsant and glucocorticoid therapy but has been observed with other medications as well (see Table 34-1). Psychogenic polyphagia has been noted after introduction of a more palatable diet or in response to a stressful event, most commonly introduction of a new pet into the household. Feeding of a low-calorie diet may also be diagnosed on the basis of a complete dietary history.

An animal with primary polyphagia caused by destruction of the satiety center may have a history of trauma or clinical signs associated with CNS disease. Depending on the extent of a hypothalamic lesion, upper motor neuron signs may be seen in all four limbs or unilaterally. A midbrain lesion often leads to incessant pacing, circling, and blindness; polyuria/polydipsia may also be present. Disorders caused by diffuse or multifocal CNS disease will have other clinical signs as well, depending on the areas affected.

Perturbation of hypothalamic control of the pituitary can lead to reproductive, thyroidal, and adrenal hypofunction and associated clinical signs. Hypothyroidism secondary to pituitary dysfunction is clinically identical to primary thyroidal failure. If adrenal insufficiency occurs secondary to a lack of adrenocorticotropic hormone (ACTH), vague, nonspecific signs of lethargy and gastrointestinal disease usually are seen. Serum electrolyte concentrations (e.g., sodium and potassium) are normal because aldosterone secretion is not affected by pituitary disease. This type of hypoadrenocorticism is referred to as *atypical*.

120
121

Historical findings associated with secondary polypha-gia can be highly varied. Animals with diabetes mellitus, acromegaly, HAC, SARDS, and hyperthyroidism usually are polyuric and polydipsic. Feline acromegaly is seen in middle-aged to older males, and naturally occurring canine acromegaly is seen almost exclusively in intact bitches. In dogs of either sex, progestin administration can lead to acromegaly, and use of this medication should be historically evident. Owners may note inspiratory stridor or a change in body conformation, such as increased interdental spaces, skin folds, or head size in acromegalic animals. It should also be noted that progestin administration to dogs and cats can increase appetite without causing acromegaly. A multitude of historical details can be associated with HAC, including abdominal enlargement, persistent panting, failure to regrow hair after clipping, lethargy, and muscle weakness. Animals with SARDS typically have the presenting complaint of sudden-onset blindness. Hyperthyroidism commonly leads to increased activity but can be associated with depression and lethargy. Gastrointestinal signs (e.g., vomiting and diarrhea) may also be present.

34.2.1

Box • 34-1 Differential Diagnoses of Polyphagia

34.2.1.1

Primary Polyphagia

Destruction of satiety center

- Trauma
- Mass lesion (e.g., neoplasia)
- Infection

Psychogenic causes

- Stress
- Introduction of a more palatable diet

34.2.1.2 Drug-Induced Polyphagia

Glucocorticoids

Anticonvulsants

Antihistamines

Progestins

Benzodiazepines

Amitraz

Cyproheptadine

34.2.1.3 Reported Specific Disorders Associatedwith Polyphagia

Feline infectious peritonitis

Lymphocytic cholangitis (feline)

Spongiform encephalopathy (feline)

Foreign body encephalitis (feline)

34.2.1.4 Secondary Polyphagia

Physiologic increase in metabolic rate

- Cold temperature
- Lactation
- Pregnancy
- Growth
- Increased exercise

- Pathologic increase in metabolic rate
  - Hyperthyroidism
  - Acromegaly
- Decreased energy supply
  - Diabetes mellitus
  - Malassimilation syndromes
    - Pancreatic exocrine insufficiency
    - Infiltrative bowel disease
    - Parasites
    - Lymphangiectasia
  - Decreased intake
    - Megaesophagus (congenital)
    - Low-calorie diet
    - Hypoglycemia
  - Unknown
    - Hyperadrenocorticism
    - Portasystemic shunt/hepatoencephalopathy
    - Sudden acquired retinal degeneration (SARDS)

Hypoglycemia has a number of causes. Of these, insulinoma is the most likely to lead to polyphagia, but other neoplasias and insulin overdose may also do so. Hypoglycemic patients may exhibit weakness, trembling, ataxia, disorientation and, possibly, grand mal seizures. Malassimilation can be caused by a number of problems such as pancreatic exocrine insufficiency (PEI), infiltrative bowel disease, parasites, and lymphangiectasia. Malassimilation syndromes and PEI generally cause large-volume, malodorous, soft stools. PEI is more common in younger dogs (i.e., those less than 2 years of age), and the German shepherd breed shows a predisposition for this disorder. In older dogs and cats, PEI is rare but, if seen, is most commonly associated with chronic pancreatitis. The category of infiltrative disease encompasses processes such as inflammatory bowel disease, neoplasia, and infections such as histoplasmosis. Historical details vary according to the underlying disease.

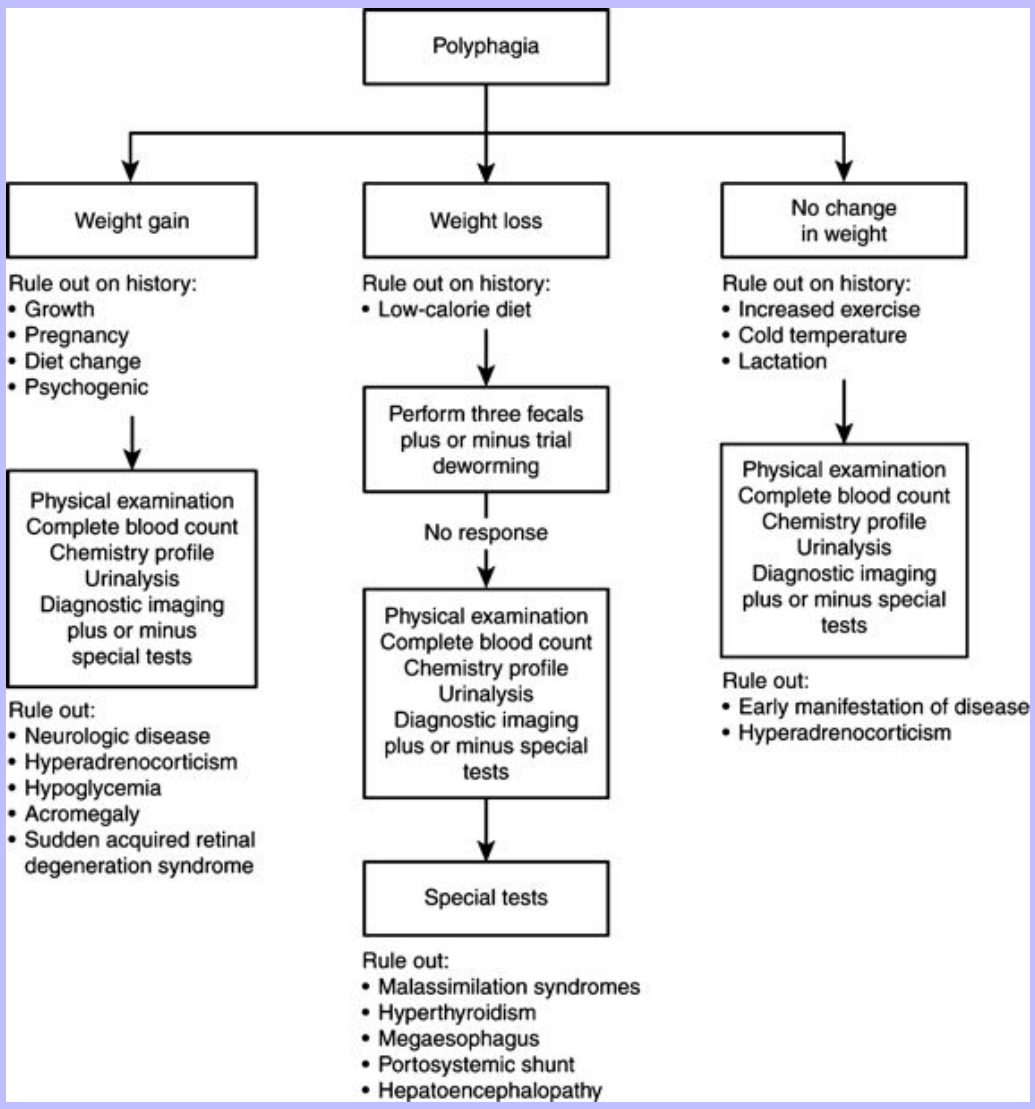
Acquired esophageal disease often leads to anorexia, but animals with congenital megaesophagus may be polyphagic and typically have a history of regurgitation. Although anorexia is more common in animals with a portacaval shunt, polyphagia has been reported in approximately 10% of cases. Depression, vomiting, weight loss, polydipsia, and neurologic signs may also be noted. Polyphagia has been reported rarely in cases of hepatoencephalopathy; other clinical findings are the result of hepatic failure and may be similar to those in an animal with a portasystemic shunt.

34.3 PHYSICAL EXAMINATION

Physical examination findings in polyphagic animals vary, depending on the underlying disease. With primary polyphagia, neurologic abnormalities such as ataxia and proprioceptive deficits may be present. A complete neurologic and fundic examination should be performed. With acute causes of central blindness, however, the fundus appears normal.

If unclear from the history, pregnancy potentially can be diagnosed by abdominal palpation and lactation by inspection of the mammae. Approximately 80% of cats with hyperthyroidism have a palpable thyroid nodule, and approximately 50% have tachycardia or a gallop rhythm. Hyperthyroidism is rare in dogs, and a cervical mass usually is palpable. Hyperadrenocorticism can have a variety of physical examination findings, including abdominal and hepatic enlargement, muscle wasting, bilaterally symmetric alopecia, cutaneous hyperpigmentation, areas of poor hair regrowth or calcinosis cutis. Even when not noted by an owner, the physical changes associated with acromegaly can be documented on physi-cal examination; a degenerative polyarthropathy may alsobe present.

Figure 34-1 Algorithm for diagnostic approach to polyphagia.



121

122

Examination findings in a dog with SARDS may be unremarkable, because in the early stages of the disease, the retinas appear normal on fundic examination. Dogs or cats with PEI, an insulinoma, megaesophagus, hepatoencephalopathy, a portasystemic shunt, or a malassimilation syndrome may have no abnormal physical findings other than the associated weight change. In rare cases, polyneuropathies may accompany an insulinoma. Aspiration pneumonia may be presentin animals with megaesophagus. Neurologic abnormalities may be detected in an animal with a portasystemic shunt, and ascites is noted in approximately 20% of afflicted dogs. Neurologic findings associated with hepatoencephalopathy may be episodic, and other examination findings vary with the cause of liver disease. Depending on the cause of malassimilation, the intestines may feel thickened. Lymphangiectasia may lead to ascites.

Occasionally, polyphagia may be a clinical sign of a disease with which it is not usually associated. For example, one cat with feline infectious peritonitis (FIP), one with foreign body encephalitis, and one with spongiform encephalopathy have been reported as being polyphagic, as have 18 cats in Great Britain with lymphocytic cholangitis. Other historical and clinical signs are present depending on the cause.

34.4 DIAGNOSTIC PLAN

The first step in diagnosis is to ascertain what change has occurred, if any, in the animal's weight (see Figure 34-1). After as many differential diagnoses as possible have been ruled out on the basis of the history, further testing is warranted. In all cases a minimum data base (MDB), including a serum biochemistry profile, complete blood count (CBC), and urinalysis, should be submitted.

For dogs and cats with weight gain, pregnancy must be ruled out. To diagnose primary polyphagia, a complete neurologic examination should be performed, any abnormalities localized, and appropriate tests obtained. A cerebrospinal fluid analysis or diagnostic imaging, such as radiography, computed tomography (CT), or magnetic resonance imaging (MRI), may be necessary.

Hypoglycemia caused by an insulinoma usually can be diagnosed by measuring paired blood glucose and insulin serum concentrations when the animal is hypoglycemic. Rarely, provocative testing may be required (see Chapter 240). The diagnosis of SARDS can be made on the basis of appropriate history, physical examination findings, an MDB that rules out other causes and, if necessary, an electroretinogram (ERG). Although certain changes in the MDB are typical of hyperadrenocorticism, they do not confirm the diagnosis and further adrenal testing must be performed; an ACTH stimulation test or low-dose dexamethasone suppression test should be performed to confirm the diagnosis (see Chapter 242). Diagnosis of acromegaly can be difficult because of the lack of a commercial assay for growth hormone, but measurement of insulin-like growth factor-I (IGF-I) may be helpful (see Chapter 235). The history, together with conformational changes, can provide evidence of the underlying disease. Acromegalic cats consistently have insulin-resistant diabetes mellitus, and imaging of the pituitary may reveal a tumor.

122
123

If weight loss is associated with polyphagia, the MDB should be preceded by three fecal examinations. If the results of these are negative, the MDB does not provide the diagnosis, and the animal is stable, trial therapy with antiparasiticides may be warranted. If deworming does not resolve the problem, additional tests must be done. Hyperthyroidism often can be diagnosed on the basis of a single serum thyroxine measurement; however, other tests, such as measurement of the free thyroxine concentration by equilibrium dialysis, may be required (see Chapter 238).

Malassimilation syndromes cover myriad differential diagnoses (see Table 34-1). Protein-losing enteropathies can be associated with hypoalbuminemia and hypoglobulinemia. Depending on the suspected cause, measurement of serum folate or cobalamin, assessment of fat absorption, abdominal radiography or ultrasonography, and/or biopsy either by endoscopy or exploratory surgery may also be considerations. For verification of PEI, serum trypsin-like immunoreactivity (TLI) should be determined. Thoracic radiographs with a positive contrast esophagram should be used to diagnose megaesophagus; this imaging may also aid in the determination of the cause. Determination of preprandial and postprandial serum bile acid concentrations can document hepatic dysfunction, but a biopsy may be required to document the cause of hepatic failure. Ultrasonography or a radionuclide scan may be used to identify a portacaval shunt.

If the disease is in the early stages, weight change may not yet have occurred, and the list of differentials may be difficult to narrow. However, a good history and physical examination combined with an MDB can eliminate

many possibilities. Although animals with HAC may not have a weight change, abdominal enlargement may create the impression of weight gain. All diseases suspected as possible differential diagnoses in this situation should be diagnosed as discussed above.

34.5 MANAGEMENT

The management of polyphagia depends on the cause. Physiologic causes of polyphagia are transient. If the condition is drug induced, the polyphagia may be temporary, as is usually seen with anticonvulsants. Psychogenic polyphagia may be corrected by removing the instigating element, if possible, or by behavioral therapy (e.g., paying more attention to the animal). If the polyphagia persists with ongoing drug therapy or if the inciting agent (stress or medication) cannot be removed, food intake should be limited to that necessary to satisfy caloric requirements. Low-calorie, high-fiber foods, such as carrots, can be added to the diet to assuage hunger and prevent obesity. Polyphagia caused by dietary factors can be managed as needed. In cases of SARDS, the poly-phagia usually is self-limiting. For all other conditions, appropriate therapy should be initiated to resolve the underlying disease.

35 CHAPTER • 35 Ptyalism

Sandra Manfra Marretta

***P**tyalism* is the excessive production and secretion of saliva. *Pseudoptyalism* is the drooling or dribbling of saliva because of an inability or reluctance to swallow, which results in an overflow of saliva from the oral cavity.

35.1 PATHOPHYSIOLOGY

Saliva is continuously produced by the salivary glands. The production of saliva may be increased by excitation of the salivary nuclei, located in the brain stem, after taste and tactile stimuli are received from the tongue and other areas in the oral cavity. Higher centers in the central nervous system (CNS) may also have an excitatory or inhibitory affect on the salivary nuclei. Increased production of saliva is a normal physiologic occurrence associated with imminent feeding, hyperthermia, and purring in cats.

Oral lesions and central nervous system disorders may stimulate an increase in the production of saliva. Diseases of the pharynx, esophagus, and stomach also may stimulate the production of excessive amounts of saliva. In some cases this excess may be clinically evident not as drooling but as frequent episodes of swallowing.

Anatomic abnormalities of the oral cavity may cause saliva to drip from the mouth even when normal amounts of saliva are produced. Drooling is evident with diseases in which the animal is unable or reluctant to swallow because of pain associated with swallowing.

35.2 HISTORICAL FINDINGS AND THEIR MEANINGS

35.2.1 Age and Breed

Young animals with congenital anomalies, including porto-systemic shunt and megaesophagus, may hypersalivate. Jaw abnormalities, such as severe retrognathism, may cause excessive drooling. In some giant breed dogs, the shape and size of the lower lip may predispose to drooling. Young animals are more indiscriminant in their eating habits, which results in a higher incidence of ingestion of foreign bodies, constipation, consumption of caustic materials, and biting on electrical cords.

35.2.2 Diet

High-protein diets can precipitate excessive salivation in animals with a portosystemic shunt. Animals with painful oral lesions may refuse to eat hard food, preferring bland, soft diets.

35.2.3 Eating Behavior

If ptyalism is caused by oral pain, the animal may drop food when attempting to eat or chew on one side.

35.2.4 Anorexia and Weight Loss

When anorexia and severe weight loss accompany ptyalism, the potential for acute or chronic oral lesions, systemic diseases, and gastrointestinal disorders should be considered.

35.2.5 Drugs and Toxins

Various drugs and toxins can cause adverse reactions, including hypersalivation, in animals. Unpleasant-tasting drugs may cause excessive salivation. Administration of higher than normal therapeutic levels of organophosphates may cause cholinergic signs including ptyalism. Overdoses of other drugs that may cause hypersalivation include: pyrethrin and pyrethroid insecticides, D-limonene (citrus oil insecticide), ivermectin, fluids containing a benzoic acid derivative, caffeine, amphetamines, cocaine, and opiates. Toxins that irritate the oral cavity include thallium, metaldehyde, and cresol. The secretions of various toads and newts and the venom of black widow spiders can cause ptyalism. Plants, including *Amanita* mushrooms, nettles, dumb cane, philodendron, dieffenbachia, poinsettia, and Christmas trees, can cause increased salivation. Household cleaning products can irritate the oral mucosa, resulting in hypersalivation.

35.2.6 Anesthesia

A potential complication of anesthesia is reflux esophagitis. Clinical signs, including hypersalivation and regurgitation, may develop 1 to 4 days after anesthetic episodes.

35.2.7 Swallowing Difficulty

Evaluation of dysphagia as a potential cause of excessive drooling can be supported by observing the dog or cat eating and drinking. Pharyngeal lesions, neuromuscular disease, and abnormally large retropharyngeal lymph nodes can cause dysphagia.

35.2.8 Regurgition

Excessive salivation may occur in animals that regurgitatesecondary to esophageal disease. In cases of chronic reflux esophagitis, hypersalivation, regurgitation, and vomiting often occur soon after eating. Regurgitation and hypersalivation may also be seen in animals with esophageal foreign bodies or tumors.

35.2.9 Vomiting

Nausea is the first stage in the complex process of vomiting, which may be accompanied by hypersalivation and frequent episodes of swallowing.

35.2.10 Behavioral Changes

Animals with oral pain may show behavioral changes, including depression and/or aggressiveness. These changes may also be associated with hepatic encephalopathy and rabies.

35.2.11 Hepatic Encephalopathy Signs

Animals with CNS signs, behavioral changes, and signs of hepatic failure including anorexia, weight loss, lethargy, polydipsia, polyuria, nausea, ptyalism, vomiting, and diarrhea should be evaluated for hepatic encephalopathy.

35.2.12 Seizures

During a seizure, ptyalism may occur secondary to autonomic discharge, reduced swallowing of saliva, and clonic movements of the jaw.

35.3 PHYSICAL FINDINGS AND THEIR INTERPRETATION

35.3.1 Halitosis

Halitosis usually is associated with oral pathology, including periodontal disease, oral ulcers, cheilitis, stomatitis, or neoplasia. Esophageal and gastric disorders less frequently may cause halitosis.

35.3.2 Oral Cavity

35.3.2.1 Oral Trauma

Animals that are drooling after a traumatic event should be carefully evaluated for oral trauma. Fractured teeth, with pulpal exposure or jaw fractures, cause significant pain and may result in secondary hypersalivation. With bilateral mandibular fractures, the rostral mandible drops and excessive drooling occurs.

35.3.2.2 Periodontal Disease

Severe periodontal disease may cause significant gingival and oral mucosal inflammation. Severe contact ulcerations may occur on the mucosa in contact with the teeth, causing extreme oral pain and ptyalism.

35.3.2.3 Stomatitis

Stomatitis, which frequently is associated with ptyalism, has many underlying causes, including local factors, immune-mediated diseases, systemic infections, toxins, and immunologic or nutritional deficiencies.

35.3.2.4 Oral Masses

Neoplasms, eosinophilic granulomas, and granulomatous lesions may occur in the oral cavity. Ulcerated masses may be painful and cause ptyalism. Caudal oral masses or those that interfere with tongue movement may cause difficulty with swallowing, resulting in excessive drooling.

35.3.2.5 Glossitis

Lingual ulcers often are painful and may result in hypersalivation. Irritation of the tongue may be caused by chemical or environmental substances, viral infections, metabolic disorders (uremia), immune-mediated diseases, and tumors.

35.3.2.6 Base of the Tongue

The base of the tongue should be examined thoroughly, with the animal under sedation if necessary, to rule out the presence of a mass or foreign body. Linear foreign bodies may be trapped around the base of the tongue, and penetrating foreign bodies may cause severe inflammatory responses and pain, resulting in hypersalivation.

35.3.2.7 Faucitis

Severe inflammation and ulceration of the glossopalatine arch occurs primarily in cats. Severe faucitis is painful, and affected cats exhibit severe discomfort when the mouth is fully opened.

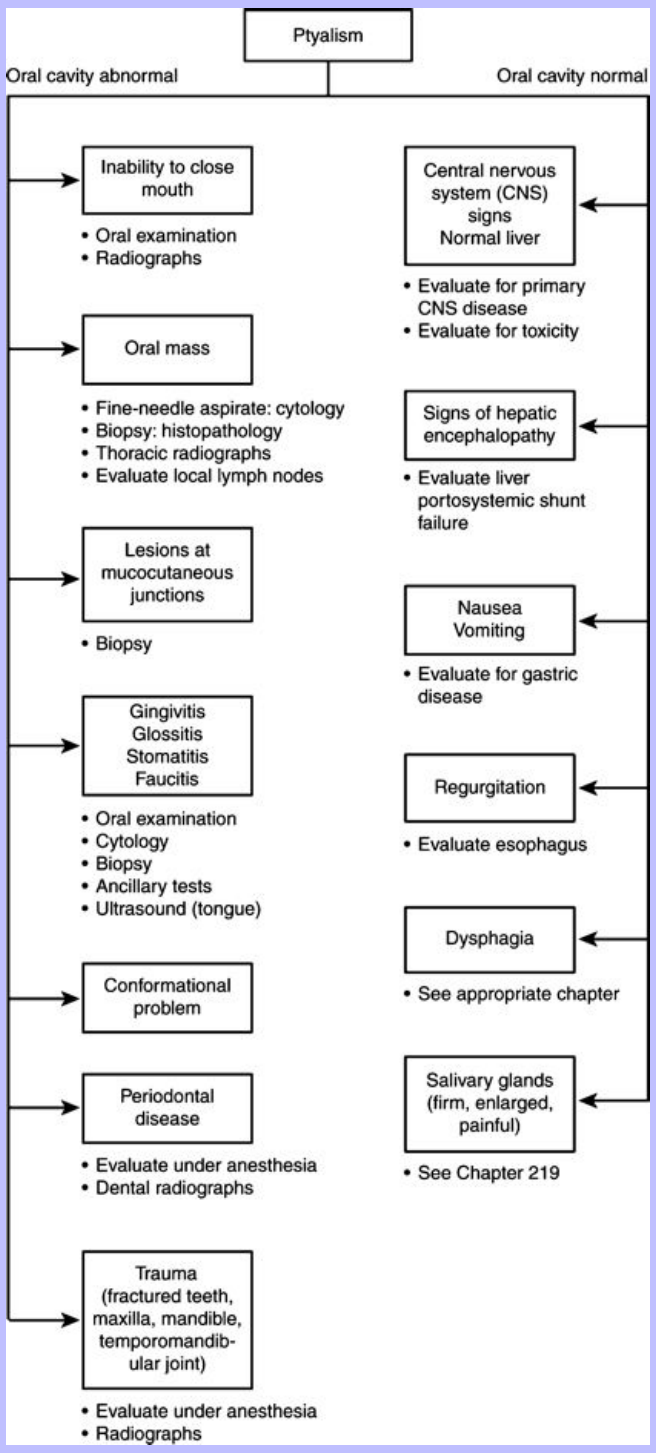
35.3.3 Blood-Tinged Saliva

Blood-tinged saliva most frequently is indicative of bleeding from the oral cavity. Less frequently, it may be associated with bleeding from the upper intestinal tract, nasal passages, or lungs.

35.3.4 Mucocutaneous Junction Ulcerations

When ulcerative stomatitis is associated with ulcerations at the mucocutaneous junctions, the possibility of an immune-mediated disease should be considered.

Figure 35-1 Algorithm for differential diagnosis of ptyalism.



35.3.5 Facial Pain

Ptyalism may occur secondary to pain associated with oralor pharyngeal disease, and these patients may resist oralexamination.

35.3.6 Dysphagia

Space-occupying lesions and severe inflammatory lesions in the pharyngeal region may cause dysphagia and excessive drooling.

35.3.7 Cranial Nerve Deficits

Lesions of the trigeminal nerve (cranial nerve [CN] V) can cause drooling secondary to an inability to close the mouth. Facial nerve palsy (CN VII) may cause drooling from the affected side because of inability to move the lip. Glossopharyngeal (CN IX), vagus (CN X), and hypoglossal (CN XII) nerve lesions can cause loss of the gag reflex or inability to swallow and secondary drooling.

35.3.8 Dropped Jaw

Trigeminal nerve (CN V) paralysis prevents voluntary closure of the mouth. The differential diagnoses in these cases include idiopathic trigeminal neuritis, bilateral mandibular fractures, and infectious diseases, such as rabies.

35.3.9 Inability to Close Mouth with Assistance

Animals with acute sustained inability to close the mouth, even with assistance, will hypersalivate. Foreign bodies or displaced teeth may interfere with normal occlusion and closure of the mouth. Displacement of the coronoid process lateral to the zygomatic arch or temporomandibular luxations may resultin intermittent or sustained locking of the jaw in an openposition.

35.3.10 Muscle Atrophy

Muscle atrophy may occur secondary to cranial nerve deficits or muscular disorders, such as myositis, that may result in difficulty swallowing.

35.3.11 Lymph Nodes

Retropharyngeal lymph node enlargement or regional lymphadenopathy may cause dysphagia.

35.3.12 Salivary Glands

Ptyalism rarely may be associated with salivary gland enlargement or necrosis.

35.4 DIAGNOSTIC PLAN

A systematic approach is required for diagnosing the underlying cause of ptyalism in animals. The initial plan in all dogs and cats should include a thorough history and physical examination, followed by appropriate diagnostic procedures based on the history and physical findings (Figure 35-1).

36 CHAPTER • 36 Gagging

William Gengler

***G**agging* is defined as the swallowing-vomiting reflex activity of the elevation of the soft palate followed by a reverse peristalsis of the upper digestive tract. *Swallowing* is the taking in of a substance through the mouth and the pharynx and into the esophagus. It is a combination of a voluntary act and a series of reflex actions. Once begun, the process operates automatically. The swallowing reflex is a rigidly ordered sequence of events that propels food from the mouth to the stomach while concurrently inhibiting breathing and preventing food from entering the trachea.

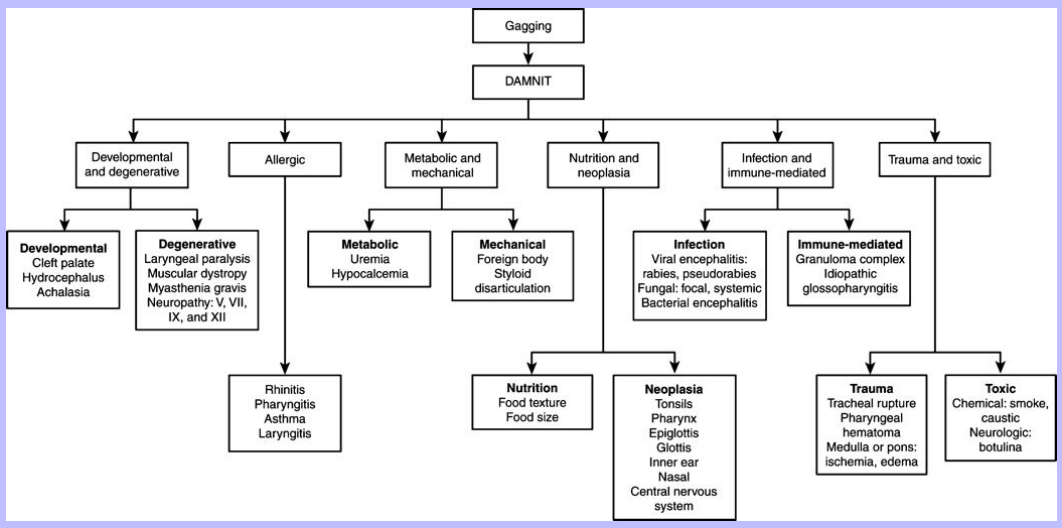
The nerves involved with swallowing are the sensory and motor branches of the trigeminal nerve (CN V), the hypoglossal nerve (CN XII), the facial nerve (CN VII), and the glossopharyngeal nerve (CN IX). The afferent limb of the swallowing reflex begins with tactile receptors, most notably those near the opening of the pharynx. Sensory impulses from these receptors are transmitted to certain areas in the medulla. The central integrating areas for swallowing lie in the medulla and lower pons, called the *swallowing center*. Motor impulses travel from the swallowing center to the musculature of the pharynx and upper esophagus via various cranial nerves.

The process of swallowing, called *deglutition,* can be divided into three phases in the dog and cat (and also in human beings): (1) the oral (or voluntary) phase, (2) the pharyngeal phase, and (3) the esophageal phase (Figure 36-1). The *oral phase* is initiated by separation of a bolus of food from the mass in the mouth with the tip of the tongue. The bolus is moved in a dorsocaudal direction in the mouth by pressing first with the tip of the tongue and then with the more caudal tongue segment against the hard palate. The bolus is forced into the pharynx, where it stimulates the tactile receptors that initiate the swallowing reflex. In the cat the oral phase is much longer, marked by bolus accumulation in the valleculae.

The *pharyngeal phase* of swallowing occurs in less than 1 second. During this phase, breathing is reflexly inhibited. The soft palate is pulled dorsally and the palatopharyngeal folds move medially, preventing reflux of food into the nasopharynx. The pharyngeal passage narrows, directing the bolus caudally. Concurrently, the vocal cords move medially and the epiglottis covers the opening of the larynx, preventing food from entering the trachea. The cranial esophageal sphincter relaxes to accept the bolus. The dorsal constrictor muscles of the pharynx contract strongly to force the bolus deep into the pharynx. Peristalsis of these muscles initiates the movement of the bolus caudally through the cranial esophageal sphincter into the esophagus.

The *esophageal phase* of swallowing is partly controlled by the swallowing center. The cranial esophageal (pharyngoesophageal) sphincter, or cricopharyngeus muscle, reflexly constricts after the bolus passes caudal to the sphincter, preventing regurgitation of the bolus. A peristaltic wave, which begins just caudal to the cranial esophageal sphincter, traverses the entire esophagus in approximately 10 seconds. The initial peristaltic wave is termed *primary peristalsis* and is controlled by the swallowing center. If primary peristalsis is insufficient to clear the bolus from the esophagus, distension of the esophagus stimulates *secondary peristalsis,* which is mediated in part by the swallowing reflex and by local stretch receptors.

Figure 36-1 Algorithm for gagging.



During primary and secondary peristalsis, the caudal esophageal (gastroesophageal) sphincter relaxes to receive the bolus into the stomach. In human beings and dogs, the cranial one third of the tunica muscularis of the esophagus is composed predominantly of striated muscle, the caudal one third is composed predominantly of smooth muscle, and the middle one third is a mixture of these two muscle types. In the cat, the esophagus changes abruptly from striated to smooth muscle at the heart. Somatic nerve fibers from the vagus nerve (CN X) form motor endplates on striated muscle fibers. Visceral motor nerves are preganglionic parasympathetic fibers that innervate the smooth muscle cells.

Gagging often is associated with retching. *Retching* is an involuntary and ineffectual attempt at vomiting, and the causes of retching are similar to those that cause vomiting. Another physical sign that resembles gagging is *expectoration,* which involves clearing the airway of mucus and discharges without nausea. For cats, expectoration can be a normal means of clearing the airway of hair after grooming.

37 CHAPTER • 37 Dysphagia and Regurgitation

Emilie Fleming

Dysphagia and regurgitation are both manifestations of swallowing disorders. Close attention to the history, clinical signs, and physical examination findings can help localize the disease process responsible (Figures 37-1 and 37-2).

37.1 DYSPHAGIA

Dysphagia, defined as difficult or painful swallowing, may be due to pain during the swallowing process, mechanical obstruction of the oral cavity or pharynx, or neuromuscular dysfunction that results in weak or uncoordinated swallowing (Box 37-1). Dysphagia generally is broken down into three types: *oral dysphagia* is difficulty prehending and forming a bolus of food at the base of the tongue; *pharyngeal dysphagia* is a malfunction of the involuntary movement of a food bolus through the oropharynx; and *cricopharyngeal dysphagia* is failure of relaxation *(achalasia)* or closure of the cricopharyngeal sphincter or cricopharyngeal asynchrony (Figure 37-1).

37.1.1 Clinical Signs

Clinical signs vary depending on the location or severity of the swallowing defect. Oral dysphagia is expressed by difficulty prehending food and by modified eating behavior, such as tilting or throwing back the head while eating. With pharyngeal dysphagia, prehension of food generally is more normal, but repeated efforts to swallow often are seen, generally accompanied by flexing and extending of the neck. With cricopharyngeal dysphagia, patients make repeated efforts to swallow and may gag or cough. They also may regurgitate immediately after or during swallowing.

37.1.2 History

Very young affected animals are more likely to suffer from congenital defects. For example, cricopharyngeal achalasia generally is seen at the time of weaning from milk to solid food. Young to middle-aged animals are more prone to ingestingforeign bodies, which may become lodged in the esophagus, or caustic substances. Older dogs, or dogs with chronic signs (e.g., weight loss, reluctance to eat) have an increased likelihoodof systemic disease. Acute signs are more consistent with a mechanical obstruction, such as a foreign body, mass, or inflammation. The presence of other cranial nerve signs in conjunction with dysphagia suggests central nervous system (CNS) disease.

37.1.3 Diagnosis

A complete physical examination is essential to enable the clinician to localize the source of the dysphagia. A thorough oral examination, often requiring sedation, is important to evaluate for foreign bodies, masses, stomatitis, and tooth root abscesses. A neurologic examination, including cranial, gait, and peripheral nerves, is essential. It also is important to evaluate the patient as a whole, focusing on body condition, the presence or absence of weight loss, and interest in food. These help narrow down the list of differential diagnoses. Because rabies is a differential diagnosis, caution must be exercised in all cases with any index of suspicion for this disease.

A diagnostic plan begins with survey radiographs of the head, neck, and thorax to evaluate for foreign bodies and evidence of aspiration pneumonia. If other systemic signs are present, a complete blood count, chemistry screen, and urinalysis should be done. If warranted, contrast fluoroscopy motion study or endoscopy can be considered. Also, further blood studies may be indicated to rule out specific disease processes.

37.1.4 Treatment

Treatment of dysphagia involves identification and elimination of the underlying disorder, which may involve medical or surgical treatment. Management with tools such as feeding tubes may be necessary. Treatment of any complications, such as aspiration pneumonia, also is important.

37.2 REGURGITATION

Regurgitation is the passive retrograde expulsion of gastric or esophageal contents (Box 37-2). Regurgitation may occur immediately or minutes to hours after eating. The regurgitant may be either undigested or digested food or liquid. The first important clinical distinction is to differentiate regurgitation from vomiting. This is done by taking a detailed and careful history, by clinician observation of the patient, or by having the owner videotape the event. Regurgitation is differentiated from vomiting by the lack of forceful abdominal contractions. In addition, the regurgitant should not be yellowish green.

130

130

Figure 37-1 Dysphagia.

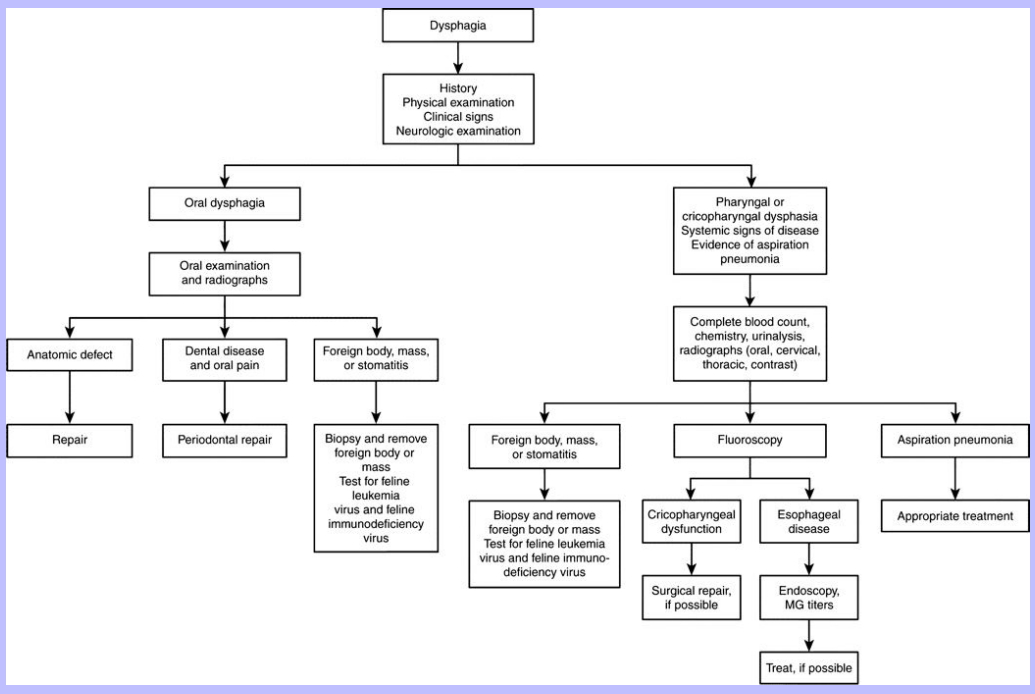

Figure 37-2 Regurgitation.

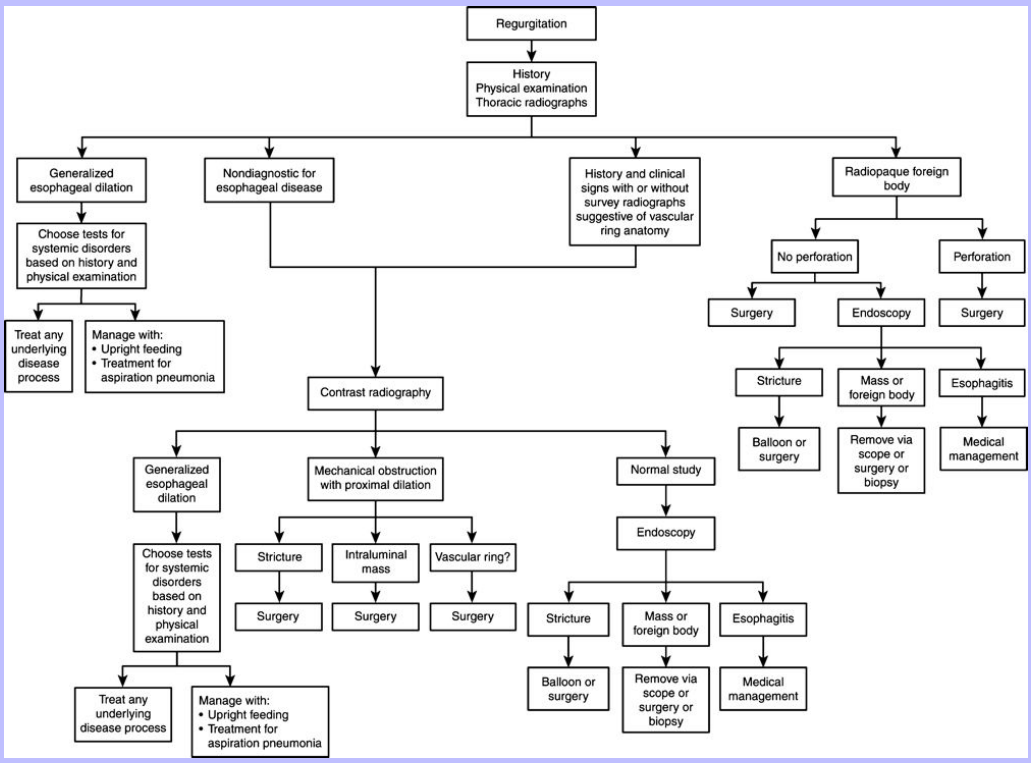


37.2.1 Box • 37-1 Causes of Regurgitation

37.2.1.1 Anatomic or Mechanical Lesions

Pharyngeal inflammation (e.g., abscess, inflammatory polyps, oral eosinophilic granulomas)

Foreign body obstruction (oral, pharyngeal, nasopharyngeal, proximal esophagus)

Neoplasia

Retropharyngeal lymphadenomegally

Sialocele

Mandibular fracture

Lingual frenulum disorder

Cricopharyngeal achalasia or asynchrony

TMJ disorder (e.g., luxation, fracture)

Cleft palate

Pharyngeal trauma

37.2.1.2 Pain

Stomatitis/glossitis/pharyngitis (FIV, FeLV, immune-mediated disease, uremic glossitis, ingestion of a caustic substance)

Tooth-related problems (tooth root abscess, fracture, periodontitis)

Trauma

Electric cord burns

Retrobulbar abscess

37.2.1.3 Neuromuscular Disorders

Myasthenia gravis (focalized or generalized)

Acute polyradiculitis

Masticatory myositis

Tick paralysis

Botulism

Polymyositis

TMJ disease

37.2.1.4 Neurologic Disorders

Rabies

Trigeminal paralysis or neuritis

Neuropathies of cranial nerves VII, IX, X, or XII

CNS disease (brain stem lesion)

37.2.2 Clinical Signs

Clinical signs may include weight loss accompanied by an increased appetite. Regurgitating animals often present with signs of aspiration pneumonia. Systemic signs of underlying disease processes that can cause regurgitation also may be noted, such as the weakness associated with myasthenia gravis.

37.2.3 Diagnosis

A complete physical examination is essential. A neuro-logic examination can help reveal a possible neuropathy or neuromuscular dysfunction. Auscultation is important to evaluate for aspiration pneumonia and other respiratory or cardiovascular abnormalities.

37.2.3.1 Box • 37-2 Causes of Regurgitation

37.2.3.1.1 Esophageal Disease

Megaesophagus (primary or secondary)

Esophagitis

Mechanical obstruction (foreign body, stricture, vascular ring anomaly)

37.2.3.1.2 Alimentary Disorders

Pyloric outflow obstruction

Gastric dilatation volvulus

Hiatal hernia

37.2.3.1.3 Neuropathies

Peripheral (polyradiculitis, giant cell axonal neuropathy, polyneuritis, lead poisoning)

Central (distemper, brain stem lesion, neoplasia, trauma)

37.2.3.1.4 Neuromuscular Junction Abnormalities

Myasthenia gravis (focalized or generalized)

Botulism

Tetanus

Acetylcholinesterase toxicity

37.2.3.1.5 Immune-Mediated Causes

Systemic lupus erythematous

Polymyositis

Dermatomyositis

37.2.3.1.6 Endocrine

Hypothyroidism

Hypoadrenocorticism

Thoracic radiographs should be examined for generalized esophageal dilatation, radiopaque foreign bodies, focal esophageal dilatation or other evidence of vascular ring anomalies, and evidence of aspiration pneumonia. Contrast radiography may be necessary for evaluation of the size and shape of the esophagus and any vascular anomalies. Endoscopy of the esophagus is useful for evaluating for foreign bodies, strictures, or esophagitis. Fluoroscopy can be used to characterize motility during swallowing.

When clinical signs suggest systemic disease or with evidence of megaesophagus, laboratory data are an important tool in ruling out underlying disorders. The initial workup includes a complete blood count, chemistry screen, and urinalysis. Depending on clinical suspicion, a thyroid hormone deter-mination, adrenocorticotropic hormone (ACTH) stimu-lation test, acetylcholine receptor antibody test, lead level determination, and antinuclear antibody (ANA) test can be considered.

37.2.4 Treatment

Treatment is aimed at any underlying disease process and at complications, such as aspiration pneumonia. Considerable effort can be put into the management of a regurgitating animal. Management of megaesophagus, for example, often includes feeding small, frequent meals from an elevated level.

38 CHAPTER • 38 Vomiting

David C. Twedt

Vomiting is a common clinical sign observed in small animals. It occurs secondary to gastrointestinal and nongastrointestinal disorders.

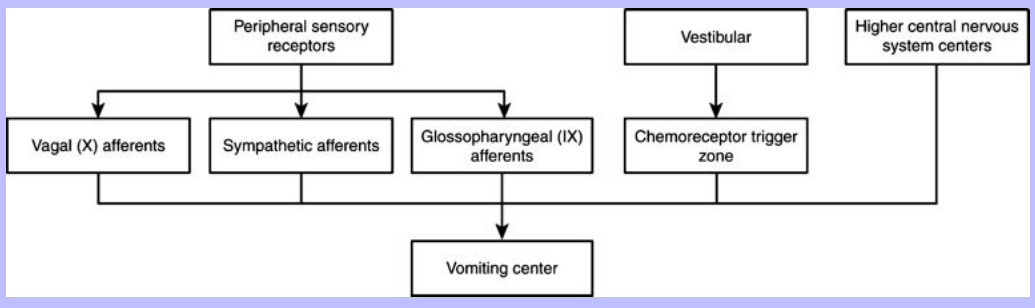
In its evolution, vomiting began as a rather primitive protective means of removing toxic or noxious ingested substances. Vomiting mechanisms then progressed to prevention of further adsorption of toxin after a toxic substance had entered the bloodstream. A mechanism that stimulates vomiting then evolved so that an animal could feed ingested food from a hunt to an offspring; this reflex is more developed and arises from higher centers in the central nervous system (CNS).

An important fact to remember is that vomiting is a clinical sign, not a disease per se. Clinically, vomiting results from a variety of disorders of the gastrointestinal system, as well as from disorders such as abdominal conditions, systemic or metabolic disease, and drug toxicity. This chapter covers basic pathophysiology, etiologies, and a practical clinical approach to evaluation of a patient with vomiting.

38.1 PATHOPHYSIOLOGY

The clinical act of vomiting is divided into three phases: nausea, retching, and vomiting. *Nausea* precedes vomiting and is associated with an episode that defies complete definition in animals. Outward signs of nausea may include depression, shivering, hiding, yawning, and licking of the lips. Increased salivation and swallowing occur; this lubricates the esophagus with bicarbonate-rich saliva that neutralizes gastric acid as it passes through the esophagus. Next, there is a reduction in gastric, lower esophageal sphincter, and esophageal motility, which is followed by increased retrograde motility of the proximal small intestine. *Retching,* the second phase of vomiting, consists of forceful contractions of the abdominal muscles and diaphragm to produce negative intrathoracic pressure and positive intra-abdominal pressure. These pressure changes are associated with movement of gastric contents into the esophagus. *Vomiting,* the third phase, occurs when the gastric contents are forcefully expelled from the mouth by the driving force generated by contraction of the abdominal muscles and diaphragm, which causes intra-thoracic pressure to change from negative during retching to positive during vomiting. As the vomit passes through the pharyngeal cavity, respiration is inhibited and the nasopharynx and glottis close to prevent aspiration.

Figure 38-1 Factors that activate the vomiting center.



Vomiting is a complex and poorly understood clinical sign that is best described as a neurologically mediated reflex act initiated by stimulation of the conceptualized *vomiting* or *emetic center* in the medulla oblongata of the brain. Activation of the vomiting center occurs either through a humoral pathway initiated by blood-borne substances or through activa-tion of various neural receptors and the pathways leading to the vomiting center (Figure 38-1). Adjacent to the vomiting center are areas for controlling respiration and salivation, which both are integrated into the vomiting process.

Neural stimulation of the vomiting center arises through either afferent vagal, sympathetic, vestibular, glossopharyngeal, and cerebrocortical pathways. Activation of peripheral receptors found throughout the body can stimulate these neural pathways. Particularly important are receptors located throughout the abdominal viscera. The duodenum contains the highest concentration of these receptors and hence has been referred to as the "organ of nausea." Disease or irritation of the gastrointestinal tract, other abdominal organs, or peritoneum can directly stimulate vomiting through vagal afferent pathways. Receptors found in the kidneys, uterus, and urinary bladder send afferent impulses via sympathetic nerves. Receptors located in the pharynx and tonsilar fossae transmit impulses thorough afferent fibers of the glossopharyngeal nerve. There is evidence that vagal receptors are located in the great vessels in the thorax.

CNS disease may directly stimulate the vomiting center through extension of inflammatory stimuli, hydrocephalus, or space-occupying CNS lesions. Supramedullary receptors may also influence the reactivity of the vomiting center. For example, psychogenic vomiting appears to arise from the cerebral cortex and may occur as the result of fear, stress, or pain. Cyclic vomiting in the dog has been associated with autonomic or visceral epilepsy arising from the limbic region in the CNS.

132

133

The vomiting center may also be stimulated indirectly via humoral pathway activation of the chemoreceptor trigger zone (CRTZ) in the area postrema. The blood-brain barrieris less effective in this area, which allows the CRTZ to be exposed to chemical stimuli found in the circulation. Blood-borne substances that stimulate the CRTZ include certain drugs, uremic toxins, and electrolyte, osmolar, and acid-base disorders, as well as a number of metabolic derangements. Drugs such as apomorphine, cardiac glycosides, and bacterial toxins are examples. The cat has poorly developed CRTZ dopaminergic receptors and fails to respond adequately to apomorphine as an emetic agent. However, xylazine, an alpha$_2$-adenergic agonist, effectively stimulates the CRTZ in cats. There is evidence that vestibular stimulation passes through the CRTZ before activating the vomiting center. Motion sickness, inflammation of the labyrinth, or lesions in the cerebellum may result in vomiting via this pathway.

38.2 CAUSES OF VOMITING

Vomiting has a vast number of etiologies. Box 38-1 presents some of the more common causes of vomiting in small animals.

38.3 CLINICAL APPROACH

A complete history is the first step in establishing a correct diagnosis of vomiting. The signalment and history, as well as a description of the vomiting episodes, are important. It also is important to glean from the history whether the animal actually is vomiting. The veterinarian should differentiate the owners' report of vomiting from gagging, coughing, dysphagia, or regurgitation. The signalment may be helpful in that young, unvaccinated pets, for example, are more susceptible to infectious disease, such as parvovirus. Vaccination status, travel history, previous medical problems, and the medication history should be determined. Certain drugs, such as non-steroidal anti-inflammatory drugs (NSAIDs), may cause serious gastrointestinal ulceration. The clinician should also investigate the possibility of toxin or foreign body ingestion and should look for other, concurrent signs that often arise with systemic or metabolic disease. For example, polydipsia, polyuria, and weight loss are typical of vomiting associated with diabetic ketoacidosis or chronic renal failure.

133

134

The history should then focus on the actual vomiting episodes. The duration, frequency, and relationship of the episodes to eating or drinking should be determined, and a complete physical description of the vomitus should be elicited. A dietary history, including the type of diet or recent dietary changes, is equally important, because vomiting may be associated with an adverse reaction to food. Vomiting of an undigested or a partly digested meal more than 8 to 10 hours after eating, a point at which the stomach normally would be empty, suggests a gastric outflow obstruction or gastric hypomotility. Gastric outflow obstructions can be caused by foreign bodies, mucosal hypertrophy, tumors, or polyps.

A description of the vomitus should include the volume, color, consistency, odor, and the presence or absence of bile or blood. Undigested food suggests gastric origin, whereas digested vomitus containing bile suggests an intestinal origin. Vomitus with a fecal odor suggests a low intestinal obstruction or bacterial overgrowth in the small intestine. The presence of blood in the vomitus *(hematemesis),* either as fresh, bright red blood or as digested blood with the appearance of coffee grounds, indicates gastrointestinal erosion or ulceration. Gastric ulceration is caused by metabolic conditions such as hypoadrenocorticism or uremia, by drug-induced ulceration, and by clotting abnormalities, gastritis, or neoplasia.

A complete physical examination should include careful evaluation of the mouth and oral cavity. This examination may reveal icteric membranes, uremic breath and ulceration, or the presence of a linear foreign body around the base of the tongue. The presence of a fever would suggest an infectious or inflammatory process. Bradycardia or cardiac arrhythmias in a vomiting animal may be a sign of a metabolic disturbance, such as hypoadrenocorticism. The abdomen should be carefully palpated for distention and tympany (e.g., gastric dilatation-volvulus syndrome), effusion (e.g., peritonitis), masses or organomegaly (e.g., neoplasia, intussusception, or foreign body), and pain (e.g., peritonitis, pancreatitis, or intestinal obstruction). The presence of gas-and fluid-filled intestines suggests obstruction, whereas plication of the bowel is characteristic of linear foreign body obstruction. A rectal examination provides characteristics of colonic mucosa and feces. Melena suggests upper gastrointestinal bleeding, and the presence of foreign material in the feces supports foreign body etiology. Animals that have colitis or that are severely obstipated may also vomit.

Finally, investigation of the CNS should be considered when the cause of the vomiting is not obvious. Vomiting is seen in some animals with vestibular disease (e.g., nystagmus, head tilt, and/or ataxia). Other CNS disease may be less obvious and usually requires a thorough neurologic evaluation. Occasionally dogs with intervertebral disk disease vomit because of pain or secondary intestinal ileus.

38.4 DIAGNOSTIC PLAN

Based on the history and physical examination, the animal should be classified as having either acute or chronic vomiting. The diagnostic and therapeutic approaches differ considerably based on this clinical classification (Figures 38-2 and 38-3).

If the vomiting episodes are acute and of short duration, they may be self-limiting and can be treated with symptomatic therapy. Most often, acute vomiting is associated with gastro-enteritis secondary to dietary indiscretions, and signs resolve quickly. A routine fecal examination for parasites should be performed in all animals with gastrointestinal signs to eliminate the possibility of parasitism. Investigation for environmental intoxicants is imperative. Young, unvaccinated dogs should always be evaluated for parvovirus because the disease frequently begins with vomiting prior to the onset of diarrhea. Radiographic studies may be necessary to confirm gastric dilatation-volvulus (GDV) syndrome, gastrointestinal foreign bodies, or obstructions. Severe acute vomiting or vomiting with concurrent systemic signs requires laboratory diagnostic evaluation and radiographic testing. Common systemic and metabolic diseases that can cause vomiting usually can be identified with basic diagnostic testing, beginning with a complete blood count (CBC), biochemical blood screen, urinalysis, and fecal examination.

Chronic vomiting generally is characterized as vomiting that has persisted for longer than 5 to 7 days or that has failed to respond to initial symptomatic therapy and requires in-depth investigation. In the majority of chronic vomiting cases, routine laboratory and survey radiographs either provide an etiology or direct the next step in diagnostics or therapy.

Vomiting may result in significant fluid, electrolyte, and acid-base changes. The most common electrolyte disturbance is hypokalemia. Acid-base changes generally are minimal in vomiting animals. However, if metabolic alkalosis is found to be associated with hyponatremia, hypochloremia, and hypokalemia, the cause is most likely to be frequent vomiting, gastric outflow, or a high duodenal obstruction.

When routine diagnostic testing fails to identify an obvious etiology, additional tests are required based on the appropriate clinical circumstances of the case. These tests may include viral or heartworm serology, a thyroid evaluation, adrenocortical testing, bile acid determinations, toxologic testing (e.g., lead poisoning), and a neurologic examination.

If laboratory testing fails to identify a nongastrointestinal cause of vomiting, the focus should move to investigation of gastrointestinal disease as a possible cause. The diagnostic approach includes contrast radiography, ultrasonography, endoscopy, or laparotomy. Frequently, inflammatory gastro-intestinal lesions are a cause of chronic vomiting; these conditions include gastritis, inflammatory bowel disease (IBD) of the small intestine, and colitis. The diagnosis should be confirmed with gastrointestinal biopsies. In cats with inflammatory bowel disease, vomiting often is the predominate clinical sign, with diarrhea being a minor component of the disease. Conditions such as gastric antral pyloric mucosal hypertrophy, antral polyps, foreign bodies, or neoplasia can cause gastric outflow obstruction, with gastric retention and vomiting. These gastric lesions usually are easily identified endoscopically or by contrast radiography.

Obstructive intestinal lesions, such as foreign bodies, intussusception, and neoplasia, usually require radiographic contrast studies or ultrasonography for diagnosis. The diagnosis of gastrointestinal motility disorders should be considered when clinical signs support abnormal gastric retention and a failure to identify inflammatory or obstructive gastrointestinal lesions. Specialized contrast studies that evaluate motility, or possibly a clinical response to gastrointestinal prokinetic agents, may support a diagnosis of gastric hypomotility.

In summary, vomiting is a complex clinical sign that is associated with a vast number of clinical conditions. Frequently, only through a complete and systematic approach is the cause of the vomiting identified. The veterinarian who understands the mechanisms of vomiting is able to select the appropriate diagnostics or therapy for this clinical sign.

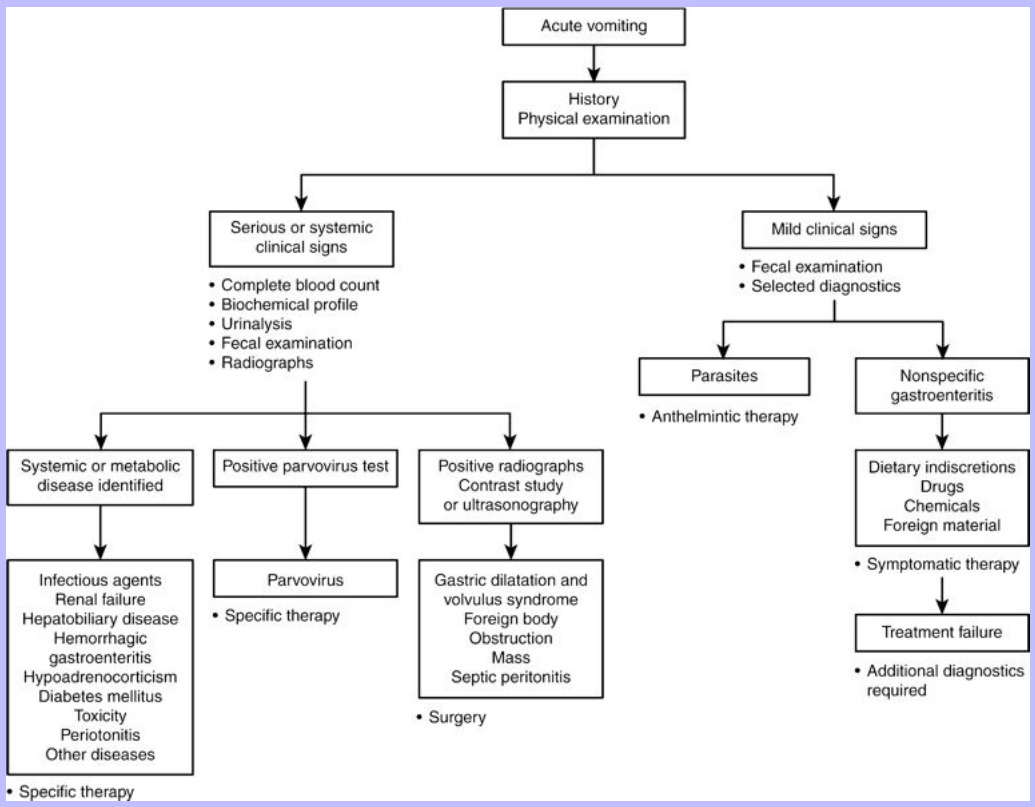

Figure 38-3 Algorithm for the diagnosis of chronic vomiting.

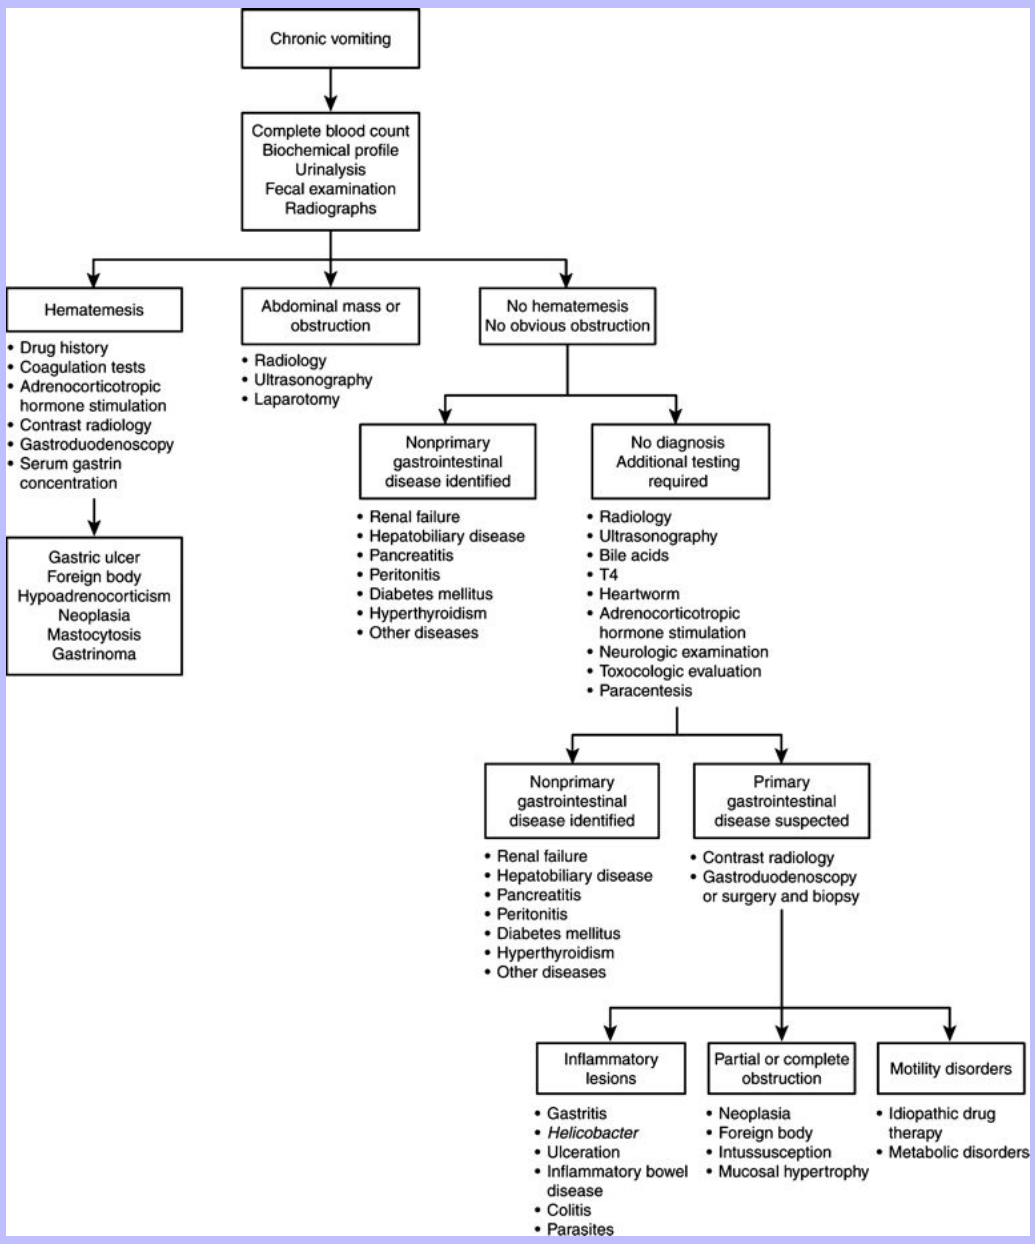


39 CHAPTER • 39 Diarrhea

Jörg M. Steiner

Fecal consistency depends on several factors, including diet, digestion, absorption of nutrients and water, and gastrointestinal milieu and motility. An abnormality of any one of these factors can lead to a change in fecal consistency. However, it is important to note that the compensatory reserve of the gastrointestinal tract is large, and minor changes in one or more of these factors often are compensated for by other components of the system. Only when the compensatory mechanisms are overwhelmed does diarrhea occur. Yet, diarrhea is one of the most common clinical signs seen in dogs and cats. Most cases of diarrhea consist of an isolated episode that does not appear to affect the animal systemically. These dogs and cats are rarely brought to a veterinarian. If they are, they do not pose a diagnostic or therapeutic challenge because no therapy is required, therefore any therapy used will lead to apparent treatment success.

Other cases of diarrhea are also mild, not associated with systemic clinical signs, and resolve naturally after only a few days. These animals require only a minimum amount of diagnostic testing to ensure that systemic complications are not present and in some cases to rule out specific causes, suchas infection with *Giardia sp*. Necessary therapeutic effortsare also minimal because remission ensues without treatment or with symptomatic therapy alone. Withholding food for24 to 48 hours and then introducing small amounts of an easily digestible diet usually is followed by remission of the diarrhea.

A third group of animals, mostly dogs and only rarely cats, have acute or even peracute severe disease. Although gastrointestinal disease is clearly present, the primary disease process is less of a concern than the animal's overall health status. Therefore the clinical approach to these dogs and cats is the same as for any others with a severe condition. The focus is on supportive care, aggressive monitoring for systemic complications, and early intervention against such complications. Finally, there is a large group of dogs and cats that have chronic diarrhea (arbitrarily defined as lasting for more than 3 weeks) that might benefit from a full medical workup. The following discussion pertains to this large group, which is commonly seen in veterinary practice.

39.1 CHRONIC DIARRHEA

The workup of chronic diarrhea in dogs and cats can be approached in many different ways. Differences may be due to certain diagnostic modalities that may or may not be readily available. Differences may also be due to the clinical expertise of the veterinarian. In addition, differences may be due to a particularly common problem in a geographic region. For example, fungal disease is more common in some geographic regions than in others, requiring a high degree of suspicion leading to the use of specific diagnostic tests in some areas. Finally, differences in evaluation may be due to a difference of opinion between clinicians.

The workup of a dog or cat with chronic diarrhea also needs to be guided by the severity of illness. Rapid weight loss, emaciation, systemic clinical signs, hypoalbuminemia, or acid-base and electrolyte disturbances all require an aggressive diagnostic approach. The workup and successful treatment of animals with chronic diarrhea could take anywhere from a few days to several months. It is important to establish realistic expectations early during client communication to avoid disappointment later on.

39.2 DIFFERENTIATION OF PRIMARY AND SECONDARY GASTROINTESTINAL DISEASE

As for any clinical problem, a careful history is important. It should include questions about the pet's current and past clinical history. Owners should be asked about the environment, husbandry (especially as it relates to the diet), and the clinical history of other pets in the household (see Figure 39-1).

If the history does not reveal any specific indicators for a cause of the diarrhea, a reasonable initial approach includes careful fecal examination (direct smear and zinc sulfate floatation) for evidence of parasitic infestation. This should befollowed by treatment with a broad-spectrum anthelmintic agent such as pyrantel pamoate or fenbendazole, regardless of the findings on the fecal examination. Fecal examination is warranted even though anthelmintic therapy will be used because evidence of a specific parasite may alter the choice of treatment. The yield of fecal examination and anthelmintic therapy varies, but the veterinarian should not dismiss the possibility of parasites being the cause of the diarrhea.

An important step for proper diagnosis and treatment is determining whether the diarrhea is caused by a primary gastrointestinal disease or by a disorder of another organ system. In most animals this determination can be made using the history and physical examination findings and performing a complete blood count, serum chemistry profile, and urinalysis. In cats older than 7 to 8 years of age, this minimum data base also should include measurement of a serum total thyroxine (T_4) concentration. If possible, additional serum should be collected and frozen for future analyses.

Central nervous system disease rarely causes chronic diarrhea, and in most cases these dogs and cats have severe neurologic signs that are apparent on physical examination.

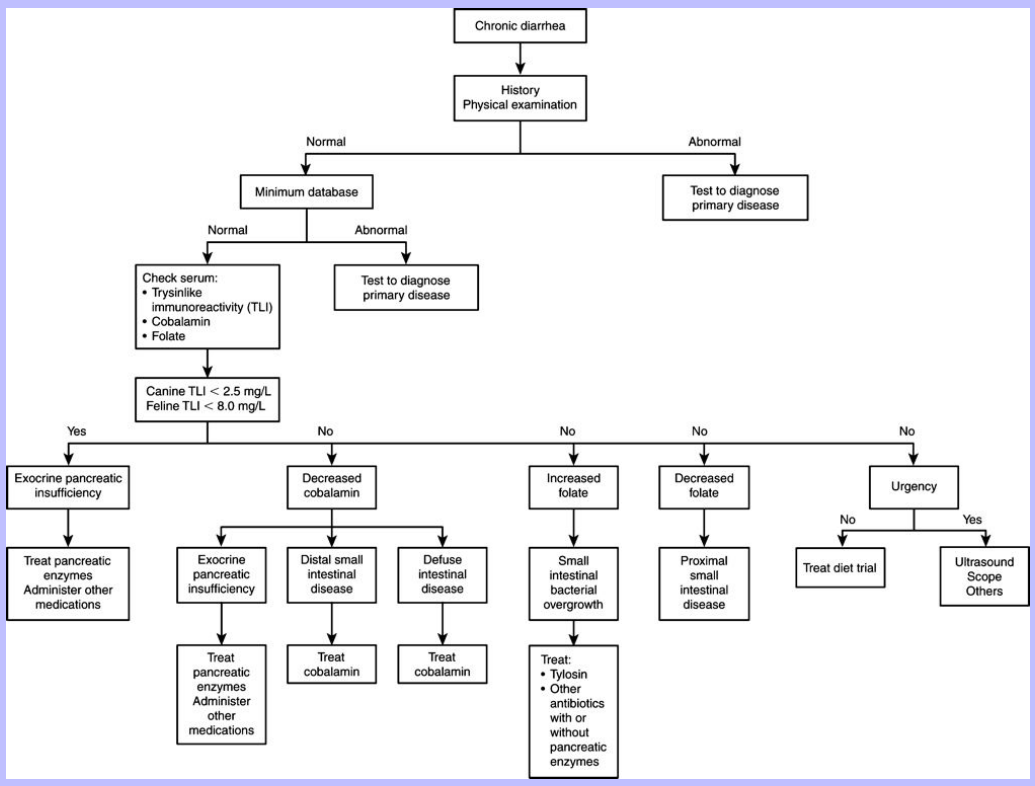
Chronic diarrhea rarely occurs in dogs and cats with heart failure. Heart failure can be ruled out by lack of historical findings, such as shortness of breath, exercise intolerance, or coughing and by lack of appropriate abnormalities on physical examination, especially during thoracic auscultation.

Liver failure or portosystemic shunts can cause chronic diarrhea. Dogs and cats with liver failure should have additional clinical signs, such as anorexia, vomiting, weight loss, or even neurologic signs. These animals may have increased serum hepatic enzyme activities and serum bilirubin concentrations and/or decreased serum urea nitrogen, cholesterol, or albumin concentrations. Finally, a decreased urine specific gravity may be noted on urinalysis. Liver failure or portosystemic shunt usually can be ruled out by the minimum data base. However, if suspicion remains, other diagnostic tests, such as measurement of preprandial and postprandial bile acid concentrations, abdominal radiographs, abdominal ultrasono-graphy, or even hepatic biopsy may be necessary to definitively rule out hepatic failure.

137

139

Figure 39-1 Chronic diarrhea.



Hypothyroidism may cause chronic loose stools or diarrhea. Dogs with hypothyroidism may have a history of weight gain, decreased exercise activity, or heat-seeking behavior. They may also be anemic and have an increased serum cholesterol concentration. If hypothyroidism is suspected, the total serum T_4 concentration should be measured. If the total serum T_4 concentration is decreased, it may be necessary to measure the serum free T_4 concentration (only equilibrium dialysis methods are reliable) and/or the serum thyroid-stimulating hormone (TSH) concentration to differentiate sick-euthyroid dogs from those with true hypothyroidism. If any suspicion remains, a therapeutic trial with thyroid hormone supplementation may be instituted to confirm the diagnosis.

Hyperthyroidism in cats usually is ruled in or out after careful palpation of the neck and determination of the serum total T_4 concentration. In some cats, definitive diagnosis may require repeat testing several weeks later or the use of other diagnostic tests, such as a triiodothyronine (T_3) suppression test.

Renal failure may cause chronic diarrhea in some pets. The most important parameters for ruling out renal failure arethe serum creatinine and urea nitrogen concentrations and the specific gravity on urinalysis.

Hypoadrenocorticism (Addison's disease) is another potential cause of chronic diarrhea, mainly in dogs. Dogs with Addison's disease may have waxing and waning clinical signs that include diarrhea, vomiting, and/or weakness. The serum chemistry profile for these animals may show hyperkalemia and hyponatremia. Dogs (rarely cats) with so-called atypical Addison's disease lack only glucocorticoids and thus are able to regulate the serum sodium and

potassium concentrations. The differential white cell count may provide a clue foridentifying these animals. Ill animals typically have a stress leukogram characterized by neutrophilia, lymphopenia, eosinopenia, and monocytosis. Dogs with glucocorticoid deficiency cannot respond appropriately and thus cannot develop a stress leukogram. Therefore most dogs with Addison's disease, typical or atypical, display a lack of a lymphopenia. Only a few actually show a lymphocytosis, but an elevated, high-normal, or even mid-normal lymphocyte count should raise suspicion of the possibility of hypoadrenocorticism. If the slightest degree of suspicion for hypoadrenocorticism exists, an adrenocorticotropic hormone (ACTH) stimulation test should be performed.

Finally, exocrine pancreatic disease often causes chronic diarrhea. Exocrine pancreatic insufficiency (EPI) in both dogs and cats leads to loose stools or diarrhea. Pancreatitis can also lead to chronic diarrhea but most often is accompanied by other clinical signs. However, cats with chronic pancreatitis may show only chronic diarrhea, possibly because they often have concurrent disease of the small intestine. Exocrine pancreatic disease cannot be ruled out by the history, physical examination, and minimum data base alone. The serum trypsin-like immunoreactivity (TLI) concentration is the test of choice to rule out EPI in both dogs and cats, and it should be performed if the workup has not led to a definitive diagnosis. A canine TLI less than or equal to 2.5 μg/L is diagnostic for canine EPI, and a feline TLI (fTLI) less than or equal to 8 μg/L is diagnostic for feline EPI. If chronic pancreatitis is suspected as a cause of the chronic diarrhea, a serum pancreatic lipase immunoreactivity (PLI) concentration should be evaluated.

39.3 WORKUP FOR PRIMARY GASTROINTESTINAL DISEASE

Once secondary disorders have been ruled out, the type of diarrhea should be characterized. In general, small and large bowel diarrhea can be distinguished. Animals with small bowel diarrhea have an increased fecal volume but only a mildly increased frequency of defecation. Blood, if present, is digested, causing melena. In contrast, pets with large bowel diarrhea often strain to defecate and have fresh blood and an increased amount of mucus covering the feces. Also, weight loss does not usually occur in dogs and cats with large bowel diarrhea, whereas those with small bowel diarrhea may or may not show weight loss. These differences, however, are not absolute, and most dogs and cats with clinical signs of large bowel diarrhea have diffuse disease with significant small bowel involvement. In contrast to human beings, isolated colitis is rare in dogs and uncommon in cats. Therefore, although it is useful to characterize the type of diarrhea, the clinician would be ill advised to make a definitive assessment based on the type alone.

Many animals with chronic diarrhea have a normal minimum data base or only nonspecific changes, such as a mild increase in hepatic enzyme activities. These animals should be worked up for primary gastrointestinal disease. As previously mentioned, fecal examination for parasitic infestation and therapy with a broad-spectrum anthelmintic agent should be attempted before any further steps are taken. Also, repeated testing (zinc sulfate floatations or enzyme-linked immunosorbent assay [ELISA]) should be performed to rule out giardiasis.

The serum cobalamin and folate concentrations are of great diagnostic importance and, in the case of cobalamin, also of therapeutic importance and should be measured together with the serum TLI concentration. The serum folate concentration may be decreased in disorders of the proximal small intestine, whereas the serum cobalamin concentration may be decreased in disorders of the distal small intestine and in EPI. In animals with diffuse small intestinal disorders, both the serum folate and cobalamin concentrations may be decreased. Decreases in the serum cobalamin concentration and increases in the serum folate concentration may be seen in dogs with small intestinal bacterial overgrowth (SIBO). The significance of the increased serum cobalamin concentration is unknown. Folate and cobalamin are both plentiful water-soluble vitamins in canine and feline diets. However, dietary folate is poorly absorbed, because it occurs as folate polyglutamate and needs to be deconjugated to folate monoglutamate by folate deconjugase, a brush border enzyme. Folate monoglutamate is absorbed by specific carriers in the proximal small intestine, therefore, longstanding and severe disorders of the proximal small intestine can lead to

depletion of folate body stores and ultimately to a decreased serum folate concentration. However, it should be pointed out that a severely decreased serum folate concentration does not commonly occur in either dogs or cats with chronic diarrhea. In SIBO, microorganisms in the small intestine synthesize folic acid, which can lead to an increase in folate absorption and in turn to an increased serum folate concentration.

Dietary cobalamin is tightly bound to dietary protein. In the stomach, dietary protein is partly digested by pepsin and hydrochloric acid (HCl), and cobalamin is released. However, cobalamin immediately binds to R-protein, which in turn is digested by pancreatic proteases in the small intestine. Free cobalamin binds to intrinsic factor, released mostly in pancreatic juice. These cobalamin–intrinsic factor complexes are absorbed through specific receptors in the ileum. Therefore severe and longstanding disorders of the distal small intestine, as well as exocrine pancreatic insufficiency, can lead to depletion of cobalamin body stores and ultimately to a decreased serum cobalamin concentration. Approximately half of all dogs with EPI have cobalamin deficiency, whereas almost all cats with EPI have cobalamin deficiency. Finally, microorganisms, present in excessive numbers in the small intestine in animals with SIBO utilize cobalamin and compete with the host for dietary cobalamin. A low serum cobalamin concentration combined with an increased serum folate concentration is specific for SIBO, and a therapeutic trial with an antimicrobial agent is indicated. Currently, the antibiotic agent of choice is tylosin (15 to 25 mg/kg given twice a day for 6 weeks). An increased serum folate concentration alone also is indicativeof SIBO, and a trial therapy is appropriate. In both situations dogs should respond within approximately 1 week of starting therapy. Failure to show at least a partial response within that period should stimulate further diagnostic workup.

139

140

Serum cobalamin is of therapeutic interest. Cobalamin deficiency in human patients has been shown to cause systemic neuropathies, dementia, compromise of the immune system, and gastrointestinal changes, such as villous atrophy, inflammatory infiltrates of the intestinal mucosa, and cobalamin malabsorption. Experimental cobalamin deficiency in cats has led to similar changes, with clinical signs of weight loss, anorexia, and an unkempt haircoat. In a recent study, cobalamin deficiency was present in more than 60% of cats with chronic diarrhea. Clinical experience would further suggest that both cats and dogs with severe cobalamin deficiency often do not respond to therapy of the underlying gastrointestinal disorder until cobalamin is supplemented. Because cobalamin deficiency causes cobalamin malabsorption, oral supplementation is not efficacious in patients with cobalamin deficiency. Also, multivitamin preparations do not contain sufficient amounts of cobalamin. Furthermore, pure cobalamin is needed for therapy. Based on body size, 250 to 800 μg is given subcutaneously in dogs and 150 to 250 μg in cats. Injections should be administered once weekly for 6 weeks, every other week for 6 weeks, one more dose a month later, and a recheck a month after that. Re-evaluation is important in deciding whether further cobalamin supplementation is indicated.

For all dogs and cats that do not have secondary chronic diarrhea, parasitism, or SIBO, additional testing or a therapeutic trial may be chosen. The choice depends on many factors but ultimately on the condition of the pet and the goals of the owner. If the pet does not have any systemic clinical signs and does not deteriorate, a dietary trial is reasonable. Many animals with chronic diarrhea are suspected of having dietary intolerance or dietary hypersensitivity. Clinically, it is not feasible to differentiate between the two. Although those with dietary intolerance would benefit from an easily digestible diet, others with dietary hypersensitivity may benefit from a hypoallergenic diet. A diet with a novel protein and a novel carbohydrate source is one option for a hypoallergenic diet. Note that diets containing a novel protein and a novel carbohydrate source are not intrinsically hypoallergenic but are unlikely to elicit an allergic response in a patient that has not been previously exposed to them. Another option is to usea diet that contains hydrolyzed proteins. Dogs and cats should show some response to a dietary trial 1 to 2 weeks after initiation, but complete remission may take up to 6 to 8 weeks. Depending on the urgency of the situation, several different diets could be introduced to identify the optimal diet for a particular pet.

If a dog or cat is not stable or is quickly deteriorating, or if the owner wants to do anything possible regardless of cost or prognosis, more diagnostic tests should be performed immediately. Some clinicians prefer to do abdominal

ultrasonography first because it is not invasive. Abdominal ultrasonography can be useful for identifying neoplastic or fungal lesions or partial obstructions by foreign bodies or an intussusception, or for visualizing mesenteric lymph nodes. However, it must be pointed out that diagnostic yields differ significantly, depending on the quality of the equipment and the expertise of the ultrasonographer. Other clinicians prefer to perform a gastroduodenoscopy first, because the diagnostic yield for this procedure is usually better than that for abdominal ultrasonography. However, it is more invasive and does not allow visualization of other abdominal structures. It should alsobe pointed out that gastroduodenoscopy may appear more definitive than it is in most cases. Although a definitive answer may be found in some dogs and cats with gastrointestinallymphoma, parasitism, or fungal disease, most animals show varying degrees of lymphocytic-plasmacytic inflammation that may or may not be normal.

A special scenario is the dog or cat with panhypoproteinemia or hypoalbuminemia with or without chronic diarrhea. These animals need to be carefully screened for hepatic disease and protein-losing nephropathy (PLN). Hepatic disease should be ruled out by a serum chemistry profile and determination of preprandial and postprandial bile acid concentrations; PLN should be ruled out by determination of a urine protein/creatinine ratio. In dogs, if there is no evidence of hepatic disease or PLN, protein-losing enteropathy (PLE) can be confirmed by measuring the fecal $alpha_1$-proteinase inhibitor ($alpha_1$-PI) concentration. This test is also useful for assessing fecal protein loss in dogs that have not yet developed panhypoproteinemia. For example, soft-coated Wheaten terriers with familial PLE/PLN often have increased fecal $alpha_1$-PI before clinical signs develop.

Other diagnostic tests may be useful in specific cases. Culture of fecal material for *Salmonella spp., Clostridium spp.,* and *Yersinia spp*. may be useful for a select group of animals, mostly those immunocompromised by concurrent disease or chemotherapy or dogs with bloody diarrhea. However, indiscriminate bacterial culture of fecal material is of little diagnostic value. Measurement of serum unconjugated bile acids and breath hydrogen can be useful for supporting a diagnosis of small intestinal bacterial overgrowth in dogs. Finally, gastrointestinal permeability and mucosal function testing in dogs is extremely sensitive for altered gastrointestinal integrity and function and shows abnormalities long before histopathologic changes are apparent.

40 CHAPTER • 40 Melena and Hematochezia

Karen M. Kelly

40.1 HEMATOCHEZIA

Hematochezia is the term used to describe bright red blood on the surface of or admixed into the stool. The origin of the red blood most commonly is the anus, rectum, or descending colon.

40.1.1 Clinical Signs

It is important to take a thorough history. The owner should be asked if there is any fresh blood in the stool, mucus, straining, or difficulty defecating. It should be determined whether the pet has been given medications, has had a dietary indiscretion or a recent diet change, or has been subjected to trauma (e.g., pelvic trauma), toxin exposure (e.g., rodenticides), or stress (e.g., boarding). In addition, it should be determined whether this is a recurrent problem and if it has respondedto previous treatments. Any travel history (e.g., parasite and fungal exposure) should be noted. The veterinarian should observe the animal's demeanor and ask the owner if the animal is lethargic, has been vomiting, or has had a loss of appetite or recent weight loss. Owners often are very concerned when they see blood in the stool, but hematochezia is rarely life threatening. Animals with hematochezia rarely have any other clinical signs aside from the blood with the stool. Exceptions to this are more serious causes, such as neoplasia and hemorrhagic gastroenteritis; for these cases, the physical examination and history can reveal weight loss, shock, lethargy, cachexia, anorexia, or inappetence, along with large volumes of fresh blood. Causes of hematochezia are listed in Box 40-1.

40.1.2 Diagnostics

A physical examination and complete rectal examination should be done. A rectal examination is performed to confirm hematochezia, to obtain a stool sample for fecal examination, and to detect polyps, strictures, neoplasia, or perianal diseases (e.g., fistulas). The anal gland should be palpated and expressed to detect infection, impaction, or neoplasia. The extent of the workup should be based on the severity and duration of the problem and the physical examination findings. For example, an animal that has a normal physical examination, other than hematochezia, could be treated conservatively with a trial course of metronidazole, a broad-spectrum wormer, and a diet with a fermentable fiber. For more persistent and recurrent cases of hematochezia, a more extensive workup is indicated, such as abdominal radiographs, a complete blood count, a serum chemistry profile, colonoscopy, and abdominal ultrasonography.

40.2 MELENA

Melena is the presence of dark, tarry, often foul-smelling stools, the result of digested blood in the intestinal tract. Melena is always a more serious clinical sign then hematochezia and demands a more extensive workup. The blood can originate from the pharynx, lungs (coughed up and swallowed), esophagus, stomach, small intestine, or upper large bowel if transit time is sufficiently slow. It is the duration of the stool in the intestinal tract, not the origin, that determines the ultimate color. Blood must be present in the intestine for some time before the bacteria can break down the hemoglobin, resulting in melena. Also, a sufficient amount of blood must be present before melena can occur. It is important to note that large-volume, upper gastrointestinal bleeding can result in short transit times and can appear as fresh blood. Not all dogs with dark stools have melena.

40.2.1 Box • 40-1 Causes of Hematochezia

40.2.1.1 Anal Disease

Perianal fistulas

Anal sacculitis or abscess

Stricture

Neoplasia (e.g., anal sac tumor)

Trauma (e.g., bite wound)

Perianal hernia

Foreign body

40.2.1.2 Rectum and Colon

Proctitis (inflammation of the rectal mucosa)

Colitis

- Idiopathic
- Inflammatory bowel disease
- Stress
- Infectious
  - *Campylobacter*
  - *Clostridium perfringens*

Parvovirus

Parasitism

- Hookworms
- Whipworms

Coccidia

Roundworms

Neoplasia

Rectal polyp

Adenocarcinoma

Lymphoma

Prolapsed rectum

Mucosal trauma

Movement of foreign material (e.g., hairballs)

Iatrogenic (e.g., thermometers, enemas, fecal loops)

Automobile trauma

Ileocecocolic area: intussusception

NOTE: Constipation often can cause excessive straining, which can result in formed stools with blood on the surface.

Modified from Tams TR: Gastrointestinal symptoms. In *Handbook of small animal gastroenterology,* Philadelphia, 1996, WB Saunders.

As with hematochezia, a detailed history should be taken and a thorough physical examination performed. The clinician should ask specifically about administration of nonsteroidal anti-inflammatory drugs and corticosteriods, both of which may cause gastrointestinal bleeding, especially when used concurrently. Any potential exposure to toxins should be addressed. Spurious dark stools can be caused by salicylates, bismuth (e.g., Pepto-Bismol), charcoal, and diets high in iron. A history of coughing (may indicate swallowed blood from pulmonary disease), gagging, and regurgitation (esophageal disease), behavioral changes (hepatic encephalopathy), and polyuria and polydipsia (renal disease) should be noted. A thorough examination of the nares and oropharynx for sources of bleeding should be included. Causes of melena are listed in Box 40-2.

40.2.2 Diagnostics

A rectal examination can help confirm the presence ofmelena and at the same time allows collection of a stool sample (Figure 40-1). In-house packed cell volume and total solids testing should be done to assess for anemia, especially in shocky, debilitated animals. A fecal examination for hookworms should not be overlooked. A

complete blood count with a reticulocyte count helps differentiate regenerative from nonregenera-tive anemia. Regenerative anemia often is present after a few days except with iron-deficiency anemia, which is common with chronic gastrointestinal bleeding characterized by a hypochromic, microcytic anemia and bone marrow disease. A chemistry panel helps in the evaluation for metabolic disease, such as liver and kidney disease. If liver disease is suspected, a bile acid determination may be helpful. A coagulation profile and platelet counts also are indicated to rule out thrombocytopenia and rodenticide intoxication. Survey radiographs of the abdomen and thorax aid detection of esophageal disease, pulmonary disease and evidence of bleeding elsewhere (e.g., ascites and pleural fluid), neoplasia, foreign bodies, and trauma to the pelvic canal.

If additional tests are required to determine the cause of bleeding, abdominal ultrasonography should be preformed. Ultrasound scanning is an easy, noninvasive test that can aid the detection of lesions. If a lesion detected by ultrasound is accessible by endoscopy (e.g., a proximal mass or diffuse small intestinal thickening), biopsies should be taken and submitted. If no lesion is detectable by ultrasound, which often is the case, there are two options. The first is endoscopy with biopsies. Endoscopy is noninvasive and allows the clinician to visualize the mucosal surfaces of the proximal gastrointestinal tract while simultaneously obtaining biopsy samples. A disadvantage is that the lower gastrointestinal tract is not visualized, and a lesion could easily be missed. The second option is exploratory abdominal surgery. The advantage is full examination of the serosal surfaces of all the gastrointestinal tract, full-thickness biopsy samples, and surgical excision of identifiable bleeding lesions. The disadvantages are inability to visualize the mucosal surface and the invasiveness of the procedure. Surgery can be combined with endoscopy to allow visualization of the mucosal surface intraoperatively as an aid to locating a lesion. When the above tests and procedures fail to provide an answer, more specialized tests can be performed, such as scintigraphy using technetium-labeled red blood cells to locate the site of bleeding and arteriography to diagnose gastrointestinal blood vessel malformations.

40.2.2.1 **Box • 40-2 Causes of Melena**

40.2.2.1.1 **Ingested Blood**

Oral lesions

Nasopharyngeal lesions

Pulmonary lesions

Diet

40.2.2.1.2 **Parasitism**

Hookworms

40.2.2.1.3 **Neoplasia**

Adenocarcinoma

Lymphoma

Leiomyoma or leiomyosarcoma

Mast cell tumor

Gastrinoma

40.2.2.1.4 Coagulopathies

Disseminated intravascular coagulation (DIC)

Rodenticide intoxication

40.2.2.1.5 Drug Administration

Nonsteroidal anti-inflammatory drugs

Glucocorticoids

40.2.2.1.6 Miscellaneous

Liver failure

Pancreatitis

Renal failure

Inflammation (e.g., foreign body, acute gastritis, hemorrhagic gastroenteritis, inflammatory bowel disease)

Hypoadrenocorticism

Gastrointestinal ischemia (e.g., shock, volvulus, intussusception)

Foreign bodies

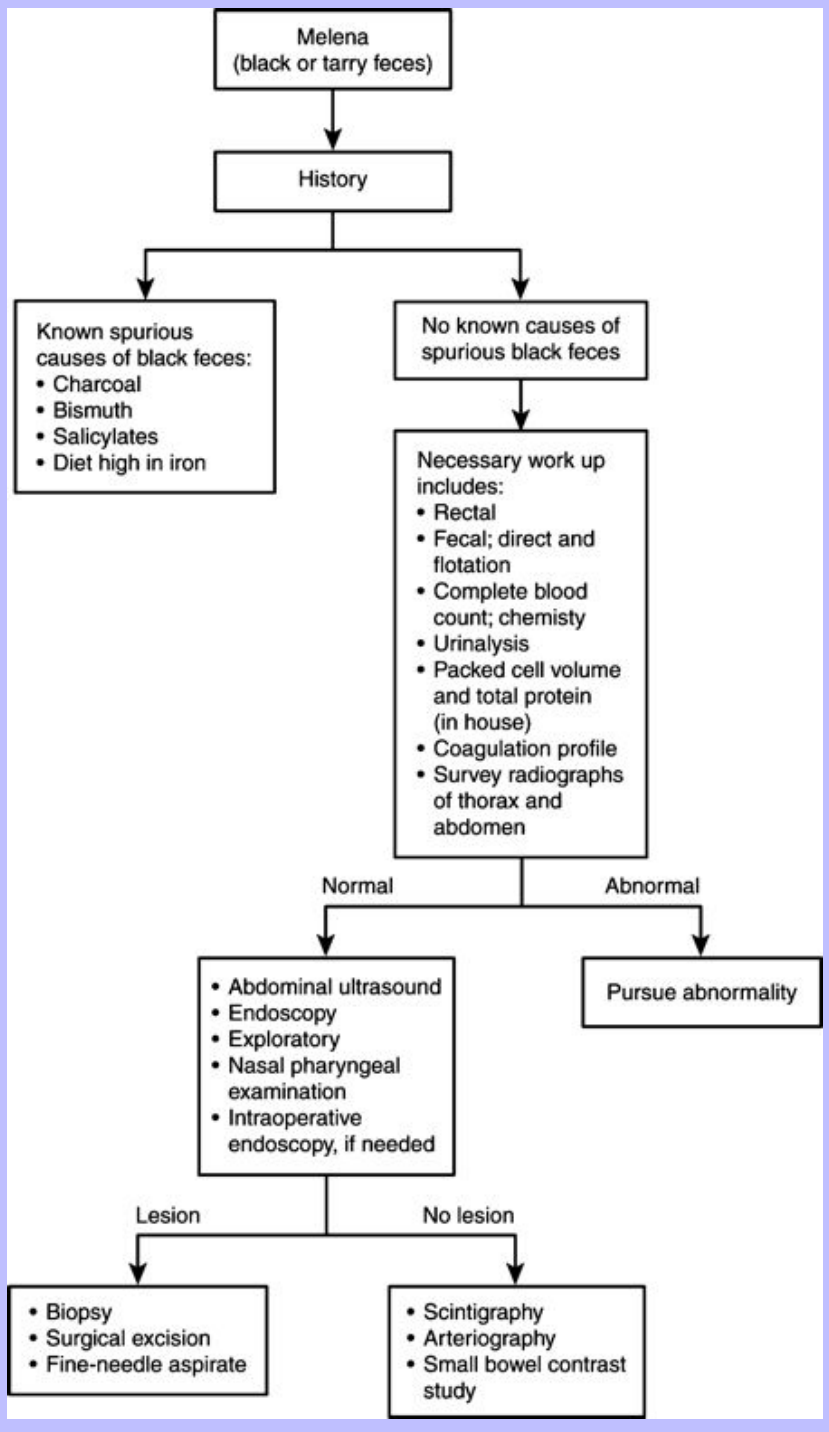
Gastrointestinal blood vessel malformations (e.g., arteriovenous fistula)

Polyps

40.2.3 Treatment

The treatment of melena largely depends on the underlying cause. For animals in shock, hospitalization with intravenous fluid therapy is indicated. Depending on the duration and volume of bleeding, a blood transfusion may be necessary. If a coagulopathy is suspected, plasma or whole blood may be indicated. Gastric acid inhibitors (e.g., famotidine and omeprazole) can be helpful. Antiemetics are indicated if nausea and vomiting are factors.

Figure 40-1 Diagnostic approach to a patient with melena.



41 CHAPTER • 41 Constipation, Tenesmus, Dyschezia, and Fecal Incontinence

Kenneth R. Harkin

41.1 DEFINITIONS

Constipation is the infrequent or difficult evacuation of feces, typically characterized by the presence of dry, hard feces.

Obstipation is intractable constipation, characterized by an inability to evacuate the mass of dry, hard feces, which can result in an impaction extending from the rectum to the ileocolic valve.

Megacolon is a pathologic condition of hypomotility and dilatation of the large intestine that results in constipation and obstipation.

Tenesmus is ineffectual and painful straining at defecation or urination.

Dyschezia is difficult or painful defecation that arises exclusively from disease of the anal and perianal tissues.

Fecal incontinence is the involuntary passage of feces and flatus as a result of dysfunction of the internal and external anal sphincters.

41.2 NORMAL PHYSIOLOGY OF THE LARGE INTESTINE

The primary functions of the large intestine are absorption of water and electrolytes, which occurs predominately in the proximal half, and storage of fecal matter until expulsion, which is the primary function of the distal half.

Movement of contents through the large intestine normally is sluggish and consists of *haustral contractions* and *mass movements*. Haustral contractions, which are combined segmental contractions of the circular and longitudinal layers of smooth muscle of the large intestine, result in focal accumulation of contents in unstimulated segments. These contractions primarily serve to mix the contents of the large intestine, increasing the exposure to the luminal surface for maximal absorption of water and electrolytes. They also serve to propel material slowly from the level of the cecum through the ascending colon.

Mass movements carry fecal material from the transverse colon to the rectum; however only a few of these occur daily, compared with the continuous action of the haustral contractions. Mass movements are maximized after a meal, facilitated by the gastrocolic and duodenocolic reflexes, which are conducted through extrinsic nerves of the autonomic nervous system. Contraction of circular smooth muscle begins at an area of distention or irritation, forcing the mass of feces into the rectum, where the desire for defecation is felt. These mass movements persist for 10 to 30 minutes. Irritation in the colon also can initiate mass movements, which may become continuous.

The stimulus for defecation is initiated by the movement of feces into the rectum. Continence is maintained by tonic contractions of the internal anal sphincter, which is composed of smooth muscle and is under the control of the autonomic nervous system, and by the external anal sphincter, whichis composed of striated muscle and is under voluntary con-trol and innervated by the pudendal nerve. Defecation is accomplished by a weak intrinsic defecation reflex (IDR) and a more powerful parasympathetic defecation reflex (PDR). The IDR is initiated when distention of the rectum activates the myenteric plexus and initiates a peristaltic wave and reflex relaxation of the internal anal sphincter. The PDR is stimulated by nerve endings in the descending colon, rectum, and anus, which

activate the parasympathetic nervous system (PNS). Motor nerves of the PDR, which arise from the pelvic nerve, intensify the peristaltic wave. Activation of the PNS also stimulates the deep breath, closure of the glottis, and contraction of the abdominal muscles that constitute the abdominal press. Defecation then depends on voluntary relaxation of the external anal sphincter. If the external anal sphincter remains voluntarily closed, the defecation reflexes are terminated after a few minutes. These reflexes can be voluntarily initiated later, but they are less effective than the intrinsic reflex. Frequent voluntary termination of the defecation reflex commonly results in constipation.

Bowel activity can be inhibited by the peritoneointestinal reflex, which is activated by the presence of peritoneal irritation; by the renointestinal and vesicointestinal reflexes, which are activated by irritation of the kidney or urinary bladder, respectively; and by the somatointestinal reflex, which is activated when the skin over the abdomen is intensely irritated.

41.3 CONSTIPATION

Although tenesmus is the most common clinical sign for an animal with constipation, vomiting, depression, anorexia, and various degrees of abdominal discomfort may also be reported. Animals may be misdiagnosed as having diarrhea when passage of liquid feces around fecal impaction occurs and consequently a complete physical examination is not performed.

Constipation can occur as a result of extraintestinal disorders or primary intestinal and anorectal disorders. Extraintestinal disorders may inhibit normal neural impulses or muscular function; they may interfere with the PDR through weakness, pain, or dyspnea; they may affect fecal consistency through dehydration; or they may cause mechanical obstruction through compression. Extraintestinal disorders include hypothyroidism, hypercalcemia, hypokalemia, chronic renal failure, myopathies, and thoracic cavity disease. Intestinal and anorectal diseases result in constipation through obstruction, inhibition of the defecation reflex because of pain, and loss of motility.

41.3.1 Clinical Evaluation

41.3.1.1 History

Detailed information regarding the duration of constipation and influencing factors may help determine the cause. The clinician should determine if there is a history of ingestion of indigestible material (e.g., bone, hair, plastic, sticks, or branches) that may increase fecal bulk or cause pain that can terminate the defecation reflex. Other historical factors that may be relevant include recent surgery, previous pelvic trauma and, possibly, radiation therapy.

144

145

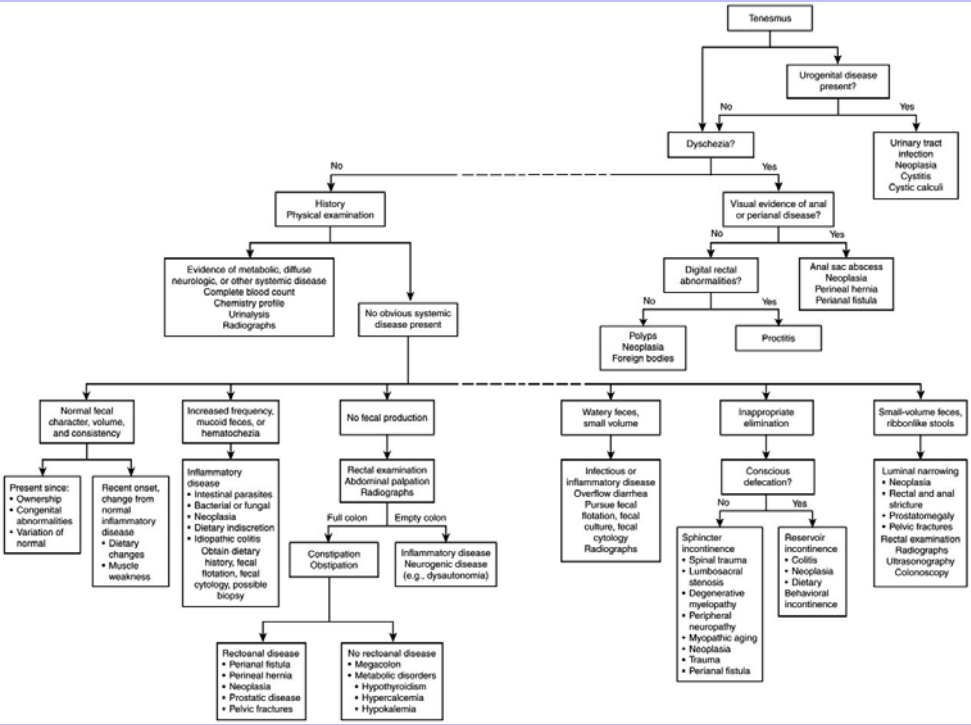
41.3.1.2 Signalment

In the feline, megacolon is a common disease. Specifically, sacral spinal cord deformities are seen in the Manx cat. Intact male dogs should be carefully evaluated for prostate disease, such as abscesses or cysts, and perineal hernia. Aged and large breed dogs should be screened for orthopedic disease, such as hip dysplasia. Juvenile dogs and cats should be evaluated for congenital abnormalities, such as imperforate anus. Dysautonomia has been diagnosed primarily in dogs from Kansas and Missouri and in cats primarily from Great Britain. The German shepherd dog should be carefully evaluated for perianal fistulas.

41.3.1.3 Physical Examination

In addition to a careful examination of all other body systems, which may yield clues to extraintestinal disease, particular attention should be given to examination of the anorectal area. Visual inspection may identify perianal fistulas or tumors, and careful digital examination may identify prostatic disease, strictures, masses, perineal hernia, foreign material, or pain.

Figure 41-1 Diagnosis and treatment of constipation, tenesmus, dyschezia, and fecal incontinence.



41.3.1.4 Diagnostic Evaluation

Routine laboratory work usually is of minimal value, except when systemic disease is suspected. Survey and contrast radiography, ultrasonography, and colonoscopy may be helpful when the diagnosis cannot be determined from the history and physical examination.

41.4 TENESMUS AND DYSCHEZIA

Tenesmus and dyschezia are clinical signs that often overlap and occasionally are difficult to distinguish. The difference is that dyschezia occurs exclusively as a result of disease of the anal and perianal tissues. Tenesmus, a result of disease of the large intestine, is seen with obstruction, inflammation, and constipation (Figure 41-1).

41.4.1 History

It is important for the clinician to determine whether tenesmus is the result of urinary tract or intestinal tract disease. Cats with lower urinary tract signs frequently are described by their owners as straining to defecate or constipated, which may result in a misguided diagnostic workup. Female dogs adopt similar postures when straining to defecate or urinate. The timing of the event may also be helpful, because tenesmus prior to defecation suggests obstruction, and tenesmus after defecation suggests irritative disorders. The character of the feces may provide further clues to the diagnosis. The presence of fresh blood or mucus suggests an inflammatory component, such as with infectious colitis, idiopathic colitis, dietary indiscretion, or neoplasia. Small volumes of ribbonlike stool suggests luminal narrowing, such as with a stricture or prostate disease.

41.4.2 Signalment

There are a few breed-specific disorders, such as histiocytic ulcerative colitis in the boxer and perianal fistulas in the German shepherd dog. Other inflammatory conditions can be seen in a variety of breeds. Infectious and inflammatory disease is suspected in young animals, whereas neoplastic disease is a primary concern in the aged animal.

41.4.3 Physical Examination

The principles of a complete physical examination are identical to those outlined for constipation. Absence of fecal material may be suggestive of an inflammatory condition. Additional care must be given to examination of the urinary tract, particularly palpation of the urinary bladder transabdominally and the urethra per rectum.

41.4.4 Diagnostic Evaluation

Routine laboratory work provides few clues to the diagnosis. Radiography, ultrasonography, fecal flotation, fecal culture, fecal cytology, colonoscopy/proctoscopy, and biopsy usually provide the information necessary to confirm a diagnosis.

41.5 FECAL INCONTINENCE

Incontinence occurs as a result of dysfunction in the ability of the anal sphincters to prevent involuntary leakage (sphincter incontinence) or the loss of the storage ability of the large intestine (reservoir incontinence).

Animals with reservoir incontinence are aware of their need and act of defecation. As a result of small intestinal or colorectal disease, which can result in irritation, loss of storage capacity or compliance, overwhelming fecal volume, or disturbances of motility, voluntary inhibition of external anal sphincter relaxation is lost.

Sphincter incontinence typically is a result of a neuromuscular disorder affecting the *continence reaction,* the reflexive and conscious contraction of the external anal sphincter. Sphincter incontinence occurs with denervation or damage to the external and internal anal sphincters or the muscles that support the pelvic canal or, possibly, with loss of sensory function. Patients with sphincter incontinence are plagued by the involuntary passage of feces. Disease of or damage to the levator ani and coccygeus muscles, damage to the pudendal nerve or sacral spinal cord, and disease or trauma to the perianaltissues can result in sphincter incontinence.

41.5.1 Clinical Evaluation

41.5.1.1 History

If the animal is conscious of defecation, characterized by posturing and possibly tenesmus, the clinician can focus on causes of reservoir incontinence. Frequent defecation, fresh blood in the stools, and mucoid stools also are clues to reservoir incontinence. Other information that may be important includes a dietary history, a history of trauma or orthopedic problems, previous dystocia, previous surgery, and the duration of disease. Behavioral problems can be mistaken as reservoir incontinence, and attempts should be made to distinguish the two. Dogs with behavior problems usually do not display the tenesmus and urgency of reservoir incontinence and defecate at inappropriate times and places. The animal's ability tourinate normally should give clues as to the integrity of the nervous system.

41.5.1.2 Signalment

Large breed dogs have a higher incidence of lumbosacral stenosis and degenerative myelopathy, older dogs may have neoplastic disease or geriatric incontinence, and younger dogs and cats may have congenital abnormalities, such as vertebral malformations.

41.5.1.3 Physical Examination

In addition to a complete physical examination, careful visual and digital examination of the perianal, anal, and rectal areas may provide clues to the diagnosis. Anal sphincter tone should be carefully evaluated; however, it is not a reliable indicator of anal sphincter function. The clinician should also assess urinary bladder tone and tail tone, as well as hindlimb function and reflexes and whether paresthesia is present. Hyperesthesia or paresthesia of the pelvic limbs is supportive evidence of lumbosacral stenosis. Depressed pelvic limb reflexes are seen with lumbosacral cord lesions, lumbosacral stenosis, peripheral neuropathies and, possibly, myopathies.

41.5.1.4 Diagnostic Evaluation

Routine laboratory work is of limited value except when systemic disorders are present. Radiography, myelography, computed tomography (CT) or magnetic resonance imaging (MRI), colonoscopy, and electromyography may be performed as needed based on suspicion of disease localization.

42 CHAPTER • 42 Flatulence

Michael E. Matz

The term *flatulence* refers to excessive accumulation of gas in the gastrointestinal tract. It may be associated with eructation, borborygmus, or flatus. *Eructation* is the expulsion of gas from the stomach. *Borborygmus* is a rumbling noise caused by the propulsion of gas through the gastrointestinal tract. *Flatus* is the anal passage of intestinal gas.

Flatulence is more commonly observed in dogs than cats and is most often noted in inactive indoor dogs. It usually results from dietary intolerances but occasionally can signal more serious gastrointestinal disease, particularly of the small bowel or pancreas. Most owners accept flatulence and borborygmus in their pets as normal and are unconcerned about its consequences.

42.1 PATHOPHYSIOLOGY

The major gastrointestinal gases are nitrogen and oxygen, which are derived from swallowed air and diffusion from blood, and hydrogen, carbon dioxide, and methane, which are primarily products of bacterial metabolism and fermentation and nonbacterial reactions (e.g., pancreatic bicarbonate interacting with acid to produce carbon dioxide) that occur in the bowel lumen. In human beings, and probably in dogs and cats, as much as 99% of flatus is composed of these odorless gases. The remaining 1% is composed of odoriferous gases, including hydrogen sulfide, methanethiol, dimethylsulfide, ammonia, skatole, mercaptans, volatile amines, and short chain fatty acids. These odoriferous gases also result from bacterial metabolism and fermentation. Sulfur-containing gases, particularly hydrogen sulfide, have been shown to be a major determinant of the malodor of canine flatus.

Most of the gas that enters the digestive tract is thought to come from swallowed air. Aerophagia mainly occurs during the ingestion of liquids and solids and can be exacerbated by rapid or competitive eating situations. Most swallowed air is subsequently eliminated by eructation from the stomach and esophagus. If not eructated, the nitrogen contained in swallowed air travels through the gastrointestinal tract with minimal absorption and subsequently is passed. It is noteworthy that the transit time for gas is considerably shorter than that for liquids or solids. Air entering the intestinal tract can be passed out the rectum rapidly (within minutes). Gases can also be removed by diffusion into blood or consumption by bacteria.

The composition and volume of flatus are affected by the quantity and variety of nutrients eaten, as well as by the type and abundance of bacterial flora. A significant amount of gas is formed from the bacterial fermentation of both dietary (e.g., fiber and poorly digestible carbohydrates and proteins) and endogenous (e.g., mucin, bile acids) substrates. Foods such as legumes (soybeans, beans, peas) that contain large amounts of indigestible oligosaccharides are apt to produce large amounts of intestinal gas. The oligosaccharides are fermented to hydrogen and carbon dioxide by *Clostridium* organisms and other bacteria. Variations in the metabolic capacity of the bacteria flora may explain the different responses animals may have to nonabsorbable carbohydrates. Fiber-containing pet foods may contribute to flatulence directly, if the fibers are fermentable by colonic bacteria, and/or indirectly through reduced dry matter digestibility. Pectins and most gums are rapidly fermentable fibers found in pet foods. Sulfur-reducing bacteria convert dietary sources of sulfur, including sulfate and sulfur-containing amino acids, to the odoriferous gases hydrogen sulfide, methanethiol, and dimethylsulfide. The production of these gases usually is increased by foods containing increased amounts of sulfate (cruciferous vegetables, onions, nuts, carrageenan) or protein.

Maldigestion due to exocrine pancreatic insufficiency or malabsorption resulting from small intestinal diseases often leads to excessive intestinal gas caused by the fermentation of malassimilated substrates. Lactose intolerance also can cause flatulence.

42.2 CLINICAL EXAMINATION FINDINGS

Owners may describe an increase in the frequency of flatus, an objectionable odor associated with flatus, the presence of borborygmus, or abdominal distention. Occasionally these signs are associated with concurrent abdominal pain, vomiting, diarrhea, or weight loss, any of which suggest more serious gastrointestinal disease. The owner may report that the pet has a hunched posture, exhibits unsettled behavior, or adopts a praying position. These signs may result from excessive intestinal gas, motility disorders that disrupt the passage of gas through the bowel, or increased visceral sensitivity to bowel distention. The animal's temperament may be important. Excessive aerophagia in a nervous animal, or animals with aggressive or competitive eating habits, can increase gastric gas, although it is unclear whether ingested air contributes significantly to intestinal gas or flatus.

A complete dietary history is essential. Owners should be questioned about any recent dietary change or dietary indiscretion. An assessment of specific foods, food ingredients, treats, and supplements, as well as the potential for dietary indiscretion, should be made. In human beings, diets high in soybeans, whole wheat products, bran, and fats can cause flatulence. Similar associations appear to occur in some dogs and cats. Spoiled food and diets high in protein or fat are more likely to yield odoriferous gases. Milk products can cause flatulence in animals with lactase deficiency. The feeding method should also be thoroughly evaluated. The amount fed, feeding frequency, how the food is offered, access to other food, and the relationship of feeding to exercise should be determined.

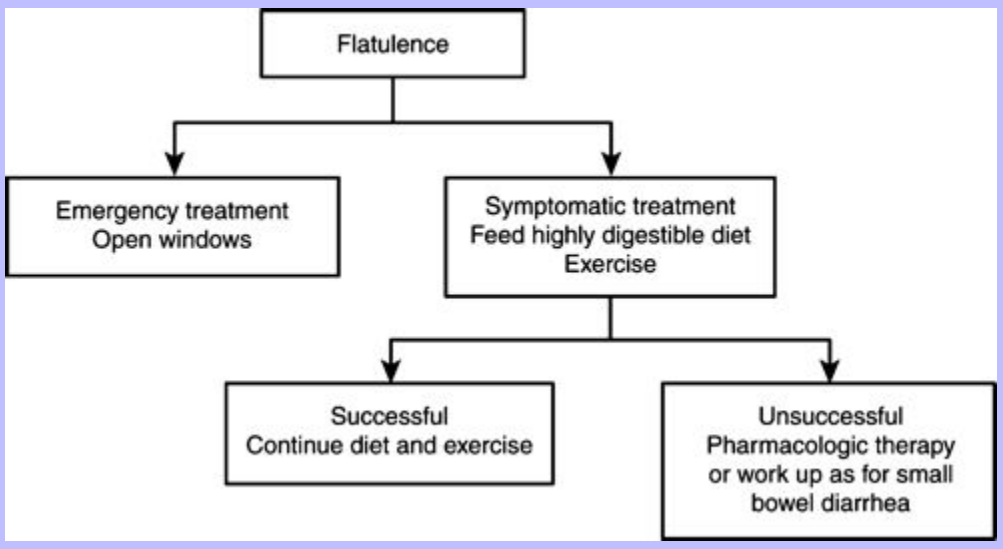
With the exception of borborygmus, the physical examination of an animal with flatulence usually is unremarkable unless concomitant gastrointestinal disease is present. Additional diagnostic tests are warranted in the latter animals.

42.3 MANAGEMENT

The management of flatulence begins with changing the diet (Figure 42-1). Feeding a highly digestible diet reduces the food residues available for bacterial fermentation. The diet should not contain excessive amounts of rapidly fermentable fiber. Vegetarian-based diets should be avoided because these products often have sulfur-containing vegetables and legumes. Optimally, the diet should be lactose deficient. Changing sources or amounts of dietary protein, carbohydrate, and fat may benefit individual animals. Diets containing rice as the primary carbohydrate source may produce less intestinal gas than diets containing other sources of carbohydrate. Suitable commercial foods are available from most major pet food manufacturers. Dietary trials may be necessary to find a food that reduces flatulence or objectionable flatus. Vitamin-mineral supplements may increase intestinal bacterial activity and probably should be avoided.

148
149

Figure 42-1 Algorithm for management of flatulence.



Reducing aerophagia, by avoiding situations that provoke nervousness and discouraging rapid or competitive eating, may also be helpful. Feeding several small meals daily may alleviate some of these problems.

Regular exercise also is beneficial, presumably because exercise stimulates gastrointestinal motility and defecation. In the event that dietary manipulation and regular exercise are not successful, symptomatic pharmacologic intervention should be considered.

Pharmacologic management involves reducing or controlling the amount of flatulence and/or the objectionable odor of flatus. Substances that can be used include simethicone, activated charcoal, *Yucca schidigera* preparations, zinc acetate, bismuth subsalicylate, alpha-galactose, and pancreatic enzyme supplements.

Simethicone (25 to 200 mg per dose, given every 6 hours) frequently is used as a treatment for borborygmus, gaseous colic, and flatulence in human beings. It is an antifoaming agent that reduces surface tension, allowing bubbles to coalesce so that they can be passed more easily. Simethicone is not absorbed from the gastrointestinal tract and can be safely used in dogs and cats at or near the dosage for human beings. Its effectiveness as an antiflatulent in dogs and cats is unknown. Both veterinary and human (over the counter) products containing simethicone are commercially available.

Activated charcoal is one of the more commonly used adsorbent antiflatulents in human beings. Its absorbency results from its porous structure, which confers a tremendous internal surface area. Charcoal is of questionable benefit for the relief of flatulence, but it may be effective in absorbing small amounts of sulfur-containing gases, which are primarily responsible for malodorous flatus. Commercial treats containing activated charcoal are available for dogs.

Y. schidigera, zinc sulfate, and bismuth subsalicylate also may be effective in reducing the unpleasant odor of flatus. The efficacy of *Y. schidigera* appears to be related to its ability to bind hydrogen sulfide and/or to decrease the numbers or activity of sulfate-reducing bacteria that generate hydrogen sulfide. Poorly absorbed divalent cations (e.g., zinc, bismuth) bind sulfhydryl compounds such as hydrogen sulfide and methanethiol to form

insoluble salts, and this effectively prevents the liberation of these gases. To be of benefit, bismuth subsalicylate probably needs to be given multiple times per day, which can make it impractical to use. Like charcoal, these agents do not appear to be particularly effective in reducing flatulence. The efficacy of the agents may be improved if administered together.

Anecdotal reports indicate that alpha-galactosidase and pancreatic enzyme supplements may be effective in reducing flatulence in some dogs and cats. Alpha-galactosidase works by improving digestion of nonabsorbable carbohydrates found in legumes. Both veterinary and human products containing alpha-galactosidase are available. Pancreatic enzyme preparations are claimed to assist the digestion of fermentable nutrients that are digested poorly by the gastrointestinal systems of monogastrics.

In most dogs and cats, flatulence can be controlled successfully, often through dietary management alone. Relapses in controlled animals often are due to dietary indiscretion. If dietary management, exercise, and supplementary therapy are unsuccessful in reducing or controlling flatulence, an investigation similar to that for a dog or cat with small bowel diarrhea (see Chapters 39 and 222) should be considered.

43 CHAPTER • 43 Abdominal Distention, Ascites, and Peritonitis

Stephen A. Kruth

Abdominal distention is potentially a serious sign of disease and should be evaluated reasonably quickly, especially when associated with discomfort, restricted breathing, fever, weakness, or other clinical signs. The initial diagnostic goal should be to identify obesity, pregnancy, a distended urinary bladder, obstipation, or gastric dilatation. If these are not the cause of the distention, the clinician should determine whether hepatomegaly, splenomegaly, or some other mass is present or whether the predominant abnormality is the accumulation of fluid in the peritoneal cavity (i.e., an effusion). In some cases both a mass and an effusion may be present. Distinguishing between organ enlargement or masses and effusion is accomplished through physical examination and abdominal imaging.

When organomegaly or a mass is the predominant abnormality, a specific diagnosis usually can be made through needle biopsy. When an effusion is present, a sample should be obtained by paracentesis and characterized as a transudate, modified transudate, exudate, chyle, or blood. If the effusion is a *transudate* (low to moderate cellularity and a low protein concentration), modified transudate, or chyle, the animal is said to have *ascites*. If the effusion is an *exudate* (high cellularity and a high protein concentration), the animal has *peritonitis*. Exudates can be septic or nonseptic (e.g., feline infectious peritonitis, bile, urine, pancreatitis).

43.1 PATHOPHYSIOLOGY OF ABDOMINAL ORGAN ENLARGEMENT

Distention of the stomach or intestines usually is due to the accumulation of gas and fluid in the lumen of the affected organ. Gas can accumulate as a consequence of aerophagia (usually secondary to respiratory disease), gastric dilatation, ileus, or obstruction. Obstipation can cause abdominal enlargement, especially in cats with megacolon. Renal or urinary bladder enlargement can follow ureteral or urethral obstruction; bladder enlargement can also be associated with neurologic dysfunction. Enlargement of the liver can be a consequence of venous congestion secondary to right heart failure; splenic enlargement can be caused by venous congestion secondary to splenic torsion. Gross organ enlargement often is due to infiltrative disorders (especially lymphosarcoma and other neoplasms), which may cause either diffuse or localized enlargement of the involved organ. Hyperadrenocorticism can also cause remarkable hepatomegaly, abdominal wall weakness, and abdominal distention.

43.2 PATHOPHYSIOLOGY OF ABDOMINAL EFFUSIONS

The peritoneum is a serous membrane consisting of mesothelial cells overlying a connective tissue stroma. The parietal portion covers the transversalis fascia of the abdominal wall, and the visceral portion envelops the abdominal viscera. The peritoneal cavity formed by these two layers is almost nonexistent in normal animals, containing only a small volume of fluid, which serves to lubricate the parietal and visceral peritoneal surfaces. Normally, peritoneal fluid (lymph) is formed at the arteriolar end of capillaries and reabsorbed both at the venous end of capillaries and by means of lymphatic uptake (predominately via the large lymphatic vessels of the diaphragm). In the normal animal, fluid movement is balanced; a large exchange of fluid and solute occurs, but a low and stable volume is maintained.

The primary event leading to the development of an effusion is an alteration in one or more of the Starling forces governing fluid movement across membranes. Increased portal hydrostatic pressure caused by obstruction of venous flow, decreased plasma colloidal oncotic pressure associated with hypoalbuminemia, and/or increased permeability of the capillary endothelium secondary to inflammation can all lead to the development of an

effusion. Decreased lymphatic uptake, usually due to reduced flow of lymph from the peritoneal cavity, can also cause effusion.

An important consequence of the redistribution of extracellular fluid into the peritoneal cavity is a decreased effective plasma volume and reduced cardiac output. This stimulates the renin-angiotensin-aldosterone system, resulting in sodium and water retention. Antidiuretic hormone levels increase in response to sodium retention, leading to isotonic expansion of the extracellular fluid space. In heart failure, elevations in the levels of endothelin and insensitivity to circulating atrial natriuretic peptide contribute to sodium retention. The net effect in any ascitic condition is an increase in total body water and sodium, which perpetuates the ascitic state if the underlying cause is not resolved.

Ascites caused by portal hypertension can be classified as *prehepatic* (restriction of blood flow into or through the portal vein), *hepatic*, or *posthepatic* (from the level of hepatic vein tributaries, through to the right ventricle) in origin, and to some extent the effusion characteristics are determined by where the abnormality lies. Ascites caused by prehepatic disorders is rare as recruitment of collateral portosystemic vessels often occurs when portal pressure increases. Portal vein obstruction due to compression by a mass, or increased circulation and thus increased hydrostatic pressure in the portal system caused by a *hepatic artery–portal venous fistula* are possible causes. With prehepatic portal hypertension, the elevated hydrostatic pressure causes increased lymph formation from the intestinal serosa, and the effusion typically is a pure transudate (at least initially; the presence of any fluid in the peritoneal cavity irritates the peritoneum, causing protein loss, increased cellularity, and formation of a modified transudate).

The most common posthepatic cause of portal hypertension is *right-sided heart failure* (which can be caused by cardiac disease or can occur secondary to tamponade resulting from pericardial effusion). Ascites secondary to right heart failure is more common in dogs than cats because the hepatic veins of dogs are more likely to act as postsinusoidal sphincters, which increase portal pressure. Rare causes of posthepatic ascites include *obstruction of the caudal vena cava* by a thrombus, compression by a mass, or anatomic changes associated with a diaphragmatic hernia. In posthepatic portal hypertension, excess lymph is formed primarily in the hepatic sinusoids and then diffuses across the liver capsule. Hepatic lymph is relatively high in protein compared with lymph formed from the intestinal capillaries, and the typical effusion of posthepatic disease is a modified transudate.

150

151

Ascites secondary to hepatic disease is due largely to portal hypertension, and the effusion can be either a transudate or a modified transudate, depending on the type of pathology and its distribution. In human beings, the mechanism of effusion formation in cirrhosis is complex and not completely understood. Three theories have been invoked to explain this form of ascites: the underfill theory proposes that the primary abnormality is a decrease in effective circulating volume (underfilling), which occurs when fluid is sequestered in the splanchnic vascular bed secondary to portal hypertension. Secondary renal sodium and water retention occurs, and an increase in hydrostatic pressure in hepatic sinusoids and splanchnic capillaries leads to increased lymph formation, which exceeds the drainage capacity of the lymphatic system. Alternatively, the overfill theory suggests that the primary abnormality is renal retention of sodium and water in the absence of volume depletion (by an unknown mechanism), leading to an increase in extracellular fluid volume (overfilling). In the presence of pre-existing hepatic venous outflow obstruction and portal hypertension, ascites develops. The third hypothesis proposes that the primary abnormality is splanchnic arteriolar vasodilatation (possibly mediated by nitric oxide), leading to underfilling of the systemic arterial vascular space and baroreceptor-mediated stimulation of the renin-angiotensin-aldosterone system. Concurrent hypoalbuminemia and decreased colloidal oncotic pressure may contribute to the formation of ascites in all of these situations.

Abdominal effusion can be caused by mechanisms other than portal hypertension. Severe hypoalbuminemia secondary either to *glomerular disease* or to severe *protein-losing enteropathies* can lead to ascites (usually a

transudate). Widespread miliary *carcinamatous* seeding of the serosa *(carcinomatosis),* as well as other cancers, can induce the formation of modified transudate or exudate through obstruction of capillaries and inflammation. With any form of inflammation, mediators increase endothelial permeability and recruit neutrophils and other phagocytic cells, which may lead to the formation of an exudate. Septic exudates usually are caused by bacterial infections and are relatively small in volume. Nonseptic exudates can be caused by *neoplasia, bile, urine,* or *feline infectious peritonitis. Chyle* (lymph of intestinal origin with a high lipid content) can leak into the peritoneal cavity from lymphatics; the causes of *chylous ascites* in dogs and cats include neoplasia, trauma, infection, and right heart failure. Rupture of blood vessels, the ureters, bladder, or biliary tree can occur secondary to *trauma*. Bleeding caused by coagulopathies (usually affecting the clotting cascades) or tumors (especially splenic or hepatic *hemangiosarcoma*) can cause hemoabdomen.

43.3 CLINICAL SIGNS

Owner concerns for a dog or cat with abdominal enlargement can include weight gain, decreased activity and decreased exercise tolerance, inappetence, or increased respiratory rate. The rate of abdominal enlargement is variable, and the condition may develop over hours to weeks, depending on the underlying cause. The history should include a review to identify signs suggestive of pathology of the cardiac, renal, hepatic, or other organ systems. Abnormalities identified by abdominal palpation can include hepatomegaly, splenomegaly, or one or more mass lesions. Low-volume effusions can give the impression of a “slippery” feel when the small bowel is palpated, and a fluid wave usually can be appreciated with large-volume effusions. Tachypnea can result from restricted ventilation caused by cranial displacement of the diaphragm by an enlarged liver or by fluid. Signs of abdominal pain may be present with peritonitis of any cause.

A careful general examination may reveal signs that direct the diagnostic approach. For example, cardiovascular abnormalities, such as jugular distention or pulsation, murmurs, or arrhythmias, are suggestive of right heart failure, and muffled heart sounds are consistent with pericardial effusion and tamponade. Jaundice is consistent with liver failure or rupture or obstruction of the biliary system, fever is suggestive of an inflammatory disorder, and generalized lymphadenopathy is consistent with lymphosarcoma.

43.4 DIAGNOSTIC APPROACH

Radiographs can be used to help differentiate organomegaly, other mass lesions, and effusions. Ultrasonographic examination of the abdomen is more useful for identifying specific organ enlargement, and alterations in organ echogenicity may be suggestive of some types of neoplasia, hepatic lipidosis, or other pathology. Abdominal ultrasound is also useful for identifying low-volume effusions. Ultrasound-guided needle biopsies and/or fluid aspiration can be performed, and cytologic diagnosis may be possible. However, histopathologic evaluation of biopsy tissue may be more reliable in terms of making a specific diagnosis. Tissue samples can also be submitted for bacterial culture, if indicated. The animal's hemostatic ability should be evaluated prior to biopsy: platelet number and function (as evaluated by mucosal bleeding time) are important considerations, along with assays of the coagulation cascades (activated clotting time or activated partial thromboplastin and prothrombin times).

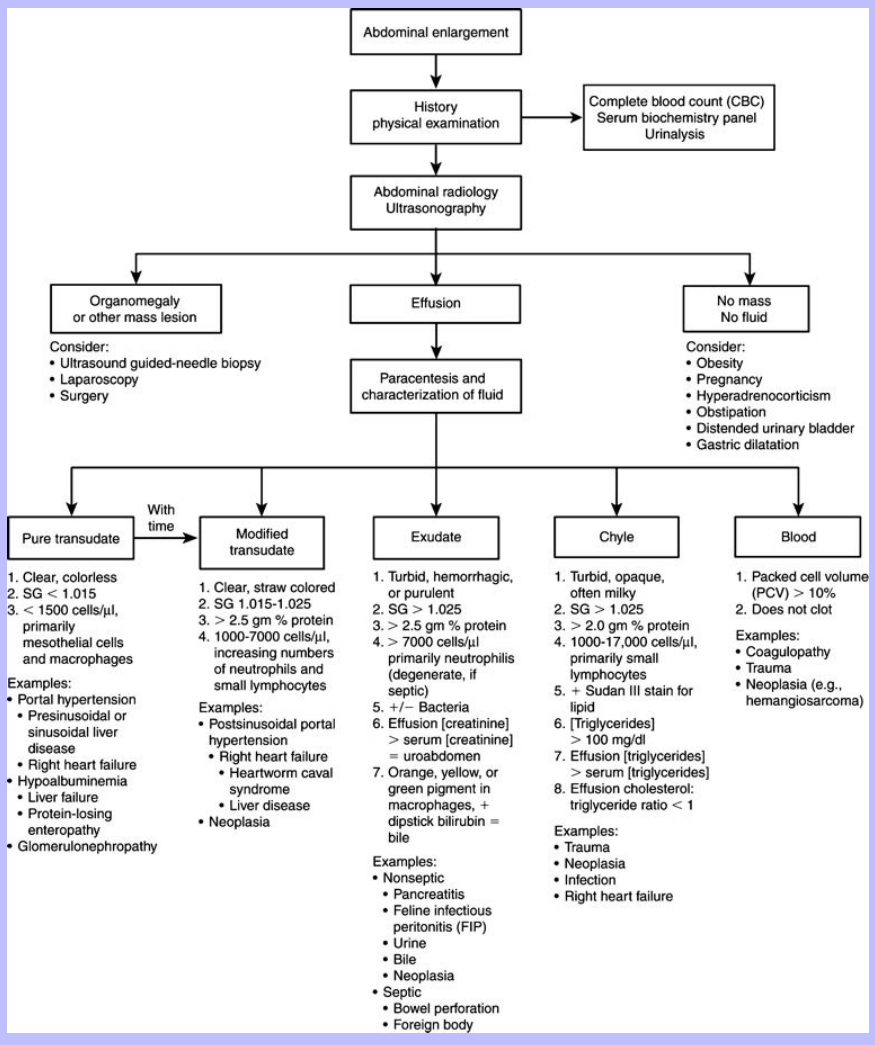
A sample of effusion can be safely obtained by aspirating the peritoneal cavity using a 22-gauge needle attached to a 12 mL syringe. After aseptic skin preparation, the needle is placed through the body wall at the ventral midline slightly caudal to the umbilicus, avoiding the liver, spleen, and urinary bladder. The animal can be standing or in lateral recumbency, and local anesthesia usually is not necessary. Nondiagnostic samples are obtained when blood is aspirated from the liver or spleen or when only small amounts of effusion are present. Other than coagulopathies, there are few contraindications for paracentesis. Complications include laceration of the liver, spleen, or, if present, a tumor, and bacterial contamination of the peritoneal cavity.

The specific gravity, protein content, and cell count of the effusion should be determined, and cytologic evaluation should also be performed. Depending on the situation, creatinine, cholesterol, triglyceride, and bilirubin levels or other assays may be indicated. Smears of aspirated fluid should be made immediately, and the remaining fluid split into ethylenediamine tetra-acetic acid (EDTA) and clot tubes so that additional smears can be made from a centrifuged pellet or, preferably, as a cytospin slide. If the fluid is bloody, the packed cell volume should be determined and compared with that of peripheral blood. Blood obtained from the spleen or other organs contains platelets and usually clots, whereas blood from previous abdominal hemorrhage usually does not contain platelets and does not clot. A sample should be saved for bacterial culture if indicated. The characterization of an effusion as a transudate, modified transudate, exudate, chyle, or hemorrhage is presented in the algorithm (Figure 43-1). In human beings, characterization of effusion often is based on the serum ascites-albumin gradient, which correlates directly with portal hypertension; however, the utility of this test has not been adequately determined in dogs and cats.

151

153

Figure 43-1 Algorithm for diagnostic approach to abdominal enlargement.



A complete blood count (CBC), serum biochemistry panel, and urinalysis are indicated for any animal with abdominal effusion. Although animals with effusions have an increase in total body water and sodium, hyponatremia sometimes is present, likely caused by increased thirst and water consumption and by impaired free water excretion. Hyperkalemia may also be present due to decreased renal distal tubular function. These animals usually have normal adrenal function (i.e., do not necessarily have hypoadrenocorticist. For animals with proteinuria, a urine protein/creatinine ratio should be determined, and an ultrasound-guided renal biopsy can be performed to diagnose and characterize glomerulonephropathies. Animals with signs of right-sided heart failure should be evaluated with thoracic radiographs, echocardiography, and electrocardiography (ECG), and tested for heartworm. Dogs or cats that may have cancer should have thoracic radiographs evaluated for pulmonary metastases. External masses or enlarged lymph nodes should be aspirated for cytology; core biopsies can be obtained for histopathology.

43.5 MANAGEMENT OF ABDOMINAL EFFUSIONS

Animals with hemoabdomen (due to trauma or hemangiosarcoma), rupture of the urinary bladder or biliary tree, or chylous effusion usually require surgical management. Dogs and cats with exudative effusions associated with pancreatitis or bacterial peritonitis should also be considered as surgical candidates, and septic effusions must be managed with appropriate antibiotics and supportive therapy. Cats with the effusive form of feline infectious peritonitis (FIP) can be made more comfortable with large-volume paracentesis while medical management of FIP is considered. Large-volume paracentesis is also indicated as a palliative measure for animals with carcinomatosis, when there is significant respiratory distress secondary to any effusion of any cause, or when diuretics are not effective for controlling ascites. Large-volume paracentesis appears to be well tolerated by most animals with abdominal effusions. The management of malignant effusions is dictated by the type of cancer and the clinical stage of the animal. Colloid therapy with plasma, albumin, hetastarch, or pentastarch may be useful for short-term management of effusions secondary to hypoalbuminemia.

The management of ascites caused by cardiac failure is based on improving cardiac performance as dictated by the primary disorder. Animals with portal hypertension of any cause (e.g., right-sided heart failure, liver disease) should be managed with diuretic therapy (furosemide, 1 mg/kg PO, IV, IM given twice daily, and/or spironolactone, 1 mg/kg PO given twice daily, increasing the dosage as necessary; these drugs can be administered concurrently to minimize electrolyte abnormalities). As total body sodium increases in ascitic disorders, a sodium-restricted diet is indicated.

44 CHAPTER • 44 Neurologic: Neurologic Manifestations of Systemic Disease

Karen L. Kline

The evaluation of a dog or cat with neurologic dysfunction is based on two questions: (1) Does this patient have disease of the nervous system? and (2) If so, is it brain, spinal cord, or neuromuscular in origin? The neurologic examination can reveal whether the animal has evidence of focal, diffuse, or multifocal, central or peripheral nervous system disease. From these findings, a differential list can be formulated and the appropriate diagnostics performed. What is essential, however, is a thorough physical examination to help determine if the signs observed are primarily of neurologic origin or are secondary to underlying systemic or metabolic disease. At times this distinction can be difficult until further diagnostics are performed; it is determining which diagnostics are appropriate that can be confusing to the clinician. Underlying systemic or metabolic illness can have a dramatic effect on the nervous system. The diagnosis and treatment of the diseases responsible for these effects are discussed in greater detail in Chapter 190. This chapter concentrates on categories of these diseases, areas of the nervous system affected, and the diseases' common neurologic presentations.

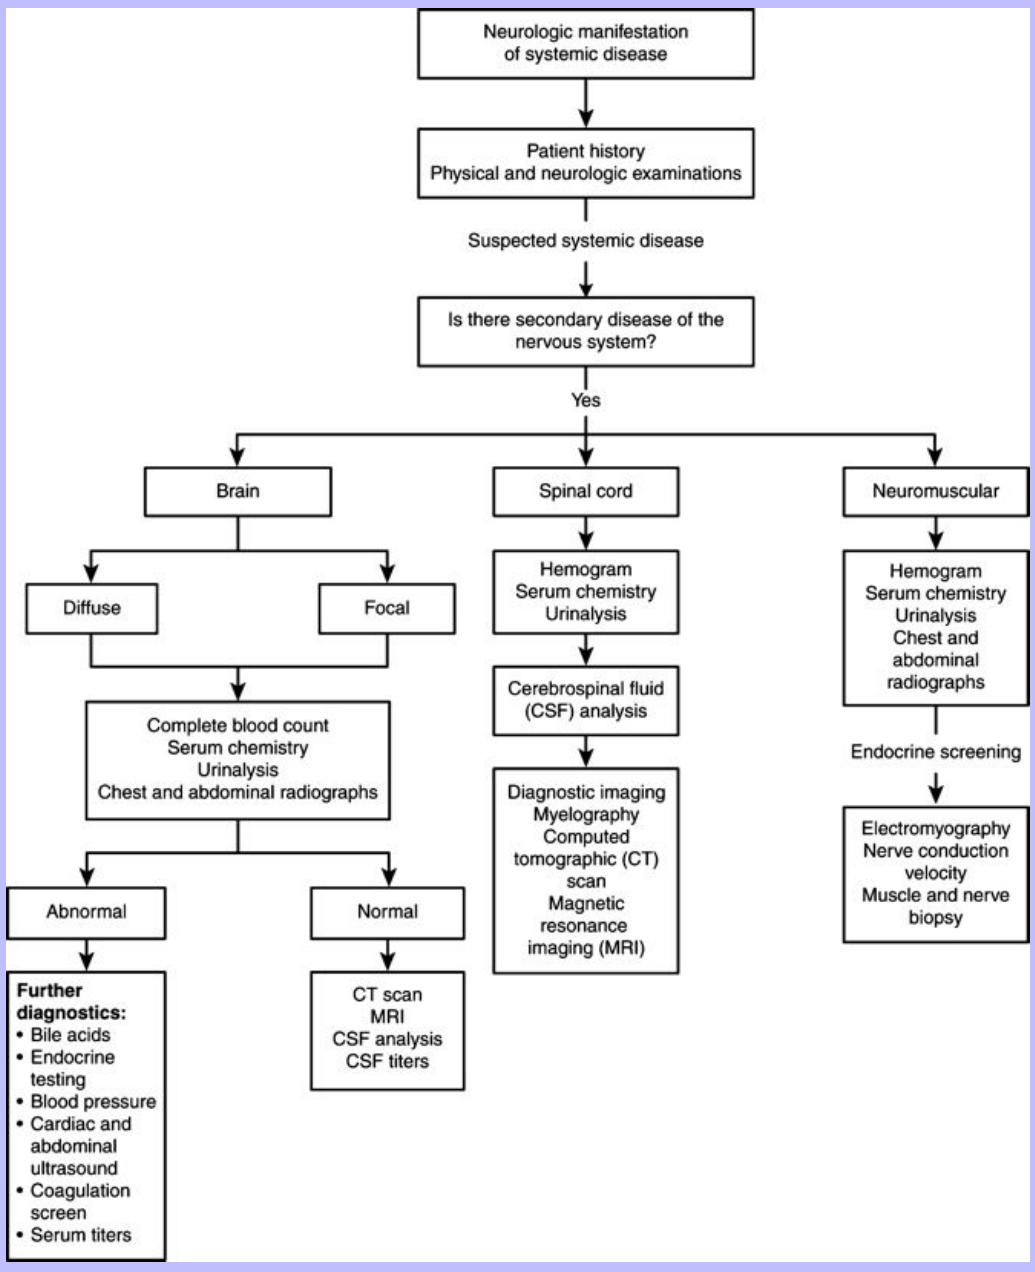
The different categories of diseases that affect the nervous system can include disorders of energy supply, ionic or electrolyte disturbances, endocrine dysfunction, metabolic dysfunction, hematologic disorders, infectious agents, immune dysfunction, and paraneoplastic syndromes (Figure 44-1).

In general, the neurologic target areas for these disturbances are the cerebral cortex and the peripheral nervous system (peripheral nerves and muscle), although other portions of the central nervous system (CNS) can be affected. These two regions tend to have a high demand for energy supply, and even subtle changes can instigate neurologic manifestations.

44.1 CENTRAL NERVOUS SYSTEM EFFECTS

Signs of CNS dysfunction vary with the location of the insult. Changes in energy supply, electrolyte disturbances, and endocrine and metabolic dysfunction tend to cause more diffuse neurologic signs, such as behavior changes, seizures, circling in either direction, pacing, partial cranial nerve and visual deficits, and generalized weakness. Hematologic, infectious, immune-mediated, and paraneoplastic disorders tend to cause more focal or asymmetric signs, although exceptions do occur. The cerebral cortex and thalamus are two areas especially prone to even subtle changes in energy supply. The brain stem and cerebellum, however, are not immune to these changes. Examples of fuel deprivation include (1) hypoxemia secondary to underlying cardiopulmonary disease, anesthetic-related injuries, bleeding diatheses, or cerebrovascular ischemic disease; (2) hypoglycemia resulting from sepsis, endogenous or exogenous hyperinsulinism, or lack of glucose production as a result of severe hepatic dysfunction or increased metabolic demand; and (3) nutritional deficiencies, the most recognized of which is thiamine deficiency, which can result in both cerebrocortical and central vestibular dysfunction.

Figure 44-1 Algorithm for the evaluation of neurologic manifestations of systemic disease.



Aberrations in water and electrolyte balance can result in secondary cerebrocortical dysfunction. Examples include hypernatremia and hyponatremia that result in shifts in the brain osmolality and that have an acute or chronic course. Changes in ion balance, such as those that occur secondary to hypercalcemia or hypocalcemia and

hyperkalemia or hypokalemia, have a direct effect on ion channels in the CNS and can lead to excitatory or inhibitory neurotransmission.

Metabolic disorders that have secondary effects on the CNS and, more specifically, on the cerebral cortex and thalamus are those that liberate endogenous neurotoxins that affect the blood-brain barrier and neurotransmission and that alter the brain's neurochemical balance. Examples of such disorders include (1) hepatic encephalopathy caused by portosystemic shunting, microvascular dysplasia, hepatic cirrhosis, hepatic neoplasia, or inflammatory or infectious causes of hepatic dysfunction (the major causative agents involved in these diseases are hyperammonemia and false neurotransmitter production); and (2) uremic encephalopathy as a result of end-stage renal dysfunction. Exogenous neurotoxins, including strychnine, metaldehyde, illicit drugs, and lead, all can cause secondary CNS effects that, left untreated, can result in death.

Endocrine dysfunction can result in a wide range of CNS effects. Examples of such diseases include hypothyroidism, hyperthyroidism, hyperadrenocorticism, and hypoadrenocorticism. Each of these diseases can disturb the normal resting metabolic energy requirements of the brain and can cause structural changes in the brain parenchyma (pituitary macroadenoma) and vessels (atherosclerosis secondary to hypothyroidism and cerebrovascular accidents secondary to hyperthyroid toxicosis).

44.2 HEMATOLOGIC DISORDERS

Diseases associated with thromboembolism and polycythemia (relative and absolute) have a direct effect on brain function secondary to resultant infarction, changes in cerebral blood flow, and vascular sludging. Thromboembolism often is a sequela to cardiac disease, hyperadrenocorticism, glomerulopathies, immune-mediated disease, and sepsis and results in focal infarction of the surrounding brain parenchyma. Absolute polycythemia, either primary or secondary, results in an increased red blood cell mass that causes an increase in blood viscosity and resultant vascular hindrance, decreased microcirculation, and local hypoxia.

44.3 IMMUNE-MEDIATED DISEASE

Systemic lupus erythematosus (SLE) has been recognized as causing CNS signs in human beings as a result of immune complex deposition and plaque formation. Although this has not been recognized in the dog, evidence is strong that the same sequelae can occur in this species.

44.4 INFECTIOUS DISEASE

Disseminated fungal infections (histoplasmosis, blastomycosis, cryptococcosis), viral infections (canine distemper virus, rabies, and feline infectious peritonitis), and protozoal infections (toxoplasmosis, neosporosis) tend to have a neurotropism and can cause severe CNS dysfunction. In these cases, all portions of the CNS can be affected, and resolution of disease can be difficult because the organisms cause secondary, sometimes permanent, neuronal necrosis and death.

44.5 PARANEOPLASTIC SYNDROMES

Two of the most common paraneoplastic CNS effects are hypoglycemia induced by insulin-secreting tumors and hypercalcemia secondary to lymphoma and apocrine gland adenocarcinoma. Although the peripheral nervous system (PNS) is more prone to the effects of hypercalcemia, animals with this electrolyte disturbance can manifest CNS signs secondary to the effect on ion pumps and neurotransmission. Metastasis to the central nervous system from a distant site (hemangiosarcoma, feline renal lymphoma) is also an important sequela in this disease category.

44.6 PERIPHERAL NERVOUS SYSTEM

The components of the peripheral nervous system are the nerve root, peripheral nerve, neuromuscular junction, and muscle. Clinical signs vary according to the region affected; most commonly, the peripheral nerve, junction, and muscle are affected.

44.7 PERIPHERAL NEUROPATHIES

Clinical signs associated most commonly with peripheral neuropathies include weakness (either diffuse or focal) with or without normal proprioception, decreased or absent reflexes, and a voice change (if the lesion involves the laryngeal innervation). Common causes of neuropathies that occur secondary to changes in energy supply include (1) hypoglycemia, in which peripheral nerve degeneration and demyelination have been reported; (2) hyperglycemia (e.g., feline diabetic neuropathy manifested in a plantigrade stance), in which increased serum glucose concentrations are thought to impede axonal transport; and (3) hypoxia, which is observed in cases of aortic or iliac thromboembolism in the dog or cat and in cases of chronic cardiovascular disease.

Endocrine causes of peripheral neuropathies include (1) hypothyroidism, which can cause both focal clinical signs (most commonly cranial nerves VII and VIII are affected) and diffuse clinical signs, secondary to axonal degeneration, necrosis, and demyelination; and (2) hypoadrenocorticism, in which sudden shifts in electrolyte balance can affect axonal health and result in hyporeflexia and profound weakness.

Other examples of diseases that cause secondary peripheral neuropathies include (1) the infectious protozoan *Neospora caninum,* which causes a lumbar intumescence neuritis in puppies; (2) paraneoplastic syndromes associated with multiple types of cancer; and (3) immune-mediated polyradiculoneuritis, which is theorized to occur secondary to immune destruction of the myelin sheath.

44.8 JUNCTIONOPATHIES

Junctionopathies are characterized by either complete lower motor neuron paralysis or progressive exercise intolerance with normal reflexes. Examples of the former condition include tick paralysis and botulism, in which an endogenous toxin binds to the presynaptic membrane at the endplate and blocks acetylcholine (ACh) release. Examples of the latter condition include acquired myasthenia gravis, in which ACh is blocked from its reception at the postsynaptic membrane by immune complexes bound to the ACh receptor site.

44.9 MYOPATHIES

The previously described causes of neuropathies can also affect the muscles. The clinical signs associated with myopathies include weakness with normal proprioception; normal to decreased myotatic reflexes; voice change; a stiff, stilted gait, and ventral neck flexion (observed most commonly in the cat). Decreased energy supplies, including glucose and oxygen, can lead to abnormal muscle oxidative metabolism and resultant weakness. Endocrine disturbances, such as hypothyroidism and hyperthyroidism, have been implicated, because thyroid hormone is very tightly regulated within the muscle membrane, and even subtle changes result in aberrant oxidative metabolism. Hyperadrenocorticism results in abnormal glycogen deposition in the muscle and may have permanent effects, even with treatment for the disease, whereas the weakness induced by hypoadrenocorticism is reversible with therapy. Electrolyte disturbances, most importantly hypokalemia and hypocalcemia, can result in severe muscle weakness and tetany, respectively, due to the importance of these two electrolytes in the regulation of muscle ion channels. Other causes of secondary myopathies include the infectious agent *Toxoplasma gondii*,

155 156

hematologic aberrations such as absolute polycythemia, immune-mediated diseases such as masticatory myositis, the polymyositis associated with SLE, and paraneoplastic syndromes (cancer cachexia).

45 CHAPTER • 45 Tremor Syndromes

Dominik Faissler

45.1 DEFINITIONS

Tremor is a common presentation in dogs and cats. The terms *tremble, shake, quiver,* and *shiver* are used interchangeably to describe this involuntary, rhythmic, and oscillatory movement. Tremor results from simultaneous or alternating contractions of agonist and antagonist muscle groups. Electromyographically, biphasic rhythmic bursts can be recorded. Clinically, tremor syndromes present with continuous, rapid, back-and-forth movements of the head, hind legs, or whole body; these movements cease with sleep.

Tremor must be distinguished from myoclonus, fasciculations, tetany, dyskinesia, and seizures. *Myoclonus* is defined as a sudden, short, jerky, shocklike, involuntary movement caused by an abrupt muscular contraction. Myoclonic jerks arise from electrical discharge of the central nervous system and can involve the head, limbs, or trunk. *Fasciculations* are arrhythmic, involuntary, visible contractions of groups of muscle fibers that indicate pathologic discharge of spinal motor neurons. *Tetany* is characterized by skeletal muscle rigidity and spasm. *Dyskinesias* are rare disorders of the central nervous system that result in involuntary, ticlike, repetitive, and episodic movements of individual muscle groups. The terms *dystonia, atheosis, chorea,* and *ballism* are used in human neurology to describe various clinical manifestations of dyskinesia.

45.2 PHYSIOLOGIC TREMOR

Physiologic tremors are difficult to see in normal animals, but they are present at low-amplitude movements, at rest or with posture. Shivering is a normal response to hypothermia, and a fast-rising body temperature in the course of a febrile process may lead to trembling. In both cases, the caudal hypothalamus plays an important role in the induction of muscle oscillations. Fear, stress, joy, and anger are the manifestations of a complex response processed in the limbic system, prefrontal cortex, and hypothalamus. These emotional conditions produce a complex pattern of reactions, including increased muscle tone, adrenergic stimulation, and physiologic muscle tremor. Trembling may also be seen after heavy exercise as a result of metabolic exhaustion and weakness.

45.3 PATHOLOGIC TREMOR

Tremor is considered pathologic when it impairs the patient's normal function. Abnormal tremor has a more synchronous activation and larger amplitude and is more easily visualized. No classification system has been devised for pathologic tremor in animals, and little information is available on the etiology and pathogenesis of this condition.

45.3.1 Type

A *kinetic tremor* (or, as it is commonly called, an *intention tremor*) is evident when the patient performs a voluntary movement, and it is most obvious when the movement is goal oriented. *Intention tremor* usually presents with slow, high-amplitude, to-and-fro movements. *Resting tremor* is most visible at rest and diminishes with voluntary movement; the amplitude of these oscillations is much lower, and the frequency is midrange. A fine, fast *action tremor* occurs when parts of the body are activated in certain positions; this type of tremor may

occur when the animal is attempting greater precision of movement. *Static tremor* is manifested when antigravity muscles are activated.

45.3.2 Distribution

Involuntary movements can be restricted to the head, and intention tremor is the most common presentation. Head bobbing in either a vertical or horizontal direction also is possible. Localized tremor may be confined to the lumbosacral area and hind legs. *Generalized (whole body) tremors* seem to be more common than focal tremors.

45.4 LOCALIZATION OF THE PACEMAKER

Lesions in the lateral cerebellar hemispheres, nucleus interpositus, and cerebellar vermis are associated with intention tremor. Experimental lesions in the rubro-olivo-cerebellar system of cats can induce either intention tremor or resting tremor. In general, except for intention tremor, anatomic localization of the pacemaker is uncertain in dogs and cats.

45.5 PREDOMINANCE OF CLINICAL SIGNS

Some diseases may cause trembling accompanied by other signs. Another group of selective, functional disorders presents with tremor syndromes in which shivering is the predominant complaint.

45.6 DISORDERS IN WHICH TREMBLING IS ACCOMPANIED BY OTHER SIGNS

45.6.1 Metabolic Disorders

In addition to other signs, head or whole body tremors may be present in renal disease, hypoglycemia, hypocalcemia, and hypoadrenocorticism.

45.6.2 Intracranial Diseases

A large number of brain diseases may cause tremors, most often with cerebellar involvement. Head tremors, intention tremors and, less frequently, whole body tremors may be part of the syndrome. Other signs often are more obvious than the tremors, such as ataxia, hypermetria, paraparesis or tetraparesis and, less frequently, broad-based stance, abnormal behavior, cranial nerve deficits, opisthotonos, and seizure-like activity. Tremors are reported to be a possible sign in multisystemic inflammatory disease in borzois and in cerebellitis caused by *Neospora caninum;* cerebellar hypoplasia due to mutation or intrauterine panleukopenia viral infection; fibrinoid leukodystrophy; the late course of neuraxonal dystrophy and Labrador retriever axonopathy; spongiform encephalopathy; neuronal abiotrophies; subacute necrotizing encephalopathy; and several lysosomal storage diseases.

45.6.3 Hind End Weakness

Tremor may be part of the clinical presentation in various disorders, including degenerative lumbosacral stenosis; lumbosacral disc herniation, tumors, or discospondylitis; and nerve root compression. In some

peripheral neuropathies, synaptic dysfunction, and certain myopathies, shivering may be an additional sign. This static tremor is most pronounced when the animal is standing. Weakness and pain are possible causes.

45.7 DISORDERS IN WHICH TREMBLING IS THE PREDOMINANT SIGN

45.7.1 Corticoid-Responsive Tremor Syndrome

A generalized tremor syndrome first was reported in white Maltese dogs. However, the widely used term *white shaker syndrome* turned out to be misleading, because a recent study showed that one half of affected dogs had no or only a par-tial white haircoat. The disease is reported in young to middle-aged West Highland terriers, Maltese dogs, poodles, dachshunds, miniature pinschers, Pekingese, and mixed-breed dogs. An inflammatory process of the central nervous system is suspected. Histopathologically, mild, diffuse meningoencephalitis, characterized by lymphocytic infiltrates and perivascular cuffing, is reported. Immune-mediated disruption of neurotransmitter metabolism, resulting in reduced conversion of tyrosine to dopamine, has been proposed as a mechanism, but this hypothesis appears less likely in light of the high number of nonwhite dogs. The most consistent clinical sign of generalized tremor syndrome is a whole body tremor that worsens with excitement. Other abnormal findings include, in rare cases, spontaneous nystagmus, head tilt, ataxia, and reduced menace response. Cerebrospinal fluid analysis reveals a mild mononuclear pleocytosis and, in some dogs, an elevated protein level. Most patients respond well to treatment with prednisone and propranolol.

45.7.2 Hypomyelination

An inherited genetic defect results in hypomyelination or dysmyelination in the central nervous system but normal peripheral nerves. In shaking pup syndrome, for example, quantitative studies have shown normal axonal diameters but a marked reduction in the number of oligodendrocytes and decreased myelin volume and thickness. Brain structures are affected more than the spinal cord white matter. Failure of precursor cell division and insufficient migration, abnormal maturation, and early cell death of oligodendrocytes are suspected. The origin of the tremor in animals with this developmental myelin disorder is not well understood.

Clinical signs correlate with the degree of myelin deficiency. Affected puppies start to show signs within the first weeks and months of life. Hypomyelinated or dysmyelinated animals have a whole body tremor that worsens when the puppy begins to move (intention tremor may be present in some cases). Exercise or excitement worsens the tremor, which resolves with sleep. Severely affected animals show a “rocking horse” stance or a bunny hop gait or are unable to stand or ambulate. A perpendicular nystagmus is possible. In some mildly affected animals, the tremor plateaus at the end of the first year of life and improves later. There is no known therapy.

In springer spaniels and Samoyed pups, hypomyelination is transmitted by a sex-linked recessive trait. An autosomal recessive mode of transmission is suspected in the dysmyelination syndrome of the chow chow. Hypomyelination also has been reported in the weimaraner, Bernese mountain dog, lurcher, and Dalmatian and in two Siamese kitten littermates.

45.7.3 Spongy Degeneration

The histologic feature of a spongy appearance of the central nervous system has been reported in several breeds. A congenital disorder of amino acid metabolism is suspected but has not been proved in dogs and cats.

A generalized tremor syndrome is reported in the Samoyed, silky terrier, Scottish terrier, and Malinois shepherd –cross puppies. No treatment is available.

45.8 TREMORGENIC TOXINS

Numerous toxins are reported to cause generalized tremor. The mycotoxins penitrem A and roquefortine are produced by *Penicillium* spp. growing on garbage, moldy dairy foods, bread, nuts, grains, or blue cheese. Clinical signs of ingestion of these mycotoxins include generalized tremors, ataxia and, in rare cases, seizures. Metaldehyde, a slug and snail poison, causes generalized tremors. Hyperesthesia, salivation, and seizures vary from mild to severe (see Chapter 70). Hexachlorophene, bromethalin, organophosphates, carbamates, chlorinated hydrocarbons, zinc phosphide, methylated xanthines (caffeine, theophylline, theobromine), pyrethroids, macadamia nuts, and strychnine are other toxins that can cause generalized tremors and ataxia. Strychnine induces severe seizures. Therapy is limited to supportive care.

157

158

45.9 IDIOPATHIC HEAD TREMOR IN DOBERMANS AND BULLDOGS

A localized tremor of the head is reported in Dobermans and bulldogs. The head movement may be in a vertical direction, similar to the affirmation tremor seen in human beings. Head bobbing in the horizontal plane also occurs. The underlying mechanism is unknown.

45.10 IDIOPATHIC TREMOR OF THE HIND LEGS

A tremor of the hind legs has been described in geriatric dogs, particularly in terrier breeds. No weakness or other neurologic abnormalities are noted. A similar syndrome has been observed in young Leonberger dogs. In this breed, a dysfunction of serotonin metabolism is suspected.

46 CHAPTER • 46 Ataxia, Paresis, and Paralysis

Donald C. Levesque

All levels of the nervous system, from the brain to the peripheral nerves, have neurons that in some wayare associated with sensory, motor, or integrative functions of locomotion. Disturbances of these pathways cause some degree of ataxia, paresis, or paralysis. However, because some orthopedic and systemic diseases can mimic thesesigns, the first goal of a neurologic examination is to deter-mine whether the signs observed in the patient actually are due to neurologic dysfunction. Once neurologic deficits havebeen confirmed, the next goal becomes localization of the lesion or lesions. A general algorithm for localization of nervous system lesions, based on the presence of ataxia, is presented in Figure 46-1. Accurate interpretation of clinicalsigns, consistent use of terminology, and an awareness of the ways in which various disease processes can affect the nervous system are essential for the most effective use of any algorithm for localization of nervous system lesions. Recognition of the various forms of ataxia and of the significance ofparesis in association with ataxia is important in lesion localization and may aid in the determination of the etiology and prognosis.

46.1 TERMINOLOGY

Ataxia, paresis, and *paralysis* are terms ascribed to neuro-logic deficits. These conditions must be distinguishedfrom limb lameness and weakness caused by non-neurologic manifestations of gait abnormalities. Ataxia is an abnormality of movement, particularly gait, characterized by a degree of sway and incoordination; it may affect the head, trunk, or limbs. Paresis is a partial loss of voluntary movement andusually is accompanied by conscious proprioceptive deficits. Paralysis is the absence of voluntary motor function andis described as flaccid or spastic. Prognostically, it is important to determine whether pain sensation is present orabsent. Paralysis is not be confused with nonambulatoryparesis.

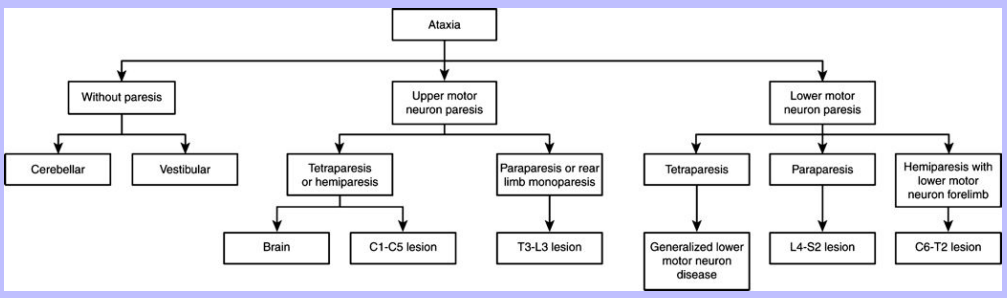
Ataxia, paresis, and paralysis are characterized as generalized or localized. Ataxia and paresis are graded on a scale ranging from mild to severe. Ataxia is further categorized as proprioceptive, vestibular, or cerebellar.

46.2 SIGNS BASED ON THE NEUROANATOMIC LOCATION OF LESIONS

46.2.1 Forebrain (Diencephalon, Basal Nuclei, Cerebral Hemispheres)

In the conscious patient, forebrain disease generally causes relatively mild limb paresis and ataxia. Unilateral lesions usually cause contralateral conscious proprioceptive deficits with minimal gait disturbance. Generalized forebrain disease (e.g., encephalitis, hydrocephalus, midline thalamic lesions) often causes generalized ataxia and mental dullness with only mild to moderate paresis. Although ataxia and paresis often are present in forebrain disease, other signs, such as seizures, disorientation, behavioral changes, circling, and visual deficits, usually predominate. Paralysis is seen only during deep stupor or coma. In general, forebrain disease has less profound effects on locomotion than do lesions of the brain stem, cerebellum, spinal cord, and peripheral nerves.

Figure 46-1 Algorithm for localization of nervous system lesions based on presence of ataxia with or without paresis.



In some instances, cerebral dysfunction mimics thoracolumbar myelopathy by causing rear limb ataxia and paraparesis without detectable forelimb deficits. This apparent paradox can be seen postictally; it also occurs secondary to side effects of anticonvulsant medications, particularly potassium bromide, in some patients. In nearly all these cases, mentation and forelimb dysfunction likely are present but subclinical. Postictal paraparesis can be differentiated from myelopathic paresis by its transient nature. Recovery from postictal paraparesis usually occurs within minutes to hours, compared with days to weeks in patients with myelopathies.

46.2.2 Brain Stem

In the conscious patient, brain stem disease can cause moderate to marked ataxia, hemiparesis, or tetraparesis but rarely paralysis. Unilateral lesions caudal to the pyramidal decussation in the medulla affect ascending sensory and descending motor pathways, causing marked ipsilateral hemiparesis. Vestibular nuclei are commonly affected, causing superimposed vestibular ataxia, head tilt, and nystagmus. The ataxia of central vestibular disease, although sharing many similarities with peripheral vestibular disease, is distinguished by the presence of ipsilateral conscious proprioceptive deficits. Other cranial nerve signs, such as facial paralysis, head muscle atrophy, or dysphagia, may also be present. Hemiplegia and tetraplegia can occur, but lesions severe enough to cause paralysis usually result in respiratory arrest.

46.2.3 Peripheral Vestibular System

Unilateral lesions of the membranous labyrinth or cranial nerve VIII can cause ataxia ranging from mild and barely perceptible to profound and extremely debilitating. Head tilt, horizontal or rotatory nystagmus, positional strabismus, and abnormal oculovestibular eye movements are nearly always present to some degree. Bilateral peripheral vestibular disease most often causes symmetric, generalized ataxia with characteristic wide, swaying head excursions in both directions; oculovestibular eye movements, including pathologic nystagmus, are absent.

Peripheral vestibular disease does not cause paresis or paralysis, therefore proprioceptive deficits are not present. However, because of the strong influence of the vestibular system on limb muscle tonus, vestibular dysfunction results in an increase in contralateral and a decrease in ipsilateral extensor muscle tone, often making it difficult for the examiner to interpret proprioceptive reactions in severely affected patients.

46.2.4 Cerebellum

Because the cerebellum functions as modulator rather than as a site of initiation of motor function, cerebellar disorders cause mild to marked ataxia without paresis or paralysis. Unilateral lesions of the cerebellum cause ipsilateral limb ataxia with dysmetria, usually hypermetria. The flocculonodular lobe of the cerebellum modulates posture and movement based on vestibular input; consequently, lesions at this location cause disequilibrium and ataxia.

46.2.5 Cervical Spinal Cord

Cervical spinal cord disease can cause mild to marked ataxia and forelimb monoparesis, hemiparesis, or tetraparesis. Forelimb monoplegia, hemiplegia, or tetraplegia also can occur. Deep pain sensation is always present in tetraplegic animals with normal respiratory function, because functional transection of the cervical spinal cord cranial to the sixth spinal cord segment results in loss of innervation of the diaphragm and intercostal musculature, with subsequent apnea. Cervical cord lesions caudal to C6 disrupt innervation of the intercostal musculature, leaving only diaphragmatic respiration.

Lesions affecting spinal cord segments C6-T2 cause forelimb hyporeflexia owing to injury of the cell bodies of lower motor neurons that innervate forelimb musculature. Forelimb reflexes are preserved with lesions cranial to C6. Cervical spinal cord disease most often causes injury to ascending and descending axons serving the rear limbs and results in rear limb ataxia with normal to exaggerated rear limb reflexes.

In unusual cases, very focal spinal cord lesions (usually a vascular or contusive type) selectively affect grey matter and spare ascending and descending white matter tracts. If such lesions affect spinal segments C6-T2, flaccid forelimb paresis or paralysis without rear limb deficits can result. Conversely, chronic caudal cervical spinal cord compression, such as can occur in cervical spondylolisthesis, may selectively affect descending and ascending white matter tracts serving the rear limbs, resulting in rear limb ataxia and paresis and no detectable forelimb deficits.

46.2.6 Thoracolumbar (T3-L3) Spinal Cord

Thoracolumbar spinal cord disease can cause mild to marked rear limb ataxia, paraparesis, paraplegia, monoparesis, or monoplegia. Rear limb reflexes are normal to exaggerated. The panniculus reflex generally is reduced or absent two to three spinal segments caudal to the site of a thoracolumbar lesion. Mildly to moderately compressive injuries generally result in ataxia with paraparesis. More severely compressive lesions can cause paraplegia. Contusive or vascular injuriesare usually more acute but cause similar signs. Cranial thoracic spinal cord lesions often cause a more “lumbering,” swaying rear limb ataxia than do more caudal lesions as a result of paresis of the thoracic paraspinal musculature. Nonambulatory paraparetic and paraplegic patients with cranial thoracic lesions often are laterally recumbent and unable to rise to a sternal position. Focal spinal cord ischemia can selectively affect only a portion of the spinal cord, causing monoparesis or monoplegia. Examples of this condition are seen in patients with fibrocartilaginous embolization or ischemia secondary to vasculitis.

Shiff-Sherrington sign, an increase in extensor tone of forelimb musculature after acute thoracolumbar spinal cord injury, is an indicator of severe spinal cord injury but does not necessarily carry a grave prognosis. Generally, the more cranial the lesion, the more exaggerated the forelimb hypertonia.

46.2.7 Lumbosacral (L4-S2) Spinal Cord

Lumbosacral spinal cord disease causes mild to marked rear limb ataxia, paraparesis, paraplegia, or monoplegia with reduced to absent rear limb reflexes. Lesions that affect segments L4 and L5 cause decreased to absent knee-jerk reflexes. Lesions that affect segments L6 through S2 cause decreased withdrawal reflexes of the rear limbs, as well as bladder hypotonia and bladder and anal sphincter hypotonia.

46.2.8 Peripheral Nerve

Peripheral nerve lesions also can cause mild to marked ataxia, paresis, or paralysis of one or more limbs. Hyporeflexia is a consistent finding.

Nerve root avulsion or severance of a major peripheral nerve to a limb results in areflexia and paralysis of the affected muscle or muscles as a result of loss of sensory and motor innervation. Degenerative, inflammatory, and toxic neuropathies generally affect all peripheral nerves and result in varying degrees of ataxia, paresis, and paralysis. Hyporeflexia is a common denominator in these patients. Gait disturbances of patients with polyneuropathy can vary from marked paresis to paralysis to almost cerebellar-appearing dysmetria. Even though the histopathologic changes in nerve fibers and affected muscles may be similar in the forelimbs and rear limbs, it is not unusual for gait abnormalities to be more obvious in the rear limbs. Presumably, this phenomenon is due to the longer distance from the brain to the motor endplates and sensory receptors in the rear limbs, which allows for greater dispersion of motor and sensory action potentials.

Most polyneuropathies in dogs and cats appear to preferentially affect motor fibers, causing ataxia, paresis, and paralysis with preservation of superficial pain sensation and, often, conscious proprioception. With very few exceptions, therefore, a patient presenting with tetraplegia, hyporeflexia, and preservation of superficial pain sensation has a neuromuscular disorder (neuropathy, junctionopathy, myopathy). A notable exception is focal myelomalacia, in which descending motor tracts are affected but ascending superficial and deep pain fibers are preserved.

47 CHAPTER • 47 Altered States of Consciousness: Stupor and Coma

Karen L. Kline

47.1 DEFINITIONS

Stupor and coma are pathologic abnormalities caused by an interruption in the structural, metabolic, and/or physiologic integrity of the brain stem or cerebral cortex. *Stupor* is characterized by a state in which the animal appears to be asleep or unconscious but can be aroused by a noxious stimulus. Once the stimulus is withdrawn, however, the animal may lapse back into the sleeplike state. *Coma* is characterized by a state of unconsciousness in which the animal cannot be aroused even by a noxious stimulus. A strong toe pinch, for example, may elicit a flexion reflex or increased extensor tone but does not cause a behavioral response, such as crying or biting. In either case, prompt action is required to attempt to reverse these signs and correct the underlying cause.

47.2 PATHOPHYSIOLOGY

Consciousness is maintained by sensory stimuli that act through the ascending reticular activating system (ARAS) on the cerebral cortex. Decreasing levels of consciousness indicate abnormal cerebrocortical function or interference with cortical activation by the ARAS. The cerebral cortex controls the content of consciousness, whereas the brain stem controls the level of consciousness. In a sense, the cerebrum is the light bulb, and the brain stem is the rheostat that regulates its brightness. All sensory pathways have collateral input to the ARAS in the pons and the midbrain, and this information is projected diffusely to the cerebral cortex, where cholinergic synapses communicate constantly with cortical neurons. Balance is maintained between the ARAS and the adrenergic (sleep) system, which projects from the midbrain and diencephalon (thalamus). Signs ranging from hyperexcitability to coma can be observed if imbalance exists between the two systems.

The causes of stupor and coma are numerous. The three most important are (1) increased intracranial pressure, (2) cerebral edema, and (3) herniation of brain tissue. Increased intracranial pressure can occur secondary to an increase in the volume of tissue or fluid (e.g., cerebrospinal fluid, edema, or blood) within the cranial vault; even small shifts in these volumescan have dramatic consequences. Causes of increased intracranial pressure include encephalitis, meningitis, mass lesions (e.g., neoplasia, granulomas, or abscesses), vascular events, traumatic injury, or underlying metabolic disturbances, such as hypertension.

Cerebral edema is an abnormal accumulation of fluid in the brain parenchyma. It is classified into three types: (1) vasogenic, which is most commonly associated with brain masses and is due to a breakdown in blood-brain barrier integrity; (2) cytotoxic, which is most commonly associated with metabolic disturbances, such as hypoxia and neuroglycopenia, that cause cell or neuronal death; and (3) interstitial, which is most likely associated with hydrocephalus. The end result of progressively increased intracranial pressure and/or cerebral edema is brain herniation.

There are four different types of herniation, two of which can induce stupor or coma: (1) caudal transtentorial herniation, in which portions of the temporal lobe shift ventral to the tentorium cerebelli and cause midbrain compression; and (2) foramen magnum herniation, the most common form, which occurs when the caudal cerebellar vermis moves through the foramen magnum, causing a compression of the displaced cerebellum and the medulla oblongata. In these cases, injury to the respiratory center, descending motor pathway tracts, and cardiovascular centers in the caudal brain stem can lead to midbrain and cerebral hypoxia and coma, which can be irreversible.

47.3 APPROACH TO THE PATIENTWITH STUPOR OR COMA

After the pet's initial presentation, close attention must be paid to immediate life-threatening injuries and their sequelae, such as hemorrhage, hypoxia, or shock. The ABCs of critical care medicine—airway, breathing, and cardiovascular status—are paramount. Concurrently, a thorough history, including onset and progression of signs, previous illness or injury, and drug use or toxin exposure, should be ascertained. Thorough physical and neurologic examinations should be performed, with emphasis placed on the cardiac rate and rhythm and the respiratory pattern. Simply observing the patient for a short time can yield considerable information. An anatomic diagnosis can be ascertained on the basis of the following: (1) mental status and level of consciousness; (2) neuro-ophthalmologic signs (vision, pupil size and symmetry, and ocular movements); (3) alterations in respiratory pattern; and (4) skeletal motor responses. Following these trends can aid prognostication and the development of treatment protocols and is essential for patient management.

47.3.1 Mental Status and Level of Consciousness

Consciousness is maintained by the midbrain ARAS, which acts as a rheostat, projecting diffusely to the cerebral cortex. Consequently, diffuse cerebral disease or midbrain disease can result in stupor, coma, or other alterations in consciousness, such as dementia. Differentiation between stupor and coma can be achieved with the application of a noxious stimulus, such as a hemostat or needle. Care must be taken to follow trends when evaluating the patient, and hasty prognostication should be avoided. In general, stupor has a better initial prognosis than coma, but exceptions can occur. Other factors include the patient's age, the underlying medical history, and the cause of the alteration in consciousness.

47.3.2 Neuro-Ophthalmologic Signs

47.3.2.1 Pupillary Reactions

Pupil size and reactivity to light can be normal in the comatose patient; alterations in these parameters can aid in neurolocalization and prognostication. Integrity of the retinae, optic nerves, and chiasm and of the rostral brain stem is consistent with pupils that are equal in size and that respond well to light and darkness. In general, lesions of the cerebral cortex andthalamus result in normal or constricted pupils that respond to both darkness and light. Lesions in the brain stem can result in unilateral or bilateral pupillary constriction (pons) or dilatation (midbrain), depending on the location. Peripheral lesions involving cranial nerve (CN) III usually result in dilated pupils with normal vision. Pupils that are bilaterally dilated (fixed) and unresponsive to light imply a guarded to grave prognosis.

161

162

47.3.2.2 Ocular Movements

The pathways that mediate ocular movements lie adjacent to the brain stem regions responsible for consciousness, making it clinically useful to evaluate ocular movements in the stuporous or comatose patient. Physiologic nystagmus or conjugate eye movements (the oculocephalic and doll's eye reflexes) are normal and require integrity of CN VIII (vestibulocochlear nerve), the brain stem (vestibular nuclei, medial longitudinal fasciculus), the cerebellum (flocculonodular lobe), and the nuclei of CN III, IV, and VI. Any disruption in this pathway results in pathologic nystagmus (rotary, horizontal, or vertical downbeat). Ocular movements are evaluated by moving the head in a slow or rapid fashion from side to side while it is held in a fixed position. In the normal animal, this movement results in several beats of horizontal nystagmus (with

the fast component toward the direction of the head movement) that stops once the head movement stops. If the nystagmus continues after the movement stops, if it occurs spontaneously, or if it changes with position, a lesion in the vestibular system is likely to exist. If there is absence of ocular movements in the comatose patient, severe brain stem injury should be suspected, and the prognosis for return to function is guarded to grave.

47.3.3 Alterations in Respiratory Pattern

Severe or progressive brain injury can result in changes in breathing patterns. *Cheyne-Stokes respiration* is characterized by hyperpnea alternating with apnea and can be an indication of a bilateral cerebral hemisphere or diencephalic lesion. Central neurogenic breathing or hyperventilation is associated with lesions in the midbrain pneumotaxic center, whereas lower pontine and medullary lesions result in apneustic or ataxic (gasping) respirations, respectively. When a change in breathing patterns is noted, aggressive therapy may need to be instituted to counteract herniation.

47.3.4 Skeletal Motor Responses

The examination of motor function in the comatose patient provides valuable localizing information. Trends must be monitored in order to follow the disease course. Injury to the descending motor systems can result in either increased or decreased extensor and flexor tone, depending on where the injury occurs. Involuntary movements, such as twitching or paddling, may indicate seizure activity. Decerebrate posture (all four limbs extended) indicates a lesion in the midbrain or pons and can occur primarily or secondary to cerebrocortical herniation; decerebrate posture indicates that the motor pathways that aid in flexion are damaged, and stupor or coma is present. Decerebellate posture (forelimbs extended with alternating hind limb flexion and extension) indicates a rostral cerebellar lesion, and the level of consciousness may not be impaired. Flaccid paralysis due to injury to the descending motor pathways implies a grave prognosis, especially when the patient is stuporous or comatose.

47.4 DIAGNOSTIC PLAN

The causes of stupor and coma are numerous (Figure 47-1). Routine laboratory data (hemogram, serum chemistries, urinalysis) can aid in determining a metabolic cause of the alteration in consciousness. Inflammatory, infectious, or toxic agents may cause changes in the hemogram, whereas metabolic or endocrine disorders may result in changes in the blood chemistries, which would suggest the need for other diagnostic tests, such as evaluation of blood ammonia levels and serum bile acids, adrenocorticotropic hormone (ACTH) stimulation, and thyroid profiles. Chest and abdominal diagnostic imaging (radiographs, ultrasonography) may also be indicated if metastatic or infectious disease is suspected. If minimal changes are noted in these parameters, a primary or intracranial cause of stupor or coma should be considered. Noninvasive methods used to determine the cause of intracranial disease include electroencephalography (EEG) and brain stem auditory evoked response (BAER). These methods are useful for evaluating the integrity of the cerebral cortexand brain stem, respectively, and they can be performed without general anesthesia. Ophthalmic evaluation may help to determine whether high intracranial pressure or infectious disease is present. Computed tomography (CT) and magnetic resonance imaging (MRI) are quite useful for confirmingthe presence and character of intracranial lesions, such as tumors, hydrocephalus, and vascular injuries. If the dog or cat is comatose, general anesthesia may not be necessary. Spinal fluid analysis typically is useful for determining whether the animal has an inflammatory or a neoplastic intracranial process; general anesthesia is required and does carry some risk if high intracranial pressure exists.

47.5 TREATMENT GOALS

Most dogs and cats with stupor or coma have life-threatening injuries that require immediate attention. Establishing a patent airway and maintaining respirations and cardiovascular status (in particular blood pressure) are critical to stabilization, regardless of the underlying cause of the insult. Bloodwork should be evaluated, and intravenous administration of fluids, anticonvulsants, osmotic diuretics and, in some cases, corticosteroids can be instituted to aid patient stabilization. Elevation of the head may help reduce excessive cerebral blood flow, and body temperature should be continuously monitored, especially in the case of seizures. Cerebral edema can be treated using injectable corticosteroids (once the blood pressure has stabilized), osmotic and loop diuretics (mannitol and furosemide, respectively), and hyperventilation. Seizures can be controlled using injectable anticonvulsants such as diazepam, phenobarbital, and pentobarbital. These treatments are discussed in more detail in the chapters on specific brain diseases. Intensive nursing care is paramount. Frequent turning (to avoid hypostatic lung congestion), bladder evacuation, ocular lubrication, optimal nutrition, and proper bedding are imperative.

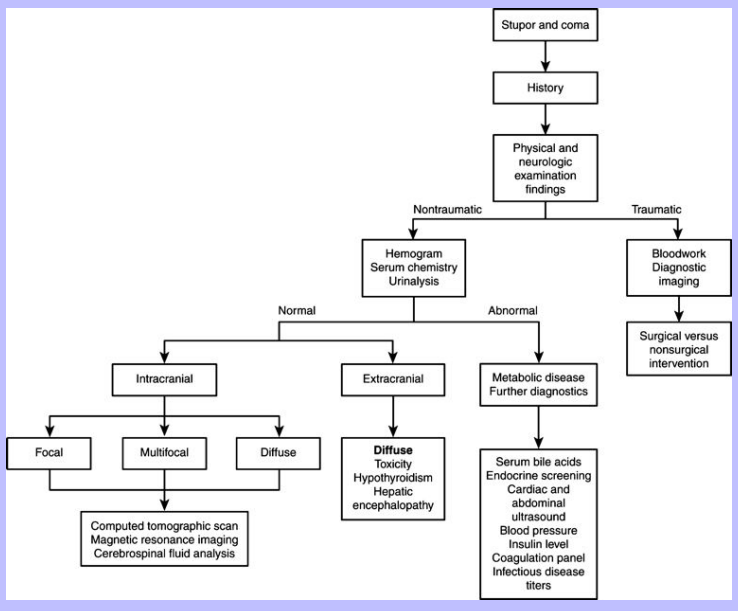
47.6 PROGNOSIS

The prognosis for animals with stupor or coma depends on the cause of the insult, other underlying disease processes, the location of the injury, the signalment of the patient, and the response to therapy. Serial neurologic evaluations that concentrate particularly on the level of consciousness, ocular movements, pupillary size, motor tone, and breathing patterns can guide the practitioner in terms of treatment options and prognostication. Patience is necessary, especially in cases of brain trauma, and trends in improvement or deterioration need to be followed. If the patient survives the immediate injury, sequelae such as seizures, permanent neurologic deficits, and long-term nursing care should be addressed with the client.

162

163

Figure 47-1 Algorithm for diagnostic approach to stupor and coma.



48 CHAPTER • 48 Seizures

Andrée D. Quesnel[†]

***A** seizure* is the clinical manifestation of an excessivedischarge of hyperexcitable cerebrocortical neu-rons. Depending on the location and extent of the seizure discharge, the clinical appearance of seizures can vary a great deal.

Without the use of electroencephalography, seizures can be classified only according to their clinical manifestations. *Generalized seizures* have a widespread onset within both cerebral hemispheres and manifest with loss of consciousness, recumbency, and generalized symmetric motor signs. Most generalized seizures manifest with violent motor activity that involves the whole body (convulsions), such as *tonic* (sustained) and/or *clonic* (repetitive) muscle contractions, limb paddling, and trembling. Jaw chomping and facial twitching are frequently observed. Signs of autonomic hyperactivity (e.g., pupillary dilatation, salivation, piloerection, micturition, defecation) are common. Rarely, the seizures may be atonic ("drop-attack") and must be differentiated from syncope and narcolepsy-cataplexy.

Partial seizures have a focal onset in one cerebral hemisphere and limited spreading within the brain. Their occurrenceindicates the presence of a focal acquired structural brain lesion. Partial seizures may be simple or complex, depending on whether consciousness is disturbed. *Simple partial seizures* arise from and are confined to neocortical structures of one cerebral hemisphere. These do not cause consciousness alterations. Unilateral motor signs such as facial twitching, tonic or clonic movements of one or both limbs, and spasmodic turning of the head to one side are often observed and are contralateral to the side of the seizure focus.

In *complex partial seizures,* the spread of the seizure involves allocortical structures and often continues bilaterally. Consciousness is either impaired or lost. There may be contralateral or bilateral asymmetric or symmetric motor signs, usually limited to some parts of the body. Bizarre activity, both stereotypical (e.g., circling) and behavioral (e.g., startling, growling, hissing, chasing and attacking imaginary or real objects, running in a panic), may also be observed, particularly in cats.

Some seizures thought to be mild generalized seizures are likely complex partial seizures. In the latter type, consciousness is impaired or lost and there is bilateral motor activity that usually does not result in recumbency; however, there is an arrest of the animal's ongoing activities (e.g., it stops if moving and may sit if standing). Motor signs are limited to bilateral facial twitching, jaw chomping, or lip smacking, sometimes with mild generalized trembling or spasms of the neck and front end. Occasionally, there may be decreased motor function that causes stumbling, crawling, or inability to get up and walk. The dog or cat may still be aware and responsive to varying degrees. Because these seizures are not manifested by complete loss of consciousness and generalized motor signs, the underlying neuronal discharge likely has a limited spread within the brain, which is a feature of partial seizures.

A third class of partial seizures are those that secondarily evolve to generalized seizures. Secondary generalization may occur so quickly that no features of partial seizures may be observed clinically.

Another hallmark of partial seizures is an *aura*. An aura is considered to be the initial portion of the seizure, experienced before the consciousness is altered and for which memory is retained in people. It corresponds to the onset of a simple partial seizure before it evolves into a complex partial or a generalized seizure. In animals, it is most often manifested by behavioral changes within a few seconds or minutes of the apparent seizure onset (e.g., attention seeking or withdrawal, depression or agitation, pacing, whining, howling). Mood changes that precede seizures for several hours or even longer should not be confused with an aura. This is rather a prodrome and is not the

result of the onset of cerebral epileptic activity. It may be observed before many seizure types and has no diagnostic value.

Localized postictal motor deficits also indicate that a partial seizure has occurred. This phenomenon, referred to as *Todd's paralysis* in human beings, consists of a transient (minutes to hours) localized loss of motor function that follows some partial seizures. It may be attributed to neuronal exhaustion or increased inhibition in the region of the seizure focus. It is observed contralateral to the focus.

Seizures may occur as brief, isolated events (usually lasting 2 minutes or less), cluster seizures (two or more over a 24-hour period), or status epilepticus (sustained or serial seizures lasting at least 30 minutes and without intervening periods of full recovery). They can be convulsive with generalized and violent motor activity (e.g., tonic-clonic generalized seizures) or nonconvulsive with milder and often subtle motor signs (e.g., partial seizures limited to facial twitching).

The term *epilepsy* should be restricted to seizure disorders with inactive intracranial causes. *Primary epilepsy* (functional, asymptomatic) is the result of functional cerebral disturbances for which there would be no underlying cause other than a hereditary predisposition (e.g., canine idiopathic epilepsy). *Secondary epilepsy* (structural, symptomatic) is caused by acquired but inactive brain lesions (e.g., posttraumatic, postischemic, and postencephalitic gliosis). The term *cryptogenic epilepsy* may be used when evidence exists of a structural brain lesion (e.g., partial seizures), but this cannot be further documented, and the etiology remains unknown.

164

165

48.1 GENERAL PATHOPHYSIOLOGY

The neuronal hyperexcitability that underlies the generation of seizures is the result of an imbalance between normal excitatory and inhibitory mechanisms. This may be due to an intracranial or an extracranial disease process. Intracranial causes of seizures include primary brain disorders, either functional disturbances of neurons (e.g., idiopathic epilepsy) or structural brain lesions that irritate the surrounding neurons. Structural brain lesions can be active (e.g., neoplasms, encephalitides) or inactive (e.g., glial scars). Extracranial causes of seizures alter the brain biochemical homeostasis in favor of excitation and may be exogenous (seizurogenic toxins) or endogenous (severe metabolic disturbances).

It is important to appreciate that seizures enhance the likelihood of further seizures, regardless of their cause. The development of progressive and refractory seizure disorders correlates well with the cumulative number of seizures, especially when they have a high rate of recurrence, and the seizures may occur relatively early in some cases. Such self-perpetuating phenomena may also be involved in acutely recurring seizures (cluster seizures and status epilepticus), which often become more difficult to control the longer interval from their onset. Rapidly recurring seizures may recruit adjacent as well as remote areas of the brain into the epileptic discharge *(kindling phenomenon)* and may also produce neuronal damage. These factors likely contribute to the development of progressive and refractory seizure disorders. Early diagnostic and therapeutic procedures, especially aggressive antiepileptic drug therapy, are crucial for optimal seizurecontrol in both acute and chronic seizure disorders.

† During the preparation of this manuscript, Dr. Andrée Quesnel died at the age of 44 after fighting lung cancer for a year.

Neurology was a great passion in her life. She had been a Diplomate in the specialty of neurology since 1994. Her main interests were seizure disorders and feline diseases.

As a professor at the University of Montreal, she was instrumental in building the neurology department. She made neurology understandable and even enjoyable for her students. As a friend and colleague, she taught us much. Not surprisingly, she was the recipient of many teaching awards.

She was rigorous, independent, and a perfectionist, but all of those who knew her will remember her laugh and her friendship more than anything.

She will be greatly missed.

—Dr. Veronique Sammut, Former Resident in Neurology, University of Montreal. February 2004.

48.2 DIAGNOSTIC APPROACH

48.2.1 Historical Findings

Careful scrutiny of the seizure history (age at the first seizure, seizure type, and initial frequency) often brings to light critical information about the underlying cause. An overview of this process appears in Figure 48-1.

In dogs, idiopathic epilepsy should be excluded if the first seizure did not occur between the ages of 6 months and 5 years, if all seizures are not primarily generalized tonic-clonic, if aura or localized postictal motor deficits have been observed, or if the first few seizures occurred at less than 4-to 6-week intervals. High-frequency seizures may develop with idiopathic epilepsy in many medium or large breeds of dogs (e.g., Border collie, Dalmatian, German shepherd, golden retriever, Siberian husky, Saint Bernard), but this usually occurs several months after the seizure onset. Another cause should be suspected in some breeds of dogs (e.g., Doberman pinscher, rottweiler, Newfoundland, brachycephalic breeds) and in cats, which are less likely to suffer from idiopathic epilepsy.

48.2.2 Physical Findings

Physical and fundic abnormalities may be related to seizures, revealing the existence of a multisystemic infectious, metabolic, hypoxic (e.g., polycythemia), or neoplastic disease.

In the neurologic examination, particular attention should be paid to tests that evaluate the thalamocortex (e.g., menace response, facial [nasal septum] sensation, and postural reactions [proprioceptive positioning and hopping]). Postictal disturbances may include bilateral and systemic deficits and should not be interpreted as evidence of structural brain disease. Subtle unilateral or bilateral but asymmetric deficits are frequently found in patients with a seizure disorder; these can be overlooked if the response obtained on both sides is not carefully compared. Such deficits indicate the presence of a structural lesion in the contralateral cerebral cortex or thalamus. Neurologic deficits that cannot all be attributed to a focal cortical or thalamic lesion indicate multifocal central nervous system involvement, which is usually caused by infectious or noninfectious (immune mediated) encephalitides.

48.2.3 Diagnostic Plan

Once the seizure history has been scrutinized and the clinical examinations performed, the likelihood of an intracranial or extracranial cause can often be established, and a rational diagnostic evaluation can be planned (see Figure 48-1).

Despite extensive diagnostic investigation, an etiology is often difficult to establish in seizure disorders with intracra-nial causes. However, the main objective is not necessarily toreach a precise diagnosis, but rather to rule out conditions thatwould require or benefit from specific medical treatment (e.g., encephalitides) and/or

surgical treatment (e.g., neoplasms). Once this has been done, symptomatic antiepileptic drug therapy is the only treatment option.

48.3 TREATMENT

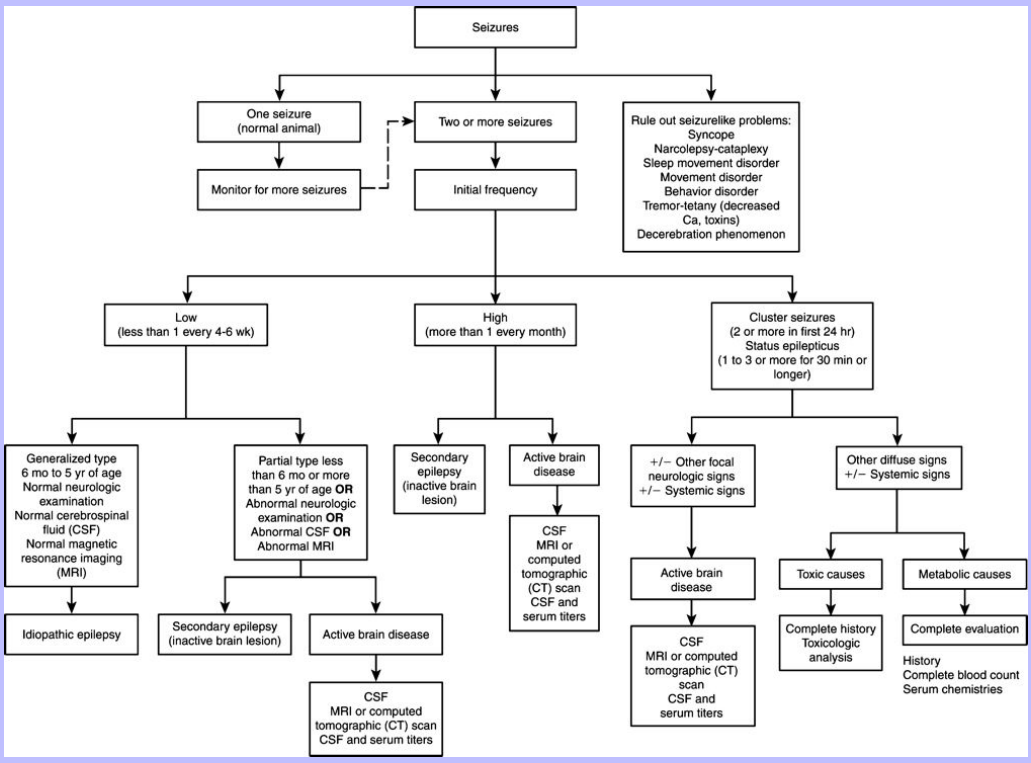
Status epilepticus and cluster seizures, whether convulsive or nonconvulsive, are emergencies. Their management is outlined in Box 48-1.

Oral maintenance antiepileptic (AED) drug therapy should be initiated as soon as two consecutive seizures have occurred in an interval of less than 6 to 8 weeks; this includes cluster seizures and status epilepticus, even the first occurrence of seizures. The importance of early, aggressive, and rational treatment cannot be overemphasized. Guidelines for oral maintenance therapy are presented in Boxes 48-2 and 48-3. The goal of treatment is to reduce the seizure frequency to less than one single seizure every 6 to 8 weeks as soon as possible.

Potassium bromide has replaced phenobarbital as the first-choice antiepileptic drug for dogs. It offers the advantage of being eliminated by the kidneys with no risk of hepatic toxicity and minimal drug interactions. When used as a first-line drug, potassium bromide seems to be as effective as phenobarbital, yet has no toxicity potential other than causing excessive side effects with overdosing or individual intolerance. Also, it can be administered once daily; it is not expensive; precise therapeutic guidelines have been devised; serum bromide concentration testing is available in most veterinary laboratories at the same cost as for phenobarbital; and it is not a controlled drug. The main inconvenience of potassium bromide is its very long half-life (3 to 4 weeks), with the resulting long delay (4 to 5 months) before steady state and maximal antiepileptic effect for a given dosage are obtained. In cases of high seizure frequency, therefore, treatment must be initiated with a loading dose in order to reach a low therapeutic serum concentration within 24 to 48 hours. However, a long half-life is an advantage for minimizing both serum concentration fluctuations between dosing intervals and the effect of missed doses.

Adverse effects of potassium bromide are similar to those of phenobarbital (polydipsia, polyuria, polyphagia). Gastrointestinal disturbances (vomiting, diarrhea, loss of appetite) are also occasionally observed and may be due to the hypertonic and osmotic nature of bromide formulations. Medicating with food or dividing the daily dosage into two doses may alleviate this problem. Signs of an excessive bromide serum concentration include sedation and hindlimb paresis that is strikingly more marked than ataxia. These are usually seen with serum concentrations above 15 mmol/L (1.5 mg/mL), although many dogs tolerate well levels up to 25 to35 mmol/L, which may provide additional antiepileptic protection in some cases. Rare idiosyncratic reactions to bromide include pruritic dermatitis, paradoxical hyperactivity, and pancreatitis. The point is unclear, but some speculate that the pancreatitis may be due to marked polyphagia and dietary indiscretion, mainly when bromide is used in combination with phenobarbital.

Figure 48-1 Algorithm for diagnostic approach to seizures.



48.3.1

Box • 48-1 Emergency Treatment of Cluster Seizures and Status Epilepticus in Dogs and Cats

I. **The animal is not seizing** at the time of presentation but has had cluster seizures (CS) or status epilepticus (SE) within the previous 12 to 24 hours.

A. Perform a complete physical and neurologic examination.

B. Collect appropriate samples for eventual laboratory testing: complete blood count (CBC), biochemical profile, urology and, in patients already on maintenance therapy, determination of the serum antiepileptic drug concentration ($[AED]_s$).

C. In naive patients, initiate oral maintenance AED therapy with a loading dose.

1. *Dogs*: Potassium bromide (KBr) 450–600 mg/kg.

a. Divide into 4 subdoses to be administered with food q 3-4h. Continue with the maintenance dosage (40–50 mg/kg q24h) the next day. If marked side effects (e.g., difficulty walking) develop within the nextfew days, administration of the daily maintenance dose may be stopped for a few days.

b. Measure $[Br]_s$ on day 3. If it is <12–15 mmol/L, especially if seizure recurrence is likely in the next few weeks (e.g., more than 1 seizure/1–2 weeks before treatment onset), give another oral mini-loading dose of 250 mg/kg for each desired 5 mmol/L increment of the [Br]s.

c. Measure $[Br]_s$ again 3 weeks later. If it is lower than on day 3 or if it is suboptimal (<15–20 mmol/L), increase the maintenance dosage accordingly. A mini-loading dose may also be given if more than 1 seizure has occurred since the treatment onset.

d. Measure $[Br]_s$ 3 months after treatment initiation or modification and adjust the dosage accordingly (see Box 48-2).

2. *Cats*: Phenobarbital (PB) 15–20 mg/kg slow IV. This should immediately provide a therapeutic serum PB concentration ($[PB]_s$) of 80–110 µmol/L.

a. Continue with a maintenance dosage (2.0–2.5 mg/kg q12h) 12 or 24 hours later, depending on the degree of sedation.

b. [PB]s may be measured just before administration of the first oral dose. A mini-loading dose of 1 mg/kg IV may be added for each 5 µmol/L to be added to the $[PB]_s$.

c. Measure $[PB]_s$ 2 weeks later and adjust the dosage if necessary, aiming at an optimal $[PB]_s$ of 100–130 µmol/L.

D. In patients already treated with AED, measure $[AED]_s$ (this first can be estimated based on the administered dosage). Add a mini-loading dose and increase the maintenance dosage if $[AED]_s$ is suboptimal, or add another AED (initial loading dose) to the treatment regimen if the $[AED]_s$ is optimal (see Boxes 48-2 and 48-3).

E. If the animal has 2 or more seizures or a prolonged seizure during the 24 hours after its presentation, continue tosection II, *A,* below.

II. **The animal is seizing** at the time of presentation (convulsive or nonconvulsive seizures).

A. Immediately stop the ongoing seizures.

1. Give a diazepam (DZ) IV bolus of 1.0 mg/kg in dogs and 0.5 mg/kg in cats. If seizure activity does not subside within 1–2 minutes, repeat the DZ bolus (can be repeated 1–2 times without significant risk of cardiorespiratory depression).

2. Restore and maintain homeostasis.

a. Maintain patent airway and administer oxygen if necessary.

b. Maintain body temperature between 38° C and 39.5° C.

c. Do not give glucose or calcium unless a deficiency is documented by laboratory testing (or is highly suspected and laboratory testing is not readily available).

d. Continuously monitor vital signs and look for potential complications (e.g., signs of increased intracranial pressure, neurogenic pulmonary edema, cardiac arrhythmias, intravascular disseminated coagulation). Provide intensive supportive care to a markedly sedated or stuporous patient.

3. Obtain samples for laboratory analysis as soon as possible (see section I, *B,* above).

B. Prevent seizure recurrence over the following hours.

1. If a maintenance PB treatment will be started (first-choice AED in cats or add-on drug in dogs), administer an IV loading dose of 15–25 mg/kg in dogs and 15–20 mg/kg in cats (see section I, *C,* step 2, above).

a. Maximal antiepileptic effect after IV administration of PB is obtained only after 20–30 minutes (slow brain penetration). If ≥ 1 seizure occurs before that time, administer another DZ bolus.

b. If maintenance PB therapy is not to be initiated or if 1 or more seizure occurs despite the administered IV boluses of DZ and PB, continue to the next step (II, *B,* no. 2).

2. Administer a continuous IV infusion of DZ at the rate of 0.5–1.0 mg/kg/h in dogs and 0.5 mg/kg/h in cats.

a. Add the DZ to maintenance fluids in an in-line burette. Avoid using saline in patients treated with KBr (this would rapidly lower $[Br]_s$ and possibly precipitate withdrawal seizures). Prepare only 1–2 hours of solution at a time (DZ is rapidly adsorbed into the administration set plastic and is inactivated by light).

b. If more than 20 minutes have elapsed since administration of the last DZ bolus, give another one at the beginning of the infusion to rapidly return to a therapeutic serum benzodiazepine concentration ($[BZ]_s$) that will be maintained by the infusion afterward.

c. If no other seizures occur within the first 4–6 hours of the infusion onset, progressively decrease the infusion concentration by 25%-steps every 4–6 hours. If 2 or more seizures occur at any time during the infusion, continue to section II, *C,* below.

3. If it is absolutely impossible to administer an IV infusion (e.g., prohibitive cost for the owners, unavailable continuous in-hospital monitoring, no possibility for referral), administer repeated IV boluses as a “salvage procedure.”

a. After an initial bolus (1 mg/kg in dogs and 0.5 mg/kg in cats), give other boluses of 0.5 mg/kg q20min for a total of 4–5 boluses, even if no other seizures have yet occurred. A therapeutic $[BZ]_S$ should be maintained for several hours.

b. Marked sedation should subside within a few hours.

4. Oral maintenance AED therapy should be initiated (loading dose protocol), or continued but improved to provide adequate long-term antiepileptic protection.

a. In patients that cannot swallow safely due to marked sedation, administer the AED scheduled doses parenterally (PB and DZ by the IM route and KBr per rectum).

C. Control refractory seizures.

1. If ≥2 seizures occur during the DZ infusion, administer another DZ bolus and increase the infusion rate (up to 1.5 mg/kg/h in dogs and 1.0 mg/kg/h in cats) for 6–8 hours before attempting to progressively decrease it.

a. In patients naive to PB, an IV loading dose may also be given (give only 15 mg/kg to avoid the risk of cardiorespiratory depression with combined IV administration of DZ and PB).

b. If ≥2 seizures recur, discontinue the DZ infusion and administer a propofol infusion (see next step [II, *C,* no. 2], below).

2. Propofol

a. Give an initial bolus of 1.0–3.5 mg/kg or more, to effect.

b. Initiate a constant-rate infusion of 0.01–0.25 mg/kg/min (use an automated syringe) and administer for at least 6–12 hours before progressively decreasing the infusion rate. If seizures recur when the infusion rate is decreased, increase the rate. Up to 24–48 hours of treatment may be necessary to control very severe CS and SE. In cats, proceed to frequent evaluation of the hematocrit and red blood cell morphology to detect Heinz body formation and possible hemolytic anemia.

c. If frequent seizures persist, proceed to general anesthesia.

3. General anesthesia

a. Propofol (dogs only): IV bolus of 4–6 mg/kg followed by an infusion of 0.1–0.3 mg/kg/min, to effect.

b. Isoflurane

c. Pentobarbital: IV bolus of 2–5 mg/kg, to effect, followed by an infusion of 5 mg/kg/h for several hours. Do not confuse dysphoric anesthetic recovery (e.g., paddling, stiffness) with seizure recurrence.

d. Always provide optimal anesthetic monitoring and supportive care (e.g., intubate, ventilate, prevent or correct hypothermia and hypotension).

III. Treatment of cluster seizures at home.

A. For dogs known to have CS, provide injectable DZ (in its original vials, not in a plastic syringe) to be administered per rectum at home: 1 mg/kg after the second or third seizure has occurred within 12 to 24 hours. This should be repeated 3–4 times at 20-minute intervals to obtain and maintain therapeutic $[BZ]_s$ for several hours. If ≥2 seizures recur despite this treatment, emergency in-hospital IV administration of AED is necessary.

48.3.2

Box • 48-2 Guidelines for Maintenance Oral Antiepileptic Drug Therapy in Dogs

I. Perform a complete blood count (CBC), serum biochemistry profile, and urology to establish pretreatment values.

II. First-choice antiepileptic drug (AED): Potassium bromide (KBr).

A. Initial dosage: 40–50 mg/kg q24h

B. Contraindication: Renal insufficiency

C. Follow-up

1. Measure $[Br]_s$ 3 weeks after initiation of therapy (50% of steady state is reached at that time) and adjust dosage accordingly, aiming at an optimal $[Br]_s$ of 20–25 mmol/L (2.0–2.5 mg/mL) at steady state (practically reached 3 months after treatment initiation or modification).

2. Measure $[Br]_s$ again at steady state and adjust the dosage using the following formula:

$$\text{Optimal daily dose} = \frac{\text{Desired } [Br]_s}{\text{Actual } [Br]_s} \times \text{Actual daily dose}$$

$[Br]_s$ may be increased up to 25–30 mmol/L as long as this does not cause excessive side effects while significantly improving the seizure control.

3. Monitor $[Br]_S$ and renal function at least once a year in young adults and every 6 months in older dogs.

4. As soon as adequate seizure control (less than 1 seizure/6-8 weeks) is not obtained or is no longer maintained despite $[Br]_s$ of 20–25 mmol/L, add a second AED (phenobarbital) to the treatment regimen. Continue KBr and maintain the $[Br]_s$ in the optimal range.

D. Other considerations

1. Initiate KBr therapy with an oral loading dose (450–600 mg/kg) if the interval is <3–4 weeks between successive seizures, including recent cluster seizures (CS) or status epilepticus (SE) (see Box 48-1 for treatment protocol).

2. Ensure a stable dietary chloride intake (brand and amount of food and treats) to avoid $[Br]_s$ fluctuations (renal elimination of bromide is directly proportional to the chloride intake). Seizure breakthrough may occur if $[Br]_s$ decreases, or excessive side effects may

develop if $[Br]_s$ increases. If a dietary change must be made, monitor $[Br]_s$ 6 weeks and then 12 weeks later and adjust the dosage if necessary.

III. Second-choice antiepileptic drug: Phenobarbital (PB).

A. Initial dosage: 2.5–4 mg/kg q12h. Increase the dosage by about 50% in puppies (possibly in kittens also) because of their higher metabolic rate.

B. Contraindication: Liver disease

C. Follow-up

1. Always measure PB serum concentration ($[PB]_s$) 2 weeks (1 week in immature animals) after treatment onset and dosage modification. Adjust the dosage to reach an optimal $[PB]_s$ of 100–130 µmol/L (23–30 µg/mL). Use the following formula:

$$\text{Optimal daily dose} = \frac{\text{Optimal } [PB]_S}{\text{Actual } [PB]_S} \times \text{Actual daily dose}$$

Also perform a CBC to detect rare but possible PB-induced blood dyscrasias (e.g., neutropenia, thrombocytopenia).

2. As soon as adequate seizure control (less than 1 seizure/6–8 weeks) is not obtained or is no longer maintained despite an optimal $[PB]_S$ and $[Br]_S$, add a third AED to the treatment regimen. Continue PB and KBr and maintain their serum concentrations within the optimal ranges.

D. Other considerations

1. Initiate PB therapy with an IV loading dose of 15–25 mg/kg if seizures are occurring at intervals of less than 7 days, including recent CS or SE (see Box 48-1 for treatment protocol).

2. PB often causes a progressive and marked liver enzyme induction that stabilizes after the first 4–6 months of treatment in dogs. This increases the metabolism of PB to the point that $[PB]_S$ may significantly decrease and may not even increase after dosage increment during the first months of treatment. Ideally, $[PB]_s$ should be monitored, and the dosage increased if necessary, at 2 and 6 weeks, then at 3 and 6 months after treatment initiation. Liver enzyme induction also leads to a mild increase of the serum alanine aminotransferase (ALT) (4–5 times the upper reference limit) and a marked elevation of ALP (sometimes >1000 U/L). This should not be interpreted as liver toxicity unless there are other laboratory abnormalities (e.g., hypoalbuminemia, elevated preprandial and postprandial bile acids), accompanied or not by clinical signs suggestive of liver failure.

IV. Third-choice antiepileptic drugs: Several human AEDs may be tried. Consult a veterinary neurologist for the most suitable AED, its recommended dosage, follow-up schedule, and so on.

V. Client communication (verbal and written)

A. Define the treatment goals and side effects/toxicity.

B. Emphasize the importance of complying with drug administration regimens, of keeping a seizure calendar (dates, duration, and intensity), and of consulting as soon as adequate seizure control has not been obtained within the expected time or is no longer achieved, as well as for any treatment modification.

C. Insist on the importance of initial determinations of $[AED]_s$ and periodic blood analysis (CBC, biochemistry and $[AED]_s$) every 6–12 months.

D. Define emergency situations and establish a precise emergency plan.

E. Recommend that intact females be spayed as soon as a diagnosis of epilepsy is made.

VI. Drug interactions and contraindications

A. Do not administer drugs that may lower the seizure threshold: acepromazine, xylazine, ketamine, estrogens, tricyclic antidepressants (e.g., amitriptyline), and bronchodilators (e.g., aminophylline, terbutaline, theophylline).

B. Do not administer drugs that interfere with the metabolism of PB (may result in rapid accumulation of a toxic $[PB]_s$): chloramphenicol, cimetidine, ranitidine, and tetracyclines.

VII. Only if no seizures have occurred for 6–12 months, consider slow weaning of AED over a period of a few months. If more than 1 seizure/6–8 weeks recurs during or after weaning, resume therapy, probably for life.

48.3.3

Box • 48-3 Guidelines for Maintenance Oral Antiepileptic Drug Therapy in Cats

Recommendations are the same as for dogs (see Box 48-2) with the following differences:

I. First-choice antiepileptic drug: Phenobarbital (PB).

A. Initial dosage: 2.0–2.5 mg/kg q12h.

B. Hepatic toxicity and enzymatic induction has not been documented in cats; significant elevation of liver enzymes should be investigated.

II. Second-choice antiepileptic drug: Diazepam (DZ).

A. Initial dosage: 0.5–1.0 mg/kg q12h.

B. Measure serum total benzodiazepine concentration ($[BZ]_s$) 5 days after onset of therapy and adjust the dosage (use the same formula as for PB), to reach a therapeutic range of 500–800 nmol/L (500–800 ng/mL). Evaluate liver enzymes at the same time to detect rare but possible idiosyncratic acute hepatic necrosis; if elevated, discontinue DZ and add potassium bromide.

III. Third-choice antiepileptic drug: Potassium bromide (KBr).

A. Initial dosage: 30–40 mg/kg q24h.

B. Because the half-life of KBr is shorter in cats (slightly less than 2 weeks), first monitor the $[Br]_s$ at 2 weeks (50% of steady state reached) and then at steady state (2 months).

C. Bromide has been reported to induce bronchial asthma in up to one third of treated cats. The onset is often acute, 2 weeks to 2 years after treatment initiation, and sometimes is life-threatening. KBr is therefore contraindicated in cats with past or actual asthmatic problems. Although glucocorticoids may alleviate clinical signs in some cats, it is preferable to discontinue treatment to avoid possible life-threatening deterioration.

Phenobarbital is the first-choice antiepileptic drug for cats. In dogs it is the drug of second choice, to be added to the treatment regimen when adequate seizure control cannot be obtained despite achievement of an optimal or supraoptimal serum bromide concentration. Phenobarbital is effective; safe when adequate follow-up is assured; and inexpensive. Although the therapeutic range is reported to be 65 to175 μmol/L (15 to 40 μg/mL), levels below 100 μmol/L(23 μg/L) are often insufficient to obtain and maintain adequate seizure control, and levels higher than 140 μmol/L (32 μg/mL) are more likely change in behavior, to cause excessive side effects and hepatic toxicity on a long-term basis. Rare hypersensitivity reactions attributed to phenobarbital include hyperactivity in dogs and pruritic dermatitis, neutropenia, and thrombocytopenia in both species.

48.4 OUTCOME

The prognosis of seizure disorders depends mainly on the nature of the underlying cause and on the response to therapy. Idiopathic epilepsy often progresses to refractoriness despite adequate treatment in some large breed dogs; this is less common in small breeds. Although seizure disorders of cats are almost always the result of structural brain lesions, these are most often inactive or self-limiting. Even if cats have severe seizures at some point during the course of the disease, the seizures can most often be well controlled or even completely stopped with adequate therapy. Refractoriness to antiepileptic drug therapy appears to be less common in cats.

49 CHAPTER • 49 Deficits of Function Due to Peripheral Cranial Neuropathies

Vince Pedroia

Signs of the most common peripheral cranial neuropathies in animals are acute blindness, Horner's syndrome, jaw drop, unilateral facial paralysis, loss of balance, dysphagia and regurgitation, and stridor (Figure 49-1 to 49-6). The same clinical scenario may introduce either a benign, self-limiting condition or a relentless, hopeless disease. Therefore it is crucial to evaluate these dogs and cats appropriately so that hasty decisions regarding euthanasia are not made, nor are useless pursuits undertaken. Furthermore, the dysfunction in question may be due to neuropathy, but the same dysfunction may be due to abnormality of the effector organ, such as the eye, vestibule, neuromuscular junctions, or muscles. In general, dogs and cats presenting with these disorders can be managed along the guidelines below. Otherwise, referral for evaluation would be recommended.

49.1 DISCOVERY AND THE NEUROLOGIC EXAMINATION

Clinical scenarios involving peripheral cranial neuropathies can be dramatic and disturbing to dog or cat guardians. These problems have a tendency to be noticed suddenly. However, they also can be incidental discoveries made during the physical examination. As always, it is important that clinicians remain attentive during the physical examination so that incidental neurologic deficits are not missed. Any of these presentations would be reason for a neurologic examination. The expression “complete neurologic examination” is often heard; this is redundant. The presence of any of these conditions would dictate that the entire nervous system be surveyed, because some signs may be very difficult to detect. For example, a patient with a balance disorder may have conscious proprioceptive deficits that may be subtle or difficult to detect, depending on the severity of the disturbance. Also, some disorders may be multifocal, and that discovery would be crucial to the differential diagnosis. Because some nerves, such as the trigeminal nerve, serve multiple functions and multiple areas, it is important to survey all its realms. In this example, there may be deficits of one sensory area but not another. It is important to tax the nervous system to reveal some signs. For example, the animal should be inverted to evoke and detect positional nystagmus.

49.2 LOCALIZATION AND CLASSIFICATION

First, no neurologic discussion is complete, or worthy of notice, without a repetition of the rule that localization is foremost. Differential diagnosis, hence prognostication, cannot ensue without localization. Because cranial nerves have their origins in the brain, because they may serve afferent, efferent, or both afferent and efferent functions, and because they may also serve autonomic functions, the basic neuroanatomy must be remembered or reviewed. For example, if the palpebral reflex is absent, it must be remembered that the deficit may be on the trigeminal afferent side of the reflex arc (rather than the facial efferent side or the brain stem), where this reflex is integrated. In general, a catalog of deficits is created as the first step in the assessment process. Some constellations of signs have powerful localizing value. For example, any combination of Horner's syndrome, facial palsy, and peripheral vestibular disorder suggests a lesion in the middle ear region.

Second, the problem should be defined from the history as chronic, acute, progressive, static, or improved.

Finally, a unifying statement about the problem is made, such as “an acute left facial paralysis and left peripheral vestibular syndrome.” This leads to a differential diagnosis. For example, using the condition described, the differential diagnosis list would include all causes of simultaneous otitis media and interna, neoplasms of the petrous region, and idiopathic cranial neuritides.

49.3 DIFFERENTIAL DIAGNOSIS

Several generalities can serve as useful guidelines:

- The causes of peripheral cranial neuropathies usually fall into three pathologic categories: idiopathic inflammation, infectious inflammation, and neoplasia.
- Afferent or autonomic abnormalities exclude myasthenia gravis and other skeletal myopathies. Facial paralysis, for example, is a common feature of acquired myasthenia gravis. However, if Horner's syndrome or vestibular signs are present, myasthenia gravis would be eliminated from the differential list.
- Deficits of facial sensation exclude a diagnosis of masticatory myopathies.
- Most of the common peripheral cranial neuropathies are idiopathic and self-limiting. Included in this list are Horner's syndrome, facial paralysis, acute jaw drop, and acute peripheral vestibular syndromes. The neuropathies leading to laryngeal paralysis, pharyngeal paralysis, and megaesophagus are likely also self-limiting, but the consequences are more severe than for the other conditions.
- Some cranial neuropathies can originate peripheral to the brain but within the cranial vault (e.g., in the cavernous sinus syndrome), usually as a result of tumors.
- Trauma is rarely a cause of cranial neuropathy in dogs and cats, except for facial nerve injury associated with surgery of the ear and Horner's syndrome as part of the brachial plexus avulsion syndrome.
- Hypothyroidism has not been proven to have a role in these conditions.

49.3.1 Acute Blindness

In general, it is important to know that most acute disturbances of vision without ophthalmoscopic abnormalities represent sudden acquired retinal degeneration. Pupillary responses may not be definitively abnormal. An electroretinogram is the test of choice. If visible fundoscopic abnormalities are present, alternative differential diagnoses must be entertained. Optic neuritis is the second most likely differential diagnosis.

49.3.2 Horner's Syndrome

Horner's syndrome can be preganglionic or postganglionic, and the differentiation can be made with topical application of 2.5% phenylephrine; this will cause a denervated iris to dilate, confirming a postganglionic localization. A few days must elapse before denervation sensitivity develops. Without other neurologic signs or physical findings, most postganglionic lesions are idiopathic and benign. Establishing the presence of preganglionic Horner's syndrome may be more problematic because the lesions may be in areas where occult disease may difficult to confirm.

49.3.3 Acute Jaw Drop

Trigeminal neuropathies are common, and the condition often diagnosed is the acute jaw drop syndrome. This syndrome is usually idiopathic, presumed to be an acute neuritis, but it can be caused by infections (e.g., *Neospora caninum*) and by lymphoma. Unilateral trigeminal neuropathy may manifest as sensory impairment and, eventually, atrophy, but bilateral involvement is required to produce masticatory dysfunction. It is reasonable to assume a diagnosis of acute, self-limiting, presumed immune-mediated trigeminal neuritis in acute jaw drop if the signs are limited to trigeminal dysfunction. Whether corticosteroids benefit these animals has not been proven. Typically, the animals can eat and drink, with assistance, until recovery ensues in a few weeks.

175
176

49.3.4 Acute Unilateral Facial Paralysis

Facial neuropathy is probably the most common cranial neuropathy. Most cases are idiopathic, and deficits are limited to the muscles of facial expression. The onset, or at least guardian notice, is usually abrupt. The disorder is presumed to be a peripheral neuritis. Central causes are implied by the presence of other deficits, such as a central vestibular syndrome or deficits of ipsilateral limb function. Facial muscle paralysis can be due to acquired myasthenia gravis, which should always be included in the differential diagnosis. Suspects should be tested for serum antiacetylcholine receptor antibodies. Other peripheral causes include disorders of the middle ear and the petrous temporal region, including otitis media and neoplasms.

Animals with facial paralysis and any evidence or history of ear disease should undergo diagnostic imaging. Bullae radiographs can be useful, but either computed tomography (CT) or magnetic resonance imaging (MRI) is an ideal means of imaging the middle ear. If any evidence of middle ear disease is found, sampling from within the bullae is indicated. Careful cleaning of the outer ear, followed by myringotomy, should be performed. Cytology and cultures also should be performed. Ideally, all dogs and cats with facial paralysis that do not have evidence of middle ear disease should have a cranial MRI that explores both the peripheral and central realms. If a diagnosis of idiopathic facial paralysis is made, there is no proof of benefit from

corticosteroids. Keratitis sicca due to poor production of tears is not usually a problem, but dryness due to exposure may be, and treatment or monitoring should be recommended.

49.3.5 Acute Loss of Balance

Unilateral hearing loss can be difficult to detect, but loss of function of the vestibular component of the vestibulocochlear nerve produces a dramatic set of signs. In general, it is not possible to distinguish clinically between a lesion in the nerve and one in the sensory organ, whether auditory or vestibular. However, the neurologic ground rule that differentiates peripheral from central vestibular syndromes is reliable: Peripheral syndromes produce a constant horizontal or rotary nystagmus, and central syndromes cause all the others. Most acute vestibular disorders are idiopathic, presumably an acute neuritis or vestibulitis, and these are self-limiting. An idiopathic disorder is distinguished from a relentless disorder by the presence of other historical, physical, or neurologic evidence that suggests the latter. A dog or cat with an acute peripheral vestibular disorder should be managed in the same fashion as for facial palsy if evidence of any ear disease is present. As with facial paralysis, all pets with a vestibular syndrome ideally should have a cranial MRI. However, because signs often abate rapidly, resolution in a short time may be used as proof that a relentless disorder is not present. If a diagnosis of idiopathic vestibular syndrome is adopted, there is no proof of benefit from corticosteroids.

49.3.6 Dysphagia and Regurgitation

Dysphagia may be due to disturbances of the glossopharyngeal and vagus nerves, but specific pathologic disorders have not been well defined. Acquired myasthenia gravis should be included in the differential diagnosis, and testing should ensue. These patients should have thoracic radiographs to detect esophageal dilatation and aspiration pneumonia. Except for acquired myasthenia gravis, these patients represent a mysterious group and often have a poor prognosis.

49.3.7 Stridor

Inspiratory stridor can be caused by various conditions, such as neoplasia or polyps of the larynx, but most cases are due to laryngeal paralysis, presumed to be the result of neuropathy of the vagus nerve or recurrent branches. The cause can be confirmed using light anesthesia achieved with a short-acting barbiturate or propofol; failure of arytenoid abduction confirms the diagnosis. These cases are treated surgically. Although solitary laryngeal paralysis has not been a feature of acquired myasthenia gravis, that diagnosis should be given consideration.

50 CHAPTER • 50 Sleep Disorders

Joan C. Hendricks

Sleep-associated problems in cats and dogs are uncommon owner complaints. Owners and clinicians cannot easily assess subjective disorders of sleep such as pathologic hypersomnolence and insomnia. Slight-to-moderate disruption of daily behavior patterns that accompany many changes in sleep do not substantially alter an animal's ability to function as a pet. The disorders that prompt an owner to bring a pet for veterinary treatment tend to be those that dramatically change the animal's overt behavior, such as sleep-associated epilepsy or narcolepsy with cataplexy. Other disorders, such as sleep apnea or cardiac arrhythmias, can be triggered by sleep and may have profound consequences for an animal despite being overlooked by most owners. It is interesting to realize that relatively minor changes in sleep behavior may herald future manifestations of abnormal central nervous system (CNS) function.

Sleep is a complex physiologic state with two distinct stages in normal mammals. During the first of these, the animal seeks a quiet, secure resting place and takes a characteristic relaxed species-specific posture. A few minutes after closing its eyes and becoming immobile, changes in CNS activity occur in the electroencephalogram (EEG): the cerebral activity alters from the rapid, desynchronized neural firing patterns of waking to synchronous discharges that produce high-voltage, slow (approximately 5 to 12 per second) wave activity. The pulse and respiratory rates slow, blood pressure decreases, and reflex arcs maintain homeostasis in autonomic systems. After a specific duration of uninterrupted slow-wave sleep (approximately 30 minutes in cats and dogs), behavioral and physiologic signs of a second stage appear. The observer notes a further relaxation of muscle tone, as a powerful postsynaptic inhibitory influence descends fromthe pontine brain stem along a ventral reticulospinal tractto the spinal motor neurons to produce postural muscle atonia. Several seconds to minutes after this atonia begins, volleys of distal small muscle twitching occur, producingrapid movements of the eyes, facial muscles, paws, and tail. Irregular respiration, heart rate, and blood pressure surges accompany these phasic bursts of small muscle movements. These small movements are the external manifestation of a highly activated brain: the flaccid musculature and lack of responsiveness belie a high rate of neural discharge throughout virtually all areas of the brain. During this second phase, most commonly known as rapid-eye movement (REM) sleep, the autonomic systems are driven by cerebral and brain stem influences during the bursts of twitching activity, which override reflex control. REM lasts as long as 10 to 15 minutesin normal cats and dogs. In humans this stage can last 20 to35 minutes and represents the sleep period when most dreams occur.

Sleep is thus a complex CNS and somatic syndrome that normally has an orderly progression. The atonia of REM sleep has the important function of preventing overt movements during the sleep period when the cerebrum is highly active.

50.1 SLEEP-ASSOCIATED AGGRESSION

An abnormal behavior that seems to occur relatively commonly is sleep-associated aggression. Owners report that a normally calm and friendly or attacks suddenly if disturbed while sleeping. Although owners may perceive this behavior as unpredictable and unprovoked, these attacks seem to be expressions of aggression—both dominance aggression related to the pet's sense of vulnerability upon arousal and territorial aggression related to defense of the resting place. No cases have been reported or documented in the literature in which animals displayed aggressive behavior directed at their owners while still asleep. Unfortunately, because this behavior is typically episodic and occurs in the home environment, it is difficult to observe directly. However, many or most dogs respond to behavioral approaches to treat aggression.

50.2 TRUE SLEEP DISORDERS

In general, true sleep disorders can be classified into two categories: (1) those in which the CNS mechanisms of sleep are normal (Figure 50-1) but other CNS or physiologic abnormalities are unmasked or triggered by sleep and (2) those in which the CNS mechanisms of sleep itself are abnormal. Knowing the physiology of sleep, augmenting a careful history with observation or (preferably) videotapes of behavior, and taking a rational approach to assessing the signs facilitates the differential diagnosis of these problems.

50.3 EXACERBATION OR UNMASKING OF ABNORMALITIES WITH SLEEP

50.3.1 Physiologic Abnormalities

Serious cardiovascular and respiratory disorders associated with sleep have been well documented in the literature and further studied in laboratory colonies of affected animals. Several families of German shepherds with histories of sudden cardiac death in apparently normal pups were identified. These dogs have an inherited predisposition to cardiac arrhythmias that are most common during sleep, especially during the REM stage. Abnormalities during standard clinical cardiac evaluation were relatively subtle, but ventricular tachycardia could be detected if pups were monitored by Holter monitors. Implanted pacemakers appear to have been successful in preventing sudden death in at-risk dogs. The mode of inheritance is complex, apparently either a polygenic or a dominant trait with incomplete penetrance. A colony of these dogs has been established, and studies of the underlying cellular abnormalities are in progress. In addition to the relevance of this basic research, it is significant that several families from widespread geographic regions were found to share a trait that can be transmitted by unaffected carriers. Thus although the syndrome is well described in German shepherds descended from a single common ancestor, the possibility exists that similar abnormalities could occur in other families and in other canine breeds.

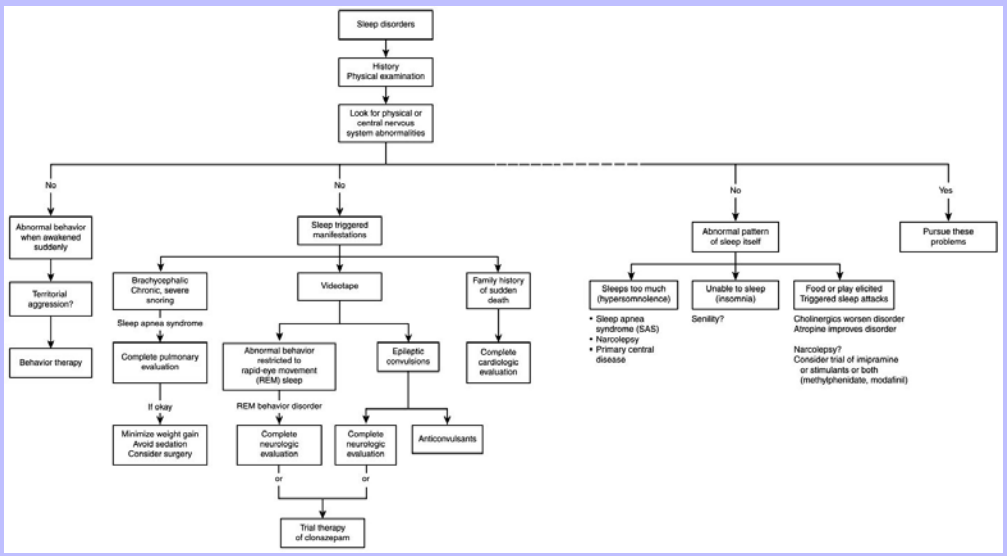
Sleep apnea has been described in English bulldogs. Even if they have normal arterial blood gases during waking, virtually all bulldogs exhibit episodes of apnea (pauses in breathing) and hypoxia during sleep, especially in REM sleep. These dogs normally compensate for their narrowed upper airways by augmenting the activity of upper airway dilating muscles during waking and much of non-REM sleep. However, during REM sleep, when muscle activity is reduced by normal atonia and reflexes are intermittently overridden by phasic cerebral influences, intermittent upper airway obstruction occurs. In laboratory studies, these pauses have been documented to occur at rates ranging from six per hour to over 100 per hour. The oxygen saturation can fall as low as 70% but most commonly falls to 85% to 90% from the normal 94% to 95%. As is true for humans with sleep apnea, these dogs are hypersomnolent and exhibit obvious snoring. However, these signs in themselves do not usually present difficulties for owners or pets. Based on other experimental evidence, it is likely that the episodic drops in oxygen saturation lead to hypertension and cardiovascular consequences in both dogs and humans, but the clinical importance of these abnormalities for dogs has not been proved.

Although it is not clear whether sleep apnea alone warrants treatment, surgery is often performed in English bulldogs to relieve waking signs of upper airway obstruction, and this surgery appears to be partially effective in relieving obstructive sleep apnea as well. The usual treatment in humans is to prescribe a face mask to be worn nightly. This constant positive airway pressure mask forces air through the nares to the pharynx to maintain a patent airway; this is obviously not feasible in canine patients. Pharmacotherapy is being investigated, and at present, some approaches that alter serotonin appear to have promise.

As in the case of the sudden cardiac death syndrome of German shepherds, it seems likely that this type of disorder, well described in the laboratory in one breed, may exist in other predisposed animals. Any anatomic narrowing of the upper airway could lead to the same signs. Thus brachycephalic conformation in any cat or dog, or an acquired narrowing caused by tumor or traumatic injury, could predispose to sleep apnea. Owners do not commonly complain of snoring, hypersomnolence, or gasping respiratory patterns in bulldogs; but they often describe these signs in response to direct questions. Owners of Shar Peis, pugs, beagles, and an obese, hypothyroid miniature poodle with obvious upper airway narrowing due to fat accumulation have described similar signs. In the latter case, treatment of the hypothyroidism resolved the profound sleepiness and sleep-induced apnea noted by the owners. This anecdotal evidence suggests that sleep apnea exists in several canine breeds. In addition, some owners of brachycephalic cats have described obvious snoring and irregular breathing, but none of these animals has been available for further laboratory assessment.

177
180

Figure 50-1 Algorithm for clinical evaluation of sleep disorders.



Diagnosis of sleep apnea requires continuous pulse oximetry and respiratory movement recordings, together with documentation of the sleep stage. This assessment can be noninvasive but is labor-intensive and impractical in a clinical setting. At present, the recommendation to a clinician who sees a pet with signs suggestive of sleep apnea is to treat the animal based largely on its waking signs.

50.3.2 Central Nervous System Abnormalities

Abnormal movements seen during sleep are often evidence of an underlying CNS disorder. The systematic changes in CNS activity that accompany normal sleep can unmask CNS disorders. Epilepsy from any cause, including idiopathic epilepsy, can be triggered by the rhythmic discharges of slow-wave sleep; however, seizures are rarely confined to sleep. Indeed, as part of the diagnostic workup of human epilepsy, the EEG is recorded during slow-wave sleep in an effort to trigger the epileptic charges. During the REM stage, abnormal movements can occur when the inhibitory pathway that normally produces atonia during REM sleep is disrupted. This pathway, which arises in the pons and descends in the spinal cord, can be interrupted by a

number of brain stem or spinal cord abnormalities, including traumatic injuries. Interrupting this inhibitory pathway permits the expression of the ongoing cerebral activity. Humans with this disorder (REM behavior disorder [RBD]) report that the observed behaviors represent the motor behavior appropriate to their dream content. Thus a patient may stand up, run, and clutch an invisible object while dreaming of playing football; or a patient may sit up and begin attacking his spouse and later describe that he was defending himself against a dream attacker. Dogs and cats with RBD, which (judging by referrals) appears to be the most common sleep disorder in pets, typically lift their heads and exhibit dramatic but intermittent paddling or locomotor activity during REM sleep. They can easily be aroused from these episodes, which occur during every REM period andcan often be recognized by an experienced observer viewing videotapes of the behavior. Although many of these animals are completely normal at all other times, in some cases it is obvious that CNS damage is correlated with the disorder, as in the case of a kitten that suffered a traumatic injury to the cervical spinal cord before the onset of signs. Even individuals that have an unremarkable physical examination may have an underlying CNS disorder. In humans with RBD and no other abnormalities at diagnosis, 38% developed overt Parkinson's disease an average of 3.7 years after the diagnosis of RBD. At the present time, the author has followed two cats with apparent congenital RBD for 10 or more years and observed no progression of signs. One of these cats eventually died and underwent a complete necropsy, and no gross or microscopic CNS abnormalities were identified.

Clonazepam, a benzodiazepine tranquilizer, reduces the level of activity during RBD in the vast majority of humans and was partially effective in the two cats. Routine anticonvulsant agents are not effective because they initially suppress REM sleep, with an eventual rebound of REM and recurrence of the behavior. Even if the disorder is not associated with other evidence of CNS disease, it can be life threatening for cats and dogs because some pets suffer urinary incontinence during the episodes, which is intolerable for some owners. In one cat treated for 10 years with clonazepam, the intensity of the behavior was reduced but not abolished. Withdrawing the clonazepam after the first 6 years resulted in an increase in motor behavior and related urination during REM, which was again partly controlled by reinstituting the treatment. Thus chronic treatment is feasible in pets with this disorder, but no improvement of the underlying abnormality should be expected based on experience to date.

In summary, evidence of abnormal movements during sleep should be assessed in view of the possibility that these movements may reveal otherwise occult CNS disease. However, some individuals (only cats identified to date) appear to have a congenital abnormality of the REM motor inhibitory pathway, perhaps caused by a biochemical change in the neural systems that normally maintain atonia.

50.4 DISORDERS OF SLEEP MECHANISMS

50.4.1 Effects of Systemic Disease

Sleep itself is affected by many systemic disorders. Systemic changes in immune function may alter sleep. It is now clear that prostaglandin D and interleukin-1-beta produce the increase in sleep that occurs with many febrile illnesses, accounting for this common symptom. One specific condition that alters sleep in humans is infection with human immunodeficiency virus (HIV), and a recent study documented that cats with feline immunodeficiency virus (FIV) show reduced sleep and disproportionately reduced REM sleep. The only owner complaints the author received regarding reduced sleep, or insomnia, involved elderly dogs who pace throughout the night. These dogs may be like humans with senile dementia, in whom the quantity and pattern of sleep become abnormal in association with increasing dementia. The opposite condition, increased sleep or pathologic hypersomnolence, can occur with sleep apnea and has also been described as an isolated idiopathic

abnormality in humans and in one case report of a dog. However, the best-described syndrome in which sleep mechanisms are abnormal is narcolepsy.

50.4.2 Narcolepsy

Narcolepsy is a fascinating but rare disease that is well documented in humans and dogs. It has also been reported in a cat, a bull, and several horses. The abnormality appears to be in the CNS trigger mechanisms of the REM sleep state. The abnormalities that appear are caused by the sudden eruption ofcomponents of REM sleep, including unconsciousness, muscle atonia, and dream imagery, into wakefulness. Without the normal temporal insulation of non-REM sleep, such manifestations are disruptive to normal life. In animals, the sudden loss of muscle tone (cataplexy) is almost always the sign noted by owners. However, in one dog, a sleepy appearance led the owners to seek veterinary advice. Although some individual cases of human and canine narcolepsy are caused by organic brain disease, the vast majority has no obvious CNS abnormality. Several subtle changes in CNS pharmacology have been documented in canine narcoleptics. An inherited form of the disease has been best documented in a colony of Doberman pinschers. The gene responsible for inherited narcolepsy in dogs was found to be an abnormality in the receptor for a previously poorly understood neuropeptide named *orexin* or *hypocretin*. The normal function of this neuropeptide is not known, but abnormalities of this system have now been shown to produce narcolepsy in mice, humans, and dogs. This is the first genetic basis of a sleep disorder to be described in any species.

The diagnostic process includes ruling out organic brain disease, and the diagnosis is best made when the behavior can be observed to be triggered by play or by food presentation, as is typical of canine narcoleptics. Fortunately, the disorder in dogs usually has only a moderate effect on their ability to lead normal lives, and in many cases it may be transient. In a colony of Doberman pinschers, the signs were maximal in pups at 4 to 7 months of age and then waned in severity. One case has been reported, however, in which the food-triggered cataplexy was so severe that complete anorexia resulted in a 20 kg weight loss and long-term treatment was required. The biochemical control of muscle atonia is well characterized, but proven pharmacotherapeutic agents in dogs are limited to imipramine. However, initial reports on treating dogs with orexin, hypocretin, or both suggest that treatments based on this new information hold considerable promise. Arousal-promoting agents can be used to relieve the hypersomnolence if necessary.

51 CHAPTER • 51 Cognitive Dysfunction in Aged Dogs

Elizabeth Head

Gary M. Landsberg

Advanced age in dogs may be associated with behavioral changes including separation anxiety, the onset of new fears and phobias, increasing irritability and aggression, stereotypic disorders, night waking, and house soiling.[1] Some of these behaviors are attributable to existing, possibly age-associated, medical conditions (including other neurologic conditions) and some may be due to primary behavior problems arising from changes in the household. However, once these have been excluded, remaining behavioral signs may be a consequence of pathologic brain aging.

51.1 COGNITIVE DYSFUNCTION: CLINICAL SIGNS

Until recently, clinicians had regarded this constellation of behavioral symptoms to indicate senility associated with advanced age. Cognitive dysfunction is not an inevitable consequence of aging in dogs, and striking individual differences are more likely the rule than the exception. Some aged animals show little or mild behavioral decline. However, a subset of aged dogs develops severe cognitive deficits that may disrupt normal function to a level prompting euthanasia. Ruehl and colleagues have identified a more general cognitive dysfunction syndrome (CDS).[2] The clinical signs have been described using a simplified acronym DISHA, which refers to *disorientation*, *interaction* changes with owners or other pets, *sleep-wake cycle* alterations, *house soiling*, and *activity* changes (which might be increased, stereotypic, or reduced). Additional signs such as increasing agitation and anxiety, altered responsiveness to stimuli (which might be heightened or reduced), altered interest in food (which might be increased or reduced), and decreased ability to perform learned tasks (which might be most obvious in working dogs) may also be seen. The number of dogs affected by CDS has been assessed in a number of survey-based studies. Approximately 48% of pet owners report that their senior dogs (7 years or older) exhibit at least one clinical sign of CDS. However, only 17% of these owners reported these signs to their veterinarian (proprietary market research, 1999; pet owner sample size: 150; data on file, Pfizer Animal Health). In another study, 180 owners of dogs aged 11 to 16 with no identifiable medical problems reported that 28% of the dogs between 11 and 12 years and 68% of the dogs between 15 and 16 years had at least one sign that might be consistent with CDS.[3] Further, CDS may be a progressive disease as aged dogs with impairments in one category were later found to have impairments in 2 or more categories.[4] Thus clinical signs of cognitive dysfunction in senior and geriatric pet dogs occur in a significant number of animals and potentially signals a progressive neurologic disorder.

51.2 COGNITIVE DYSFUNCTION: LABORATORY STUDIES

Questionnaire-based tools used in the clinic to identify dogs with CDS provide a measure of global brain dysfunction. However, these behavioral checklists are insensitive to early and subtle changes in learning and memory associated with pathologic aging in dogs. In fact, cognitive dysfunction is generally recognized as a syndrome in dogs 11 years of age and older, and signs may not be apparent until the last 18 to 24 months of a dog's life.[1] At this time no biomarker exists for CDS in aged dogs. An alternative technique to detect cognitive dysfunction in aged dogs involves the use of neuropsychologic tests that provide quantitative measures of cognitive function without reliance on questionnaires.[5] These tests are systematic, standardized, objective and a

more sensitive measure of age-related cognitive decline. In fact, they can identify age-related deficits in learning and memory from as early as 7 years of age.[4] Although these tests are too lengthy and complex to be applicable for clinic use, a number of cognitive functions assayed with these laboratory-based tasks are also likely to be contributors to the clinical signs that might be noted by pet owners.

In studies using a battery of reward-motivated neuropsychologic tests, several cognitive domains or functions can be evaluated in aged dogs. These tests involve teaching dogs to use visual information to solve different problems. Simple learning problems include discrimination tasks that involve showing dogs two objects that are different in appearance. Dogs must learn that only one of the two objects covers a food reward. Aged dogs can learn these problems, as can younger dogs. Once dogs have learned this visual discrimination problem, the reward can be switched to the previously incorrect object. This is called *reversal learning* in which dogs must be able to change a previously learned behavior, a type of cognitive ability that depends upon the intact function of the prefrontal cortex. Aged dogs have difficulty learning to switch to selecting the previously incorrect object, suggesting a lack of ability to modify learned behaviors. These laboratory tests depend on cognitive abilities that would be involved with modifying previously learned behaviors; thus aged dogs may be slower to modify problem behaviors. Other behaviors that are consistent with prefrontal cortex dysfunction include pacing, stereotypic behaviors, and an inability to inhibit behaviors (e.g., house soiling).

The aging process can also significantly affect memory. Spatial memory is defined as the ability of dogs to remember *where* they had last obtained a hidden food reward and is compromised in a subset of aged animals.[6] Functionally this type of memory impairment may be reported in companion animals as disorientation, wandering, and getting lost. Dogs also show age-dependent impairments in their ability to recognize objects seen previously.[7] This type of dysfunction may be reflected in decreased recognition of familiar people or animals.

Age-related differences have also been demonstrated in behavioral reactivity tests. The curiosity test, for example, allows the dogs to examine and play with a variety of toys to assess an animal's reaction to novel objects. In this brief 10-minute test, young dogs show significantly more exploration and contact with novel objects than old dogs, with cognitively impaired aged dogs showing the least object contact. Further, cognitively impaired aged dogs show higher levels of locomotion during a curiosity test than their age-matched unimpaired peers. The curiosity test measures exploratory behavior and is more amenable to clinical use because it requires brief 10-minute testing sessions and a small test area, suggest-ing that it may be a useful clinical screen for aged animals with cognitive dysfunction.[8]

51.3 COGNITIVE DYSFUNCTION: NEUROBIOLOGIC BASIS

Cognitive dysfunction that is not attributable to other systemic or central disease may reflect underlying age-associated neuropathology. A number of morphologic features of aging are found in the canine brain.[9] For example, cortical atrophy and ventricular widening occur with age in dogs.[10] The abnormal accumulation of proteins within and around neurons with age may be toxic to the brain. One form of pathology, the accumulation of diffuse plaques, contains a number of proteins, of which the primary constituent is the β-amyloid peptide (Aβ). The extent and location of Aβ deposition in the aged dog brain is linked to the severity of cognitive deficits.[11,12] For example, aged dogs that are severely impaired on a reversal learning task have the most extensive prefrontal cortexAβ pathology.[13] Another key feature of the aged canine brain is the progressive accumulation of oxidative damage to proteins and lipids[14] and a reduction in endogenous antioxidant activity. Damaged proteins and lipids can lead to neuronal dysfunction, which may subsequently compromise cognitive function. In support of this

hypothesis, a diet rich in antioxidants and mitochondrial cofactors can significantly improve cognitive function in aged but not young dogs.[15]

51.4 TREATMENT OPTIONS

Age-dependent cognitive impairments in companion animals, as mentioned previously, may reflect systemic or a CNS disease. Once other contributing factors are eliminated, the appropriate treatment can be implemented. Currently, one pharmaceutical is approved for the treatment of cognitive dysfunction in aged dogs in North America. Anipryl© is a monoamine oxidase B inhibitor that can improve cognitive signs in aged dogs.[16] Its mode of action appears to be to enhance catecholamine transmission, as well as decrease the production and increase the clearance of toxic free radicals. In Europe, two drugs are presently licensed for the treatment of cognitive decline in senior dogs that are purported to enhance cerebral vascular blood flow. Nicergoline is an alpha 1 and alpha 2 adrenergic antagonist, whereas propentofylline may improve blood flow by inhibiting platelet aggregation and thrombus formation. Alternatively, a specially formulated senior canine food isalso available (Prescription Diet® Canine b/d™) that contains antioxidants and mitochondrial cofactors that significantly improve cognition in both laboratory and clinical studies.[15]

51.5 SUMMARY

Aged dogs, like aged humans, are vulnerable to the development of progressive brain pathology that is associated with clinical signs of cognitive dysfunction. However, it is important to rule out other contributing systemic diseases or other central nervous system (CNS) disorders that can also cause cognitive impairments. Along with behavioral therapy, a variety of medical and dietary treatment options have been licensed; however, availability varies among countries.

52 CHAPTER • 52 Behavioral Disorders

Andrew Luescher

Behavior problems of pets are extremely common. According to a variety of studies the prevalence of behavior problems in dogs and cats lies between 40% and 80%. In an epidemiologic study, approximately 40% of dogs had growled at their owners, and 15% had bitten their owners. Around one third of cats appear to have at least an occasional problem with inappropriate elimination. Behavior problems jeopardize the human-animal bond and are a main cause of relinquishment and euthanasia of healthy dogs and cats. Therefore pet owners, pets, and the veterinary profession benefit from the prevention and treatment of behavior problems in patients.

Behavior services in a small animal practice may include prepurchase counseling, counseling of new pet owners, puppy classes, behavioral intervention, and clinical behavior service. Counseling of new pet owners for problem prevention is a service that is performed routinely, but not always effectively or appropriately, at the first puppy or kitten visit. These first visits set the stage for all future doctor-patient and doctor-client relationships. If handled effectively, they can bond a client and patient to the clinic. Inappropriate actions such as rough handling or frightening (“dominating”) the young pet can cause continuous problems with fear or aggression at future visits. Client counseling is best performed with use of a check sheet inserted into the pet's file. Problem prevention includes socialization and exposure to varied environments, house training or litter-box training, consistent interaction and training, encouraging appropriate play, teaching a bite and claw inhibition, and teaching the “leave-it” and “drop-it” commands. To prevent food guarding in puppies, treats should be added to the food while the puppy eats. Puppy and (where available) kitten classes should be recommended. It is advantageous to offer these at the clinic.

Behavioral intervention refers to recognition of a behavior problem that underlies a medical problem. In cases of wounds inflicted by another dog, for example, the aggression between the dogs should be addressed. In cases of self-inflicted wounds, information that relates to possible separation anxiety or panic attacks should be sought. Furthermore, information on management and behavioral issues should be solicited at every yearly visit. For example, it would be important to find out if a dog had been relegated to the garage. This would indicate a high risk of imminent relinquishment, and preventive behavioral intervention would be urgent.

If clinical consults are offered, they should be performed in a methodical way in special appointments. The diagnosis should be based on a minimal medical database (i.e., physical exam with basic neurologic exam, CBC, chemistry profile including a thyroid panel, urinalysis, and additional tests as indicated), a thorough history and direct observation and/or observation from videotapes. The history may involve collection of general information regarding early history; housing, feeding, exercising, and training the pet; the animal's behavior in various situations to assess temperament; and the specific problem. The latter information should include triggers of the behavior; the behavior itself, including body language; and consequences of the behavior. Because behavior problems often change over time, this information should be gathered for the earliest incidents in addition to the most recent few. Observations need to include normal dog-owner interactions. Particular attention should be paid to behavior that results from motivational conflict or frustration.

Treatment modalities include changes in management (housing, feeding, exercise, training methods), behavior modification (e.g., systematic desensitization, counter-conditioning, and response substitution), and pharmacologic treatment.

While behavior modification is being addressed, exposure to the natural stimulus must be avoided. Systematic desensitization involves training the patient to a relaxed down-stay, and exposing the patient to the stimulus at a low intensity. The patient is rewarded for staying relaxed. The stimulus intensity is increased incrementally, and the

patient always is rewarded for relaxation. If the dog shows a reaction, the owners have progressed too quickly and need to go back a few steps in the training. Systematic desensitization requires identifying the stimulus, reproducing the stimulus, and having control over the stimulus intensity. If these requirements cannot be met, or the natural stimulus cannot be avoided for the duration of behavior modification, drug desensitization may be necessary. In this case, the patient is put on an effective dose of an appropriate drug and exposed to the natural stimulus as often as possible. He is rewarded for desirable behavior. Over time, the patient is weaned from the drug.

The term *counter-conditioning* is used inconsistently in the literature. This author uses it for a technique based on Pavlovian conditioning. It involves association of a situation that previously evoked fear and/or aggression with something pleasant. The pleasant stimulus can be food or play, for example. It is very unlikely that fear is reinforced by giving food but could easily be reinforced by picking the animal up or sheltering it (avoidance conditioning).

Response substitution is a technique by which an animal is trained to perform an appropriate behavior in a situation in which it used to perform an unacceptable behavior. The animal first needs to be trained to perform the desired behavior on a cue. Then, whenever the animal shows any inclination to perform the unacceptable behavior, the owner distracts it, gives the command, makes the animal do the appropriate behavior, and reinforces that behavior with a reward. They need to either supervise the animal constantly, or put it in a situation in which it will not perform the inappropriate behavior when not supervised. The animals may not be given any chance to perform the inappropriate behavior.

Often these techniques are used in combination. Variations of these techniques are used depending on the situation or problem. The instructions given here are examples, not the only correct form, of behavioral treatment of the specific problem.

183

184

52.1 CANINE BEHAVIOR PROBLEMS

52.1.1 Aggression

Depending on the author, some dozen different types of canine aggression are recognized, including conflict-related, dominance, possessive, territorial aggression, interdog, play-induced, excitement induced, fear induced, pain-induced, redirected, maternal, and predatory aggression.

They fall into the three major groups of affective aggression, predatory behavior (part of feeding behavior), and play aggression. Redirected and learned aggression are not really diagnoses but imply a mechanism of modification of a type of aggression.

52.1.1.1 Aggression to Household Members

Aggression to household members is often exhibited in situations in which the dog is threatened or "challenged." This type of aggression has generally been diagnosed as dominance aggression. Dominance aggression would be expected primarily in adult dogs and intact males. Dogs would be expected to have a self-confident personality and show offensive body language when aggressive. However, recent research showed that the majority of cases start at a very young age. Typically, initial aggression is shown in response to discipline or over food within the first 2 months of ownership. The affected dogs have a different disease history (severe early disease, dermatologic disease) than nonaggressive dogs. They are more excitable as puppies and more excitable and fearful (shy of people) as adults. Their body language before and during an attack is ambivalent and indicates a motivational conflict. Frequently, in the initial incidents the dog shows defensive body language, but over time it becomes more and more offensive. There is a breed predisposition;

Spaniels, Terriers, and toy breeds are more likely to bite. Dogs most likely to be aggressive are neutered males, neutered females and intact males are less likely, and intact females are least likely to be aggressive (although in small breeds, females are more likely to bite than males). Neutering can make females more aggressive. Dogs that are aggressive to their owners are also likely to be aggressive to strangers, which indicates this aggression is not confined to the dogs' social group.

It appears that the aggressive dogs are in a motivational conflict (approach-withdrawal conflict) relative to people. When a person approaches, aggressive dogs' anxiety level increases and they show aggression. As the person responds by backing off, the threat diminishes. The dogs thus learn that they can resolve their conflict and reduce their anxiety by showing aggression. Thus aggression becomes conditioned through avoidance conditioning; this type of conditioning produces persistent behavior. Based on this putative pathogenesis, we have proposed the term *conflict-related aggression*.

Treatment should address the dog's basic disposition (e.g., fearfulness, hyperexcitability), the way in which the dog is managed, and the cause of conflict (i.e., the inconsistency in the owner-dog interaction).

Recommended management changes include twice daily meal-feeding (as opposed to *ad lib* feeding) and regular twice-daily exercise. The situations in which confrontations are likely should be avoided. This may imply that the dog needs to be confined (e.g., in a separate room or exercise pen) unless being trained. Confinement is also indicated when the owners are afraid of the dog, when smaller children are involved, or when the owner is unable to ignore the dog. A head halter with a leash attached is placed on the dog, so that the owner can control all aggression-inducing situations in a safe, nonconfrontational, and consistent way. Toys or other assets that have caused confrontations should be removed. The dog is not to be let on furniture *if* that caused a problem. The dog should be reintroduced to situations in which he showed aggression only in the context of systematic desensitization and response substitution.

Owners are instructed to avoid all casual interaction (i.e., ignore the dog most of the time) and only interact with the dog in a command-response-reward format. This ensures that all interactions with the dog are consistent and thus predictable. Highly structured obedience exercises, especially ones that desensitize the dog to owner-behavior perceived as threatening, are very useful. Clicker training is especially helpful when dealing with these dogs, because it is a hands-off method of training and avoids confrontations between owner and dog. No punishment, choke chain, or scolding are to be used. A head halter assists the owner in training and walking the dog. Punishment or the “alpha roll-over” are *not* appropriate in dealing with aggression. Situations in which the dog still shows aggression are addressed by systematic desensitization, counter-conditioning and response-substitution.

Food guarding can be addressed through management, that is, by feeding the dog in a separate room and calling the dog out of the room once he is finished eating. It can also be treated through systematic desensitization. In the latter case, the dog is tied in a different place than where he is normally fed, and fed from a different food bowl (preferably a saucepan with a long handle). The ration is measured out into yet another dish that is placed out of the dog's reach. The dog is asked to sit and a few kibbles are placed into the food bowl, and the dog is offered the food. This is repeated until all the food is fed, and all meals are fed in this way for about a week. Then, the amount of food given at one time is increased. Next, the amount of food is decreased again to a few kibbles, but the owner lets go of the food bowl while the dog eats. The amount is then increased again. Eventually, a third of the food can be placed into the food bowl, and the owner adds the remainder of the ration gradually with a ladle. Once this goes well, all the food can be placed in the food bowl, and the owner tosses treats into it while the dog eats. This should be done occasionally throughout the dog's life (in very mild cases, this last step is all that needs to be done).

No drugs have been proven effective in the treatment of any type of canine aggression, although there is anecdotal evidence of positive effects with SSRIs.

52.1.1.2 Possessive Aggression

Guarding of food and objects is a natural but unacceptable canine behavior. It becomes exacerbated if the dog is afraid of a confrontation over the item (it may therefore be regarded as a special case of conflict-related aggression). It can be addressed by management or through training. The latter option includes training “leave-it” and “drop-it” commands, or exchange exercises (a form of systematic desensitization). For exchange exercises, the dog is tied to an immovable object, initially away from where he most commonly shows aggression. The dog is asked to lie down and stay. A toy that the dog does not value much is laid down at some distance from the dog, the leave-it command is given, the toy is picked up, and the dog is rewarded for staying relaxed. At subsequent trials, the distance is reduced. The exercise is repeated with increasingly valuable toys.

52.1.1.3 Territorial Aggression

Territorial aggression is exhibited to strangers or strange dogs either on the owner's property or in the owner's proximity. It is a normal but unacceptable canine behavior. Treatment involves training the dog to sit near the door and staying while the door is opened, while the doorbell is rung, or while a stranger stands at a distance and progressively closer to the door. It is important to prevent the dog from ever showing aggression until the training program is completed.

184

185

The dog should be walked twice daily off the property on head halter and leash. Whenever a person approaches, the owner should go out of the way and keep the dog busy with fast-paced obedience, reinforcing appropriate behavior with ample food treats. Once the other person has passed, they can continue their walk. Each time, the distance to the other person can be reduced (depending on the response of the dog), until the owner can heel the dog by the other person, and then reward the dog for having passed without aggression. This method can also be used with a volunteer who stands still while the owner performs obedience training with the dog at decreasing distance. The dog can also be systematically desensitized to a stranger approaching.

52.1.1.4 Aggression Between Dogs

Aggression to strange dogs or *interdog aggression* can be status-related, territorial, fear-based, or even predatory. Treatment is similar to that of territorial aggression and includes the same exercises on walks, systematic desensitization to a dog passing by or approaching, response substitution (having a helper with a dog stand still and doing obedience with the patient at decreasing distances, rewarding frequently), and counterconditioning (making the situation when another dog is in sight very pleasant). Punishment is contraindicated with any form of aggression, in this case in part because the patient would learn that the presence of another dog means he will likely get punished.

Aggression between dogs living in the same household, often referred to as “sibling rivalry” (a misnomer because they are not usually siblings), can have various reasons as well but most cases are either status-related or related to owner attachment (sometimes called “alliance aggression”). Fights are usually severe, especially among females.

Status-related aggression may occur between dogs that are close in social status. Fighting may also begin when a younger dog reaches adulthood, or when an older dog is no longer able to maintain his position. Treatment of status-related aggression involves deciding which dog will likely end up dominant and treat him as such (giving attention or food first, giving this dog privileges that the other dog does not have), and treating the other dog as subordinate (ignoring, cutting privileges, possibly confinement, rewarding subordinate behavior). Furthermore, systematic desensitization and response substitution (as for interdog aggression) can be used. The dogs may need to be separated and/or muzzled when exposed to each other. The times the dogs are exposed to each other should be as positive as possible (counterconditioning).

Alliance aggression is aggression to another dog in the same household shown only in the proximity of the owner. It is usually, but not always, the lower-ranking dog that initiates the aggression. The aggressive dog is usually overdependent on the owner and becomes very anxious if the other dog gets close to the owner. He may also feel much more confident in the presence of the owner.

The most important aspect of treatment is to ignore both dogs for 3 to 4 weeks, except when working with them. The dogs should be exposed as much as possible to each other. If there is any indication that the dogs will be aggressive, the owner should distract them with a loud noise (clapping hands, rape alarm) and immediately leave. In some cases the dogs will need to be muzzled when exposed to each other. It should be determined which of the two is the dominant dog (from a videotape taken when they are on their own, without owner present), and that dog should be treated as such.

The aggressive dog can be desensitized to the owner paying attention to the other dog. While the aggressive dog is tied and in a down-stay, the owner interacts with the other dog at decreasing distance and rewards the aggressive dog frequently for staying relaxed. Dogs that exhibit alliance aggression are often not aggressive to each other in other places, or out in the yard. In this case, they can be exposed to each other initially on neutral ground, then kept together in the backyard, and then gradually allowed access to increasing parts of the house.

52.1.1.5 Predatory Aggression

Predatory aggression is highly genetically controlled and may therefore be difficult to treat. It is a particularly dangerous form of aggression because there is no warning and the bite is not inhibited. Systematic desensitization and response substitution (in combination) can be successful. The owner is instructed to do obedience training at a distance from the “prey” (e.g., horses, cars going by), using a head halter and food rewards. Gradually, the owner reduces the distance. Confinement and control, as well as a muzzle, are useful in managing the behavior. A good recall can help to control dangerous situations. Socialization of the puppy to the species that it should not consider as prey (e.g., children) is essential. Selection of a breed with little predatory behavior helps in prevention.

52.1.2 Separation Anxiety

Separation anxiety is a common problem. Among these cases, dogs obtained from shelters are overrepresented. Affected dogs are usually very friendly and dependent on the owner, and more highly trained than dogs with other behavior problems. Because of their owner attachment, these dogs become anxious when separated form the owner (i.e., when the owner is either not home with the dog, or not accessible to the dog) and express this anxiety in a variety of ways (e.g., by destroying property, barking, salivating, pacing, urinating or defecating, self-mutilation). Diagnostically it is important to note that these behaviors start within a short time of the owner

leaving. First line treatment may include two daily walks to reduce anxiety; ignoring the dog for approximately 30 minutes before leaving, and after coming home until the dog settles; giving a hollow toy containing food treats some 5 to 10 minutes before leaving; and ignoring attention-getting behavior at any time. In addition, owners may want to train the dog to a long down-stay and then use that command to prevent the dog from following them all the time, and when doing planned departures (see below). Mixing up the order of predeparture cues makes departure less predictable, and desensitization to these same cues (by presenting them frequently without leaving) will reduce the dog's response to them. Drug treatment concomitant with behavior treatment is often indicated. The drug clomipramine (Clomicalm, Novartis) is the only drug licensed in the United States for the treatment of separation anxiety.

If necessary, the owner can do planned departures, leaving the dog for initially very short and increasingly longer times, while giving the dog a safety cue (e.g., the sound of the radio). If at all possible, dogs with separation anxiety should not be confined when left alone, because usually this makes the anxiety worse. If the owners keep the dog confined and do not want to risk leaving him loose, they may want to use the planned departure technique with the dog loose in the house during practice departures. In this way they can find out without great risk if it is safe to leave the dog loose (if done this way, being loose becomes a safety cue for the dog).

52.1.3 Fear

Fear is a combination of physical, emotional, and physiologic responses to a threatening stimulus or situation that, in the wild, would protect the animal from harm. Fear may become a maladaptive *"phobia"* when the response is out of proportion to the threat. The dog may be afraid of specific stimuli or be globally fearful. The cause of fearfulness may be genetic, or early experience (lack of socialization and exposure before 14 weeks of age, or an adverse experience in the fear period 8 to 10 weeks of age). Specific fears are usually learned. 185 186

Learning can exaggerate any fear. Learning is most easily achieved through avoidance or escape conditioning. However, it is very difficult to reinforce fear with food. Giving food to a fearful dog is therefore not contraindicated, but recommended, because it may make the situation more pleasant (counterconditioning).

Specific fears can usually be treated very effectively with systematic desensitization, counterconditioning, and response substitution. For generalized fear or when fear-evoking stimuli cannot be avoided, or if the stimulus cannot be replicated (e.g., thunderstorms), drug desensitization is indicated. The dog is given a large enough dose of a drug with anxiolytic effects to reduce fear to the point at which the dog is capable of habituation to the stimuli (the above behavior modification techniques should be used simultaneously). Once the dog functions well at that dose, the dose is slightly reduced. When the dog no longer shows fear on the lower dose, the dose is further reduced, and the dog is thus gradually weaned off the drug. Throughout the procedure, the dog should be rewarded for acting confidently. Even after successful treatment, the dog should be periodically exposed to the fear-inducing stimuli and rewarded for not responding fearfully, to prevent spontaneous recovery of the fear response. A fear response is not ever to be punished.

52.1.4 Hyperexcitability

A high level of activity may be normal for a certain breed and age of dog. Although there are various physiologic and environmental reasons for abnormally high activity or excitability, the most common cause is inadvertent conditioning with owner attention. Consequently, the first treatment strategy is to ignore the dog, especially when excitable. Relaxed, calm behavior should be rewarded. Obedience training, especially a long, relaxed down-stay, and regular twice-daily walks will also help in most cases.

52.1.5 Canine House Soiling

Before a diagnosis of house soiling is made, medical causes, urine marking, separation anxiety, and other anxiety-related disorders have to be ruled out. Causes of house soiling include insufficient initial house training, long periods of cage confinement during puppyhood so that the dog learned to soil his bed, and various other factors that can result in the loss of house training.

To treat house soiling, the factors that affect elimination have to be understood. Elimination is most likely after rest, eating, and physical activity. It is also stimulated by the smell of previous elimination. The dog should be fed two to three times a day (depending on his usual number of stools per day) and walked thereafter to the same location. The dog should also be taken to that location when first waking from sleep, after play, and frequently in between. When the dog eliminates at that location, he should be rewarded. If he does not eliminate this time, he can be brought back to the house but should be taken out again within 10 minutes or so. Indoors, the dog should be under constant supervision (crate confinement or on leash with the owner). The soiled areas should be treated with a high-quality enzymatic cleaner and can then be made aversive with bi-weekly application of pine-oil cleaner or citrus-scented liquid, or small amounts ($^1/_4$ teaspoon) of mothball powder brushed into the pile of the carpet *(mothball crystals are toxic)*.

52.1.6 Canine Urine Marking

Canine urine marking can be a territorial behavior, greatly facilitated by testosterone in intact males (especially in the presence of other intact dogs or bitches in heat), or related to anxiety. It involves deposition of small amounts of urine in specific places, usually on or near vertical objects. The strongest stimulus is environmental competition of other males and freshly voided urine from other dogs.

Stimuli that elicit urine marking should be identified and, if possible, eliminated. If urine marking is anxiety-related, then the cause of the anxiety has to be addressed. The marked areas should be cleaned and deodorized as described for house soiling. Castration reduces leg lifting in the house in about 60% of cases.

Behavior modification involves constant supervision in the house, possibly with the dog tied to the owner with a leash (umbilical cord technique). Whenever the dog shows any signs of wanting to mark a place, the leave-it command (it will have to be taught in advance) or response substitution should be used. Punishment generally does not work as it is usually not applied consistently, and because the dog may learn to lift the leg only when the owner is absent.

52.1.7 Compulsive Disorder in Dogs

Compulsive disorder is expressed as repetitive or sustained, apparently abnormal behaviors performed out of context. Compulsive behaviors could be categorized as related to locomotion, oral activity and grooming, aggression, vocalization, and hallucinatory behaviors. In dogs, locomotory behaviors include circling, tail chasing, pacing, jumping in place, chasing light reflexes, and freezing. Oral behaviors and behaviors related to grooming manifest, among others, as leg or foot chewing, licking, flank sucking, scratching, chewing objects, pica, and snapping in the air (“fly-snapping”). Compulsive behaviors related to aggression include self-directed aggression, attacking the food bowl or other inanimate objects, and possibly unpredictable aggression to people. Vocalization may be rhythmic barking or whining. Hallucinatory behaviors may be staring at “shadows,” chasing light reflexes, and startling. Dogs that wake up suddenly without any discernible trigger and jump or are aggressive may suffer from hallucinatory compulsive disorder.

Compulsive behaviors may be considered an expression of stress, frustration, and/or motivational conflict. Frustration refers to the situation in which an animal is motivated to perform a behavior, but prevented from doing so. Motivational conflict results from two opposing, similarly strong motivations (such as approach and withdrawal). Prolonged and particularly repeated frustration and conflict may result in conflict behaviors developing into compulsive disorder. A genetic predisposition is probably present in any case of compulsive disorder. Physical lesions or irritations, such as ones caused by allergy, may trigger CD in some cases by increasing stress and by directing the compulsive behavior towards a particular body site. Owner attention may reinforce existing compulsive behaviors, or condition normal conflict behaviors to the extent that they appear compulsive. Disease that increases stress and/or irritability may contribute to CD, as may other stressful behavioral problems (e.g., interdog aggression or separation anxiety) or certain temperament traits (e.g., fearfulness).

A diagnosis of CD is based primarily on a detailed history and on ruling out other possible behavioral and medical causes for the observed behavior. One aspect of the history that is particularly important for the diagnosis is the development of the problem. In many cases (especially locomotory behaviors), compulsive behaviors are first shown in a specific conflict situation but later may generalize to other contexts in which the animal experiences a high level of arousal. Once established, compulsive behaviors are displayed outside of their natural context and are often excessive. The animal is in full consciousness while performing the behavior and aware of its surroundings (although in some cases they may not respond to any stimuli in their environment, and may even run into furniture, etc.). The behavior can usually be interrupted, albeit often with difficulty, and the animal does not exhibit a postictal phase. Their performance is not dependent on the owner's presence.

186

187

The differential diagnosis has to consider various behavioral, neurologic, dermatologic, and other medical conditions. To exclude other possible causes for the behaviors, a minimal medical database consisting of a physical exam including a basic neurologic exam, and CBC, chemistry profile, thyroid panel, and urinalysis should be obtained. Additional tests may be needed in specific cases.

Behavioral differentials include acute conflict behavior only shown in specific contexts, and conditioned behavior only shown in a person's presence. Neurologic rule-outs are seizures, forebrain and brain stem lesions, lesions of the vestibular system (circling), lumbosacral stenosis (tail chasing), hydrocephalus, sensory neuropathies, and neuromas (self-mutilation).

Any dermatologic lesion, skin-gland disease, or endocrine disease that results in itching or pain can cause licking. Preexisting wounds or pressure point granulomas can also direct compulsive licking towards a particular area.

Treatment is directed at identifying and removing the cause of conflict, frustration, and stress. In cases in which the cause of stress cannot be removed, it may be possible to desensitize the animal to the stressful situation. Casual (i.e., inconsistent) interaction should be avoided and replaced with highly structured interactions in a command-response-reward format. Formal obedience sessions allow for such consistent interaction. Punishment should not be used at all. A consistent feeding and exercise schedule provide for a consistent routine. Sufficient exercise helps reduce anxiety. Rotating toys and providing food-dispensing toys are also recommended.

In most cases, drug therapy may prove necessary or will at least facilitate treatment. Pharmacologic intervention is most likely achieved with serotonin re-uptake inhibitors such as clomipramine (Clomicalm, Novartis Animal Health US, Greensboro, NC) at 3 mg/kg bid, or fluoxetine (Prozac, Eli Lilly, Indianapolis) or

paroxetine (Paxil, GlaxoSmithKline, Pittsburgh) at 1 mg/kg sid-bid. It may take more than 4 weeks to see a drug effect. The author usually gives the drug until at least 3 to 6 weeks after the drug appears to have a satisfactory effect and then weans off gradually over at least three weeks, by reducing dose but maintaining dosing frequency. If during the weaning process the behavior reappears, the dose is increased again and maintained at the effective level for some time before resuming weaning. Weaning is important to avoid a rebound effect.

The above behavioral treatment with or without drug treatment is likely to reduce the frequency of the behavior. If the dog still performs the behavior occasionally, consistent response substitution can be highly effective in the treatment of compulsive disorder.

52.2 FELINE BEHAVIOR PROBLEMS

52.2.1 Inappropriate Urination and Defecation

Cats that are house-soiling with urine may be differentiated from those that are urine marking by the amount of urine that is released. When marking, a cat eliminates small amounts of urine at a time, usually on vertical objects, whereas a house-soiling cat tends to empty his bladder, which results in a large spot. The exception is cats that mark with full urination and/or defecation on human's concentrated body odor (e.g., beds, bath mats, dirty clothes). In these cases, the cat has a conflict with the person on whose smell he marks with urine or feces.

Cats may stop using their litter-box for a variety of reasons. They may have developed an aversion to the litter, the pan, an odor or the location; they may have developed a preference for certain substrates or locations; they may be under some environmental stress; or they may have underlying disease, most commonly urinary tract infection or cystitis, and in older cats also arthritis or cognitive dysfunction.

The first step in treatment is to identify which cat of a multicat household is the culprit (Figure 52-1). To differentiate disease-related from behavioral house soiling, a physical exam, CBC, profile, urinalysis, and urine culture are indicated. Then litter-box factors need to be addressed. The number of boxes should equal the number of cats plus one. Owners should scoop the box daily and wash it out regularly with warm water only. Many cats do not like covered boxes. Location of boxes is crucial. Laundry rooms and basements are usually not preferred areas, whereas hallways and closets are most suitable. In a multicat household, a core area for each cat should be established, containing food, water, lying area, scratching post and litter-box, in the cats' preferred locations. The most important factor that determines litter acceptance is particle size; most cats prefer small particle size. Litter material should not be scented. A variety of litter materials can be offered. Litter-box liners are often aversive to cats and should not be used. Soiled areas should be cleaned and made aversive as described under canine house soiling.

If cats have established a substrate preference (e.g., for carpet) the cat can be retrained by confining it to a room with different flooring. A piece of carpet is placed in the litter-box. Each day, a somewhat smaller piece of carpet is provided, and a little more litter material is sprinkled on it, until the cat is completely switched over to litter. The cat can then be taken out of the room daily for short and increasingly longer periods of time, under close supervision. It is recommended to feed the cat free choice food and to change its water frequently.

52.2.2 Feline Marking or Spraying

Spraying is a form of territorial marking with small amounts of urine, or rarely, small amounts of feces. It is most common in intact males or males that produce steroids from other sources (check penis for barbs). Among

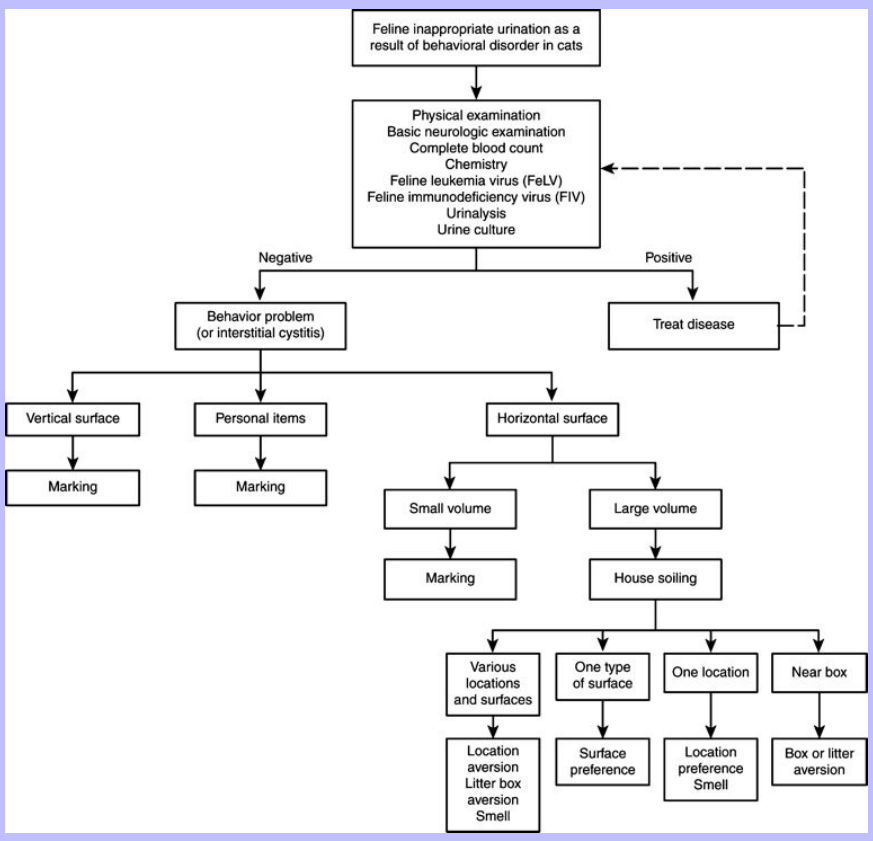
neutered animals, males are twice as likely to spray than are females. Spraying usually occurs in only a few specific areas, most commonly on prominent vertical objects, and often near windows and doors. Spraying is usually related to stress resulting from the presence of other cats, changes in the environment, changes in schedule, food and water restriction, or other factors. Some cats mark with full urination or defecation on concentrations of body odor of a specific person. This usually indicates some conflict related to that person, such as fear or overattachment. The smell of previously soiled areas will compel a cat to re-mark the same area.

In a multicat household it is important to determine which cat is marking. Although disease is not a common cause for urine marking, it should always be ruled out first. Intact animals (especially males) should be neutered. Environmental and social stressors should be addressed. In multicat households, different core areas for the cats, with food, water, lying area, scratching post, and litter-box should be established. Provision of cat trees enables cats to use the third dimension to get out of each other's way. Outside cats may need to be kept away, or the patient needs to be prevented from seeing them. The sprayed areas should be cleaned with a good enzymatic cleaner. Making the sprayed areas aversive is controversial. Application of a feline pheromone analogue (Feliway, Veterinary Products Laboratories, Phoenix), as a spray or by diffuser, may reduce spraying. The temporary use of an anxiolytic drug such as paroxetine (Paxil, GlaxoSmithKline) or clomipramine (Clomicalm, Novartis) may be necessary. It is recommended to offer free-choice food and provide fresh water frequently.

187

188

Figure 52-1 Algorithm for diagnosis and treatment of feline inappropriate urination.



52.2.3 Territorial Aggression, Intercat Aggression

This type of aggression is seen most frequently when a new cat is introduced to the household, or when a resident cat is reintroduced after a stay at the veterinary hospital or boarding. One cat may stalk the other cat, and the victim usually shows fear, which increases the probability of an attack.

Letting the cats “fight it out” does not work. Systematic desensitization and counterconditioning are recommended. Cats can be exposed to each other in carriers at a decreasing distance. Each time, the carriers are swapped, so the cats are exposed and take on each other's smell. While exposed to each other, they get their favorite food to eat. They can also be exposed to each other on leashes. While exposed, the owners should play with the cats and give them their favorite treats, gradually reducing the distance. When not systematically exposed to each other, the cats should be separated with only the bare necessities provided, and ignored. The rooms in which the cats are kept can be swapped after each exposure, so the cats are exposed and take on each other's smell. The smell can also be transferred between cats by rubbing a towel alternately on either cat. Drugs are often used on both cats (in the aggressor to reduce aggression, in the victim to reduce fear).

52.2.4 Petting Aggression

Some cats get very aggressive when petted for a prolonged time. The reasons are not well understood. Treatment involves avoiding prolonged petting or systematically desensitizing the cat to tolerate petting.

52.2.5 Redirected Aggression

This is not a diagnosis, but it describes aggression that is redirected to an alternate target, when the intended target is not accessible. It is often triggered by the view of outside cats. The cat that is indoors redirects its territorial aggression to another resident cat (which results in intercat aggression) or a person. *188* *189*

52.2.6 Play Aggression

Play aggression becomes a problem if the cat delivers uninhibited bites and causes injury. Affected cats are usually young, are living as the only cat in a household, and were taken early from their mothers. Often, owners contribute to the problem by playing roughly with the cat when it is a little kitten, and failing to teach a bite and claw inhibition. Play aggression is not usually preceded by a threat. The cat often hides behind some furniture and waits until a person walks by and then dashes out and attacks the person's ankles. Hands dangling over the armrest of a chair are also favorite targets.

To prevent further injury, the cat should wear a collar with as many bells as possible, so the owner becomes aware when the cat approaches. Some protective device or a canister of compressed air may also be effective. The cat should be distracted with the compressed air, and its behavior can then be redirected by tossing a toy. Teaching a bite and claw inhibition by immediately interrupting play as the cat gets rough is also important. Interesting toys that are rotated daily, and hiding food will keep the cat busy. A companion kitten may also help. The owner should teach the cat appropriate play by engaging it daily in play with interactive toys. They can also train their cat to obey commands and to do tricks.

52.2.7 Compulsive Behavior

In cats, examples of compulsive behavior include overgrooming (psychogenic allopecia), wool-chewing, vocalization, hallucinatory behavior, aggression to self, and many cases of the hyperesthesia syndrome. The diagnostic procedure and differentials are the same as described for dogs. Differentials for neurologic signs include FIV. Dermatologic differentials are particularly important in overgrooming cats. Skin scraping, dermatophyte culture, and trichogram are indicated. The patient should be treated for fleas and mites, undergo a food trial for 8 to 12 weeks, and undergo a trial of corticoid therapy before being treated with an anticompulsive drug.

The treatment is basically the same as in dogs. In multicat households, various core areas with food, water, a litter-box, a soft lying area, and a scratching post should be established, because social tension often contributes to stress. Cat trees allow cats to make better use of the third dimension and get out of each other's way. In some cases, an area needs to be provided where only the patient can go (e.g., electronically controlled cat door in a door). Feeding of dry food should always be ad libitum. It can be distributed around the house so that the cat is kept busy foraging for longer times. A large variety of interesting toys that are rotated may serve as an unspecific means of decreasing arousal. Particularly attractive toys such as food dispensing toys can be given at times when the performance of the compulsive behavior is likely.

Drug therapy is usually necessary as part of the treatment. Response substitution can also be used for cats. The cat is continuously supervised or placed in a situation in which it will not perform the behavior. Every time the cat is about to perform the compulsive behavior, it is distracted (startled), and then its attention reoriented by throwing a toy. If the cat is clicker trained, the same procedures as described above for dogs can be used.

53 CHAPTER • 53 Cardiorespiratory: Coughing

Kelly Anderson-Wessberg

A cough is a sudden, forceful expiration against a closed glottis. Sudden opening of the glottis and turbulent airflow create the noise identified as a cough. Coughing may occur as a conscious action or as a reflex. The coughing reflex is stimulated by mechanical or chemical irritation of the pharynx, larynx, trachea, bronchi, and smaller airways. Less commonly, disease processes involving the pleura, pericardium, diaphragm, nose, nasal sinuses, and mediastinum may also stimulate the coughing reflex.

Coughing may be the first indicator of a serious disease. On the other hand, coughing may be confused with other symptoms such as sneezing, gagging, panting, labored breathing, reverse sneezing, retching, and vomiting. The presence of a terminal retch is often misinterpreted as vomiting. Reverse sneezing has a characteristic sound with audible inspiratory and expiratory components. Failure to differentiate a cough from these other signs results in misdiagnosis and treatment failure.

The causes of coughing in small animals may be divided into the following categories (Box 53-1): inflammatory, neoplastic, cardiovascular, allergic, traumatic and physical factors, parasitic, and fungal.

53.1 DIAGNOSTIC APPROACH

53.1.1 Signalment and Historical Findings

The age and breed of the animal will influence the likelihood of certain conditions. Puppies and kittens are more likely to suffer from infectious respiratory diseases. Toy and miniature breeds such as Chihuahuas, Pomeranians, toy poodles, Yorkshire terriers, Shih Tzus, and Lhasa apsos are predisposed to collapsed trachea. Lungworm typically occurs in dogs less than 2 years of age, although it may occur in older animals. The history should focus on the general health of the pet, previous medical problems, recent diagnostics performed (heartworm testing, general blood profile, fecal examination, radiographic studies), vaccination status, heartworm prevention, exposure to other animals, and other symptoms the pet is experiencing. The history should include all recent and current medications, dosages, length of treatment, and response to each medication. Environmental history may provide important additional information. Exposure to dog parks, grooming facilities, kennels, and stray animals increases the likelihood of contagious disease. Any changes in the animal's environment should be noted along with the health of the other pets in the household. An accurate travel history should be obtained. Certain respiratory diseases are common in specific geographic areas and unlikely to occur in others. Coughing is a side effect reported in as many as 15% of human patients receiving ACE inhibitors. The cough is due to increased sensitivity of the cough reflex resulting in a dry, nonproductive cough. Increased bradykinin levels are thought to play a role. In dogs, coughing as a side effect from ACE inhibitors does not seem to be a common problem.

53.1.1.1 Box • 53-1 Causes of coughing in dogs and cats

53.1.1.1.1 Inflammatory

Pharyngitis

Tonsillitis

Tracheobronchitis

Chronic bronchitis

Bronchiectasis

Pneumonia—bacterial, viral, fungal

Granuloma

Abscess

Chronic pulmonary fibrosis

Collapsed trachea

Hilar lymph node enlargement

Secondary to esophageal dysfunction

Inhalation

Foreign body

53.1.1.1.2 Neoplastic

Primary

Mediastinal

Metastatic

Tracheal

Laryngeal

Ribs, sternum, muscle

Lymphoma

53.1.1.1.3 Cardiovascular

Left heart failure—pulmonary edema

Cardiomegaly—especially left atrium

Heart failure

Pulmonary emboli

Pulmonary edema—vascular origin

53.1.1.1.4 Allergic

Bronchial asthma

Eosinophilic pneumonitis

Eosinophilic pulmonary granulomatosis

Pulmonary infiltrate with eosinophilia (PIE)

Immune disease

Sinusitis (?)

Reverse sneeze (post nasal drip?)

53.1.1.1.5 Parasitic

Larval migration (*Toxocara* spp., *Ancylostoma caninum*, *Strongyloides stercoralis*), *Filaroides* spp. (dog), *Aelurostrongylus abstrusis* (feline lungworm), *Paragonimus kellicotti* (dog, cat), *Dirofilaria immitis* (dog, cat), *Capillaria aerophilia* (dog, cat), *Crensoma vulpis* (dog)

53.1.1.1.6 Protozoal

Toxoplasmosis (cat)

Pneumocystis (dog)

53.1.1.1.7 Fungal

Blastomycosis

Histoplasmosis

Coccidiomycosis

Cryptococcosis

Aspergillosis

53.1.2 Nature of the Cough

A description of the cough provides additional diagnostic clues. Specific questions regarding the cough should include the following: how does the cough sound, is it productive or nonproductive, what stimulates the cough, when does it occur, how often does it occur, is the cough worse at night or during the day, is it stimulated by exercise, is the timing of the cough related to eating or drinking, and does the cough respond to diuretics or other medications? Cardiac disease initially results in nocturnal coughing, but advanced cardiac disease may result in coughing during any time of day or night. Tracheal collapse typically produces a characteristic “goose-honk” sound easily recognized by most owners and experienced clinicians. Coughing due to tracheal

collapse or tracheal irritation is stimulated by excitement, drinking water, and by pulling on the collar. A productive cough may be produced by the following conditions: chronic bronchitis/bronchiectasis, pneumonia, pulmonary edema, esophageal dysfunction, and hemoptysis. A nonproductive cough may be produced by the following conditions: bronchitis, early cardiac disease, left atrial enlargement without pulmonary edema, lymphadenopathy, allergic lung disease, and tracheal irritation or collapse. These lists are not meant to be all-inclusive and some diseases may produce both types of cough. Also, some animals may be experiencing more than one disease process at a time, thus having multiple reasons for a cough.

53.1.3 Physical Examination

As with other body systems, a thorough physical examination is required for obvious reasons. Emphasis is placed on the cardiorespiratory system. Careful auscultation will reveal the presence or absence of a murmur, crackles, wheezes, rales, upper airway noises, or evidence of pleural effusion. In the presence of tracheal sensitivity or collapsing trachea, palpation of the extrathoracic trachea may stimulate the coughing response.

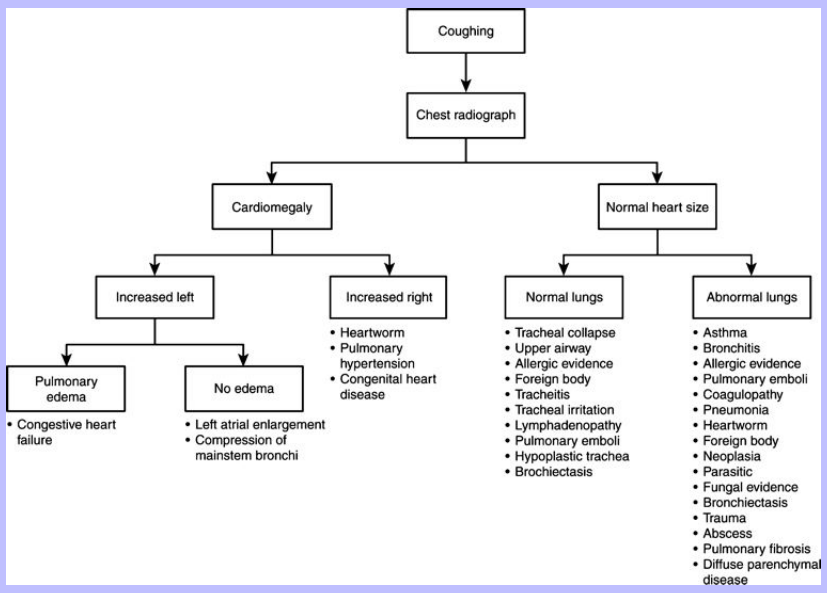
53.1.4 Radiographs

Thoracic radiographs may provide information leading to a diagnosis, but they are not necessary in every case. Radiographs should be analyzed for evidence of cardiac enlargement, pulmonary disease, pulmonary edema, and narrowing of the trachea. If pulmonary edema is identified, left heart enlargement is expected. Right heart enlargement alone does not typically result in a cough. It is important to distinguish coughing due to cardiac enlargement and coughing due to pulmonary edema. Left atrial enlargement may result in compression of the mainstem bronchi. Although some findings may be obvious, it may be impossible to distinguish between neoplasia, fungal infection, and pneumonia on radiographic examination alone. An algorithm for a general approach to interpreting thoracic radiographs in the presence of a cough is presented in Figure 53-1.

190

191

Figure 53-1 Algorithm for interpretation of thoracic radiographs in the presence of a cough.



53.1.5 Further Diagnostics

In some cases, it may be necessary to perform further diagnostics in an effort to obtain a diagnosis and proper treatment plan. A complete blood cell count, general chemistry profile, fecal examination, and heartworm test (in endemic regions) should precede further diagnostics. Descriptions of further diagnostics involving the cardiac and respiratory systems can be found elsewhere in this textbook.

53.2 TREATMENT GOALS

The ideal treatment for a cough is based on a definitive diagnosis and treatment of the underlying problem. However, it is not always possible to obtain a definitive diagnosis, and in such cases, treatment options must be based on clinical assumptions or a preliminary diagnosis. If no specific diagnosis has been made, there is no underlying problem identified, or the cough persists despite treatment of the underlying problem, the use of antitussives should be considered. Table 53-1 outlines commonly used antitussive agents. As a general rule, antitussive agents are contraindicated in cases when suppressing a cough masks important clinical symptoms or when a cough is actually encouraged as part of therapy. Specific treatment of underlying disorders can be found elsewhere in this textbook.

191

192

Table • 53-1 Drugs Commonly Used for Canine and Feline Coughing

GENERIC NAME	TRADE NAME	DOSAGE
Bronchodilator		
Aminophylline	Many names	Dog: 10 mg/kg PO, IV tid Cat: 5 mg/kg PO bid
Theophylline	Many names	Dog: 6 mg/kg PO tid
Slow release	Theo-Dur	Dog: 20 mg/kg PO bid
Slow release	Slo-bid	Dog: 25 mg/kg PO bid
Antitussive		
Hydrocodone	Hycodan, Tussigon	Dog: 0.22 mg/kg PO bid-qid
Hydrocodone/Chlorpheniramine	Tussionex	Dog: 0.5 to 1 tsp PO sid-tid
Butorphanol	Torbutrol	Dog: 0.5 mg/kg PO bid-qid
Antiinflammatory		
Prednisone		Dog: 0.5 mg/kg PO bid, then taper dose
Prednisone/trimeprazine	Temaril-P	Dog: 1 tablet/20 lbs PO bid
Expectorant/Antitussive		
Guafenesin/dextromethorphan	Robitussin-DM	Dog: Similar to adult children dosages

54 CHAPTER • 54 Dyspnea and Tachypnea

Dianne Mawby

D*yspnea* is defined as labored or difficult breathing. The human patient is likely to communicate this to the physician as "air hunger." *Respiratory distress* is a similar term. *Tachypnea* is defined as an increased rate of respiration. *Panting* is a method of heat regulation and does not imply respiratory difficulty in the dog; however, panting in the cat usually indicates stress or hyperthermia. *Orthopnea* describes the inability to breathe except in an upright position.

The pathophysiology of respiratory distress usually stems from the lack of oxygen or excess of carbon dioxide in the body. Hypercapnea and acidemia are sensed in the central respiratory center and hypoxia is sensed through the peripheral chemoreceptors located in the carotid and aortic bodies. The body tries to resolve the problem with either increased ventilatory rate or increased ventilatory depth or both.

54.1 HISTORICAL FINDINGS

History should include geography and environment, recent exposure to other animals, past illnesses, past injuries, and vaccination and heartworm preventative status. The current complaint should be addressed regarding duration, progression, previous treatment, and response to therapy. The owner can also supply information involving upper respiratory problems such as nasal discharge, sneezing, noisy breathing, abnormal breathing patterns, and recent exposure. Coughing is discussed in Chapter 53. Other relevant history includes exercise intolerance, change in appetite, and general demeanor.

54.2 CLINICAL SIGNS

Dyspnea can result from physical obstruction of the nares and upper airways. Animals with complete nasal passage obstruction breathe through the mouth, whereas patients with upper airway obstruction usually have inspiratory dyspnea. Lower airway or bronchial disease is accompanied by expiratory dyspnea because normal expiratory forces increase pressure on diseased airways. Bronchospasm and decreased luminal size due to excretions results in wheezes. Lung parenchymal disease decreases air-blood interaction resulting in dyspnea with increased ventilatory rate and depth. Gas exchange is affected by thickened alveolar-capillary membrane due to inflammatory or neoplastic cells, edema, hemorrhage, or through capillary shunting of blood through unventilated alveolar capillaries. Another cause of ventilation-perfusion mismatch is pulmonary thromboembolism (PTE), which can also result in severe dyspnea.

Pleural space expansion causes decreased lung compliance and will result in shallow tachypnea. Dyspnea can result when the capacity of the restricted lungs is further challenged, such as with exercise or stress.

Other diseases can be reflected by the respiratory system. With severe acidosis, the body attempts to restore acid-base balance by exhaling carbon dioxide. This can cause tachypnea, which may be interpreted as dyspnea. Infectious, neoplastic, vascular, or traumatic damage to the central nervous system can result in abnormal rate or rhythm of ventilation, which may be mistaken for pulmonary tachypnea or dyspnea.

54.3 PHYSICAL FINDINGS

Physical examination of the dyspneic patient can be quick and efficient but should not be pursued until the patient is stable. Oxygen supplementation using a face mask is suggested but, if not tolerated, the oxygen hose alone may

prove to be effective. However, the animal may need to recover from the stress of transport and continued stress of handling may be harmful. In these circumstances the patient should be left undisturbed in an oxygen cage.

Body condition and general appearance should be evaluated. The integument is examined for signs of trauma or tumors. Enlarged peripheral lymph nodes can indicate underlying inflammatory, infectious, or neoplastic disease. The musculoskeletal system may also give clues to the cause of respiratory distress if lameness is due to fungal infection or hypertrophic pulmonary osteoarthropathy, or if it indicates trauma (such as fractures). Cats have a propensity for metastasis of primary bronchogenic carcinoma to the digits.

The cardiovascular system is intimately associated with the respiratory system. The mucous membranes can indicate anemia, shock, or cyanosis. The heart is auscultated to evaluate arrhythmias, murmurs, or decreased intensity. Characterization of peripheral pulses indicate perfusion, pulse pressure, and cardiac arrhythmias. Abdominal palpation can reveal abnormal masses, organomegaly, or ascites, which can cause secondary respiratory problems through metastasis or physical compromise. A complete neurologic and ocular examination may reveal diseases that also affect the respiratory system.

The upper airway consists of the nasal passages, pharynx, larynx, and trachea. External nares can be stenotic from cartilage malformation and unilateral or bilateral discharge could indicate upper airway disease. The nasal cavities may not be patent as a result of obstruction with soft tissue or excessive discharge. *Stertor* describes the snoring noise that is made with partial obstruction of the nasal or nasopharyngeal area. The bridge of the nose and the hard and soft palate are examined for abnormalities that may affect the nasal passage. Masses at the back of the throat cause airway obstruction. Everted laryngeal saccules and elongated soft palate occur in the brachiocephalic complex and result in inspiratory dyspnea. The oropharynx may be visualized but examination of the larynx may require heavy sedation or anesthesia. Laryngeal paralysis can cause dyspnea, especially with exercise, excitement/stress, or hyperthermia. The inspiratory dyspnea resulting from upper airway obstruction causes a harsh, high-pitched sound on inspiration, which is called *stridor* (Figure 54-1). Tracheal collapse may cause coughing and may progress to obstruction. The collapse may be in the cervical or intrathoracic trachea and may also involve mainstem bronchi. The characteristic “goose-honk” cough usually historically precedes complete airway collapse.

The lower respiratory tract is examined by observing breathing patterns, palpation, percussion, and auscultation. Breathing patterns may help localize the problem. The obstructive pattern usually has increased rate and depth. Upper airway obstruction results in difficulty with inspiration and lower airway obstruction causes expiratory difficulty. Mixed patterns of increased inspiratory and expiratory effort can occur. Restrictive breathing pattern implies decreased lung compliance, which results in decreased depth and increased rate such as with pleural effusion.

Palpation of the thorax can reveal masses or trauma such as rib fractures. Young cats have an easily compressible thorax, which can be compromised by mediastinal masses or pleural effusion. Feline bronchitis can obstruct outflow of air from the lower airways resulting in a barrel-chested appearance over time.

Percussion of the thoracic wall can help localize areas of increased or decreased resonance. Pneumothorax results in increased resonance on percussion and decreased lung sounds with auscultation. A fluid line may be percussed with pleural effusion when the animal is standing or in sternal recumbency. Fluid or hernias cause decreased resonance with percussion and muffled heart and lung sounds with auscultation.

Normal respiratory sounds with auscultation are termed *bronchovesicular* and are produced by tissue vibration and air movement. Increased bronchovesicular sounds result from increased air flow or turbulence. Upper airway noises can be referred to the thorax due to the direction of air flow; therefore purring, stertor, and stridor can be

ausculted in the chest and must be distinguished as such. Abnormal lower airway sounds are termed *continuous* or *discontinuous*. Continuous sounds include rhonchi and wheezes that result from partial obstruction of airways from bronchoconstriction or secretions. Discontinuous sounds usually occur during inspiration and are referred to as *crackles* or *rales*. These sounds result from the opening of alveoli and small airways that are otherwise collapsed or partially filled with fluid. Absence of respiratory sounds may indicate pleural effusions, pneumothorax, diaphragmatic hernia, or masses.

54.4 DIAGNOSTIC AND THERAPEUTIC PLAN

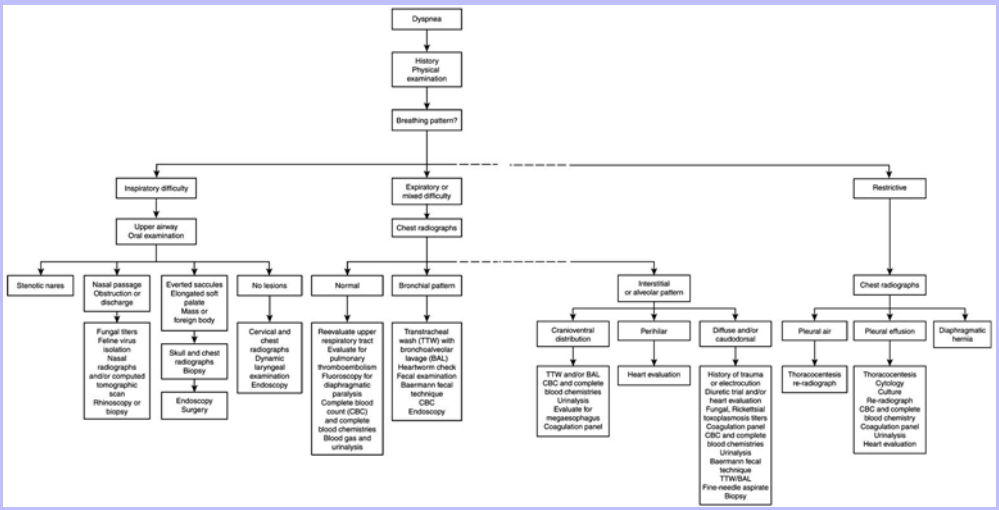
To increase oxygen delivery to the dyspneic patient, either mask, nasal tubing, or oxygen cage can be used. Oxygen concentration of 100% can only be tolerated for a few hours before toxicity develops; therefore long-term therapy is usually limited to 40% oxygen. If the animal is dyspneic, cyanotic, and frantic, sedation is essential. Control of upper airway problems may require general anesthesia and placement of an endotracheal tube, during which any obstruction can be visualized and bypassed. If the problem is identified and not readily resolved, a tracheostomy can be performed as a short-or long-term solution.

If the dyspnea is of a mixed or expiratory pattern, then evaluation for lower airway or parenchymal disease is indicated. Crackles heard with auscultation indicate edema or exudate. Wheezes can indicate lower airway disease. Blood can be obtained from the stable patient to determine blood gases and to evaluate for anemia, thrombocytopenia, coagulopathy, and metabolic or infectious causes of disease. A pulse oximeter reading may provide information on hemoglobin saturation. Radiology is an important diagnostic tool for prioritization of differential diagnoses of parenchymal disease, if it can be done without excessive stress. Diuretics are indicated for pulmonary edema. Cardiogenic edema may need to be initially managed with a diuretic plus a venodilator such as topical nitroglycerin. Bronchodilators are used for lower airway and parenchymal disease to increase airflow. If indicated and the patient is stable, transtracheal wash or bronchoalveolar lavage may provide diagnostic information. Fine needle aspiration of diseased lung parenchyma can also be done if inflammatory, infectious, or neoplastic etiologies are suspected. This procedure and complications of FNA are described elsewhere in this text. If an inflammatory process is suspected, corticosteroids are indicated after diagnostic samples are obtained. This may not always be possible with a severely dyspneic animal.

193

194

Figure 54-1 Algorithm for inspiratory stridor.



Pulmonary thromboembolism (PTE) patients can be severely dyspneic and have normal radiographs. Definitive diagnosis of PTE involves selective angiography or nuclear medicine scans. Supportive care with efforts directed towards resolution of the underlying disease is the best treatment for PTE. Patients with severe parenchymal disease may benefit from mechanical ventilation, which requires general anesthesia.

Thoracic imaging is useful in identification of problems of the pleural space, but thoracocentesis may be needed first for therapeutic and diagnostic purposes. If air or fluid is obtained, evacuation of the pleural space will resolve the dyspnea and allow radiologic examination for underlying disease. If a diaphragmatic hernia is present, then surgery is necessary for complete resolution.

55 CHAPTER • 55 Abnormal Heart Sounds and Heart Murmurs

Robert Prošek

Cardiac auscultation is an important tool in the clinician's armamentarium. Interpretation of heart and lung sounds is predicated on the clinician's understanding of their genesis in health and a variety of clinical disorders. Cardiovascular sounds of short duration are referred to as *transient heart sounds* and include the normally heard first heart sound (S_1) and second heart sound (S_2). Heart murmurs are auditory vibrations of longer duration created when laminar flow is disrupted.

Implementing good technique with a quality stethoscope is fundamental. During auscultation the animal should be standing or sitting in a quiet environment. Both sides of the thorax should be carefully auscultated with the stethoscope's diaphragm and bell with special attention to the areas overlying the cardiac valves. The clinician should correlate the various heart sounds to the events of the cardiac cycle. A good orientation is the palpation of the precordial impulse (left apex beat) that occurs just after S_1, and the arterial pulse that is felt between S_1 and S_2.

55.1 TRANSIENT HEART SOUNDS

55.1.1 The First (S_1) and Second (S_2) Heart Sounds

The first heart sound is associated with closure and tensing of the atrioventricular valves (mitral and tricuspid) at the onset of systole coinciding with the QRS complex on the electrocardiogram. S_1 is longer, louder, and lower pitched than the second heart sound. Causes of increased intensity of S_1 include thin chest wall, tachycardia, high sympathetic tone, systemic arterial hypertension, and anemia. Diminished intensity of S_1 may be auscultated in animals with obesity, pleural or pericardial effusion, diaphragmatic hernia, dilated cardiomyopathy, hypovolemia, emphysema, or a prolonged P-R interval. Splitting of S_1 is occasionally auscultated at the cardiac apex in healthy, large breed dogs or may result from electrical disturbances (ectopic beats, bundle branch blocks, cardiac pacing) or mechanical factors (tricuspid or mitral stenosis).

The second heart sound is associated with closure of the semilunar valves (aortic and pulmonic) at the end of systole following the T wave on the electrocardiogram. In dogs and cats, pulmonic valve (P_2) closure follows aortic valve (A_2) closure by a very short interval, which causes S_2 to be heard as a single sound. On occasion an audible split second heart sound may be seen in healthy, large breed dogs during inspiration due to a longer right ventricular ejection period. Pathologic splitting of S_2 due to delayed closure of the pulmonic valve is most commonly auscultated in dogs with pulmonary hypertension as occurs with heartworm disease and right-to-left patent ductus arteriosus. Delayed closure of P_2 also occurs with left-to-right intracardiac shunts (atrial septal defects), pulmonic stenosis, right bundle branch block, ectopic beats, and ventricular pacing. Premature A_2 closure can on occasion be noted with mitral insufficiency and mitral stenosis. Paradoxic splitting of S_2 results from delayed closure of the aortic valve and is sometimes audible in dogs with aortic stenosis, left bundle branch block, ectopic beats, and systemic hypertension.

55.1.2 The Third (S_3) and Fourth (S_4) Heart Sounds

The third and fourth heart sounds occur during diastole and are not audible in normal dogs and cats. S_3 and S_4 heart sounds are of lower frequency than S_1 and S_2 and are usually best heard with the bell of the stethoscope. When heard, S_3 or S_4 may sound like the triple cadence of a galloping horse. The term *gallop rhythm* should probably be avoided because the presence of an audible S_3 or S_4 has nothing to do with the heart's underlying electrical rhythm.

Rapid ventricular filling generates the S_3 sound, also known as *S_3 gallop*, *protodiastolic gallop,* or *ventricular gallop*. An audible S_3 is most commonly heard with diastolic volume overloading as in dilated cardiomyopathy, patent ductus arteriosus, and mitral insufficiency. In dogs with mitral insufficiency, the S_3 gallop may be mistaken for the second heart sound if a loud pansystolic murmur extends through the second heart sound. Protodiastolic gallop sounds in cats are most commonly associated with dilated cardiomyopathy, anemia, and hyperthyroidism.

The presystolic gallop, also called *S_4 gallop* or *atrial gallop,* is heard just before S_1 and occurs just after the P wave on the electrocardiogram. This low-frequency sound is generated by blood flow into the ventricles during atrial contraction; hence the absence of S_4 gallops with atrial fibrillation. An audible S_4 in the cat and dog is usually associated with increased ventricular hypertrophy and stiffness and is sometimes audible in animals with third-degree atrioventricular block.

At fast heart rates, rapid ventricular filling and atrial systole transpire very close together, which makes differentiation between S_3 and S_4 impossible. The resulting single accentuated sound is referred to as a *summation gallop*.

55.1.3 Ejection Sounds, Systolic Clicks, Opening Snaps, and Pericardial Knocks

Ejection sounds are left basilar high-frequency sounds generated by opening of the semilunar valves or dilatation of the great vessels during early systole. These sounds are occasionally noted in pulmonic stenosis, aortic stenosis, tetralogy of Fallot, and heartworm disease. Systolic clicks are mid to late high-frequency sounds usually heard best over the mitral valve area. Systolic clicks are occasionally associated with degenerative valvular disease, mitral valve prolapse, and mitral dysplasia. The genesis of the sound in dogs is uncertain but is likely caused by the sudden tensing of redundant valve leaflets or elongated chordae tendineae as they buckle into the left atrium. A systolic click should be differentiated from a split or gallop heart sound. Pericardial knocks are uncommon early diastolic sounds caused by restrictive pericardial disease. Timing of the sound is similar to S_3 and appears to be generated by abrupt restriction to ventricular filling by a diseased pericardium. (See Figure 55-1 for timing of transient heart sounds and description of murmurs.)

55.2 CARDIAC MURMURS

Cardiac murmurs represent sounds of longer duration than the transient heart sounds. Cardiac murmurs are caused by turbulent blood flow in the heart or adjacent blood vessels created upon disruption of normal laminar flow. The development of turbulent blood flow can be created by high-velocity flow, flow from narrow restricted area into a larger area, or low blood viscosity. The relationship of cardiac murmurs with flow velocity, vessel size, and blood

viscosity is defined by the Reynold's number. When the number reaches a critical high level, blood flow becomes turbulent.

$$\text{Reynold's number} = \frac{(\text{Radius})\ (\text{Velocity})\ (\text{Density})}{\text{Viscosity}}$$

Murmurs can be characterized and described by their timing within the cardiac cycle (systolic, diastolic, portions thereof), location (point of maximal intensity), radiation, intensity (loudness), shape, and frequency (pitch).

55.2.1 Timing

Systolic murmurs may start immediately at the first (S_1) heart sound and last through the second (S_2) heart sound (pansystolic murmur), may start immediately after S_1 and last until S_2 (holosystolic), or may occur in early (protosystolic), mid (mesosystolic), or late (telesystolic) systole. Diastolic murmurs most commonly occur in early diastole (protodiastolic), throughout diastole (holodiastolic), or can occasionally be audible only at the end of diastole (presystolic).

55.2.2 Location and Radiation

The location of a murmur refers to the valve area at which the murmur is heard best (point of maximal intensity). Alternatively, location can be described simply by the terms *apex* or *base* (e.g., left apex or mitral valve area). Some murmurs may also radiate to other areas, yielding important clues as to the source of the murmur. For example, the murmur of subvalvular aortic stenosis (PMI at left heart base) may radiate to the ventral neck area due to turbulence in the carotid arteries and may also be heard on the right cranial thorax.

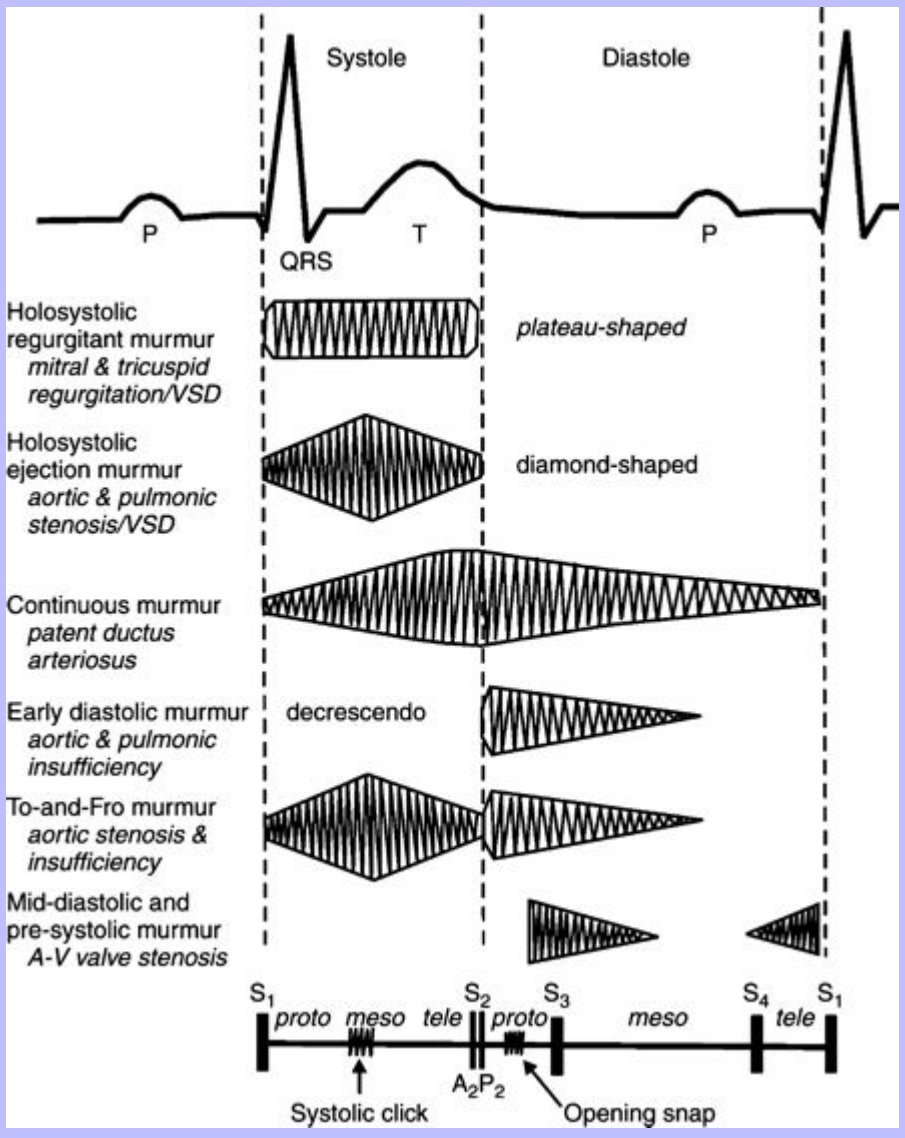
55.2.3 Intensity (Loudness)

The intensity of the murmur is commonly graded on a 1 to 6 scale, with grade 1 murmur the softest and grade 6 the loudest (Box 55-1). A grade 1 murmur is the faintest murmur and is heard in a quiet environment with particular effort, whereas grade 5 and 6 murmurs are associated with palpable vibrations on the chest wall (palpable thrill). The intensity of the murmur at its origin is determined by blood flow velocity and the rate of flow (velocity × flow = force). The intensity of the murmur at the body surface is affected by direction of the turbulent jet, character of tissue between auscultation area and the turbulent jet, and the frequency of the murmur. Often the intensity of a heart murmur is not directly correlated with the severity of a lesion. However, describing the loudness of a murmur is important for serial examinations, and in certain heart diseases at least a rough correlation exists.

196

197

Figure 55-1 Murmur shapes and descriptions with some common examples. Also depicted are normal and abnormal transient heart sounds and their location within the cardiac cycle. *Proto,* Early; *meso,* mid; *tele,* late; A_2, aortic valve closure; P_2, pulmonic valve closure; S_1, first heart sound; S_2, second heart sound; S_3, third heart sound; S_4, fourth heart sound.



55.2.4 Pitch (Frequency)

A murmur's quality and pitch relate to its frequency components, which may be high, medium, low, or of mixed frequency. Most murmurs consist of midrange mixed-frequency sounds. On occasion high-frequency musical tones or low-frequency “honks” are auscultated. Musical murmurs are most commonly identified in dogs with modest mitral valve disease.

55.2.5 Shape

Heart murmurs are often described by their frequency profile within the cardiac cycle in relation to their shape on a phonocardiogram. Terms that are commonly used include *plateau-* or *band-shaped murmurs* for those murmurs of equal intensity throughout their duration; decrescendo for murmurs that gradually taper off from an initial peak; and crescendo decrescendo (diamond-shaped, ejection murmur) for murmurs that build up to a peak intensity and then taper in intensity.

55.3 SYSTOLIC HEART MURMURS

55.3.1 Mitral Insufficiency

The murmur of mitral insufficiency is best heard at the left apex (mitral valve area) and commonly radiates dorsally and to the right thorax making reliable diagnosis of tricuspid regurgitation difficult. The characteristic murmur is plateau (band-shaped) and holosystolic; however, in its early stages the murmur may develop in mid-to late-systole. Mitral insufficiency murmur is typically of mixed frequency and harsh sounding, but it may be high-pitched or musical (whooping) in quality. Mitral insufficiency can be caused by chronic degenerative valvular disease (endocardiosis), endocarditis, hypertrophic obstructive cardiomyopathy, congenital malformations, and diseases that cause left heart enlargement and dilation of the mitral annulus (e.g., patent ductus arteriosus, dilated cardiomyopathy).

197 198

55.3.1.1 Box • 55-1 Grading of Cardiac Murmurs

55.3.1.1.1 Grade 1

Very soft, localized murmur detected in a quiet room after intently listening for a few minutes

55.3.1.1.2 Grade 2

Soft murmur but easily heard after a few seconds

55.3.1.1.3 Grade 3

Moderate intensity murmur

55.3.1.1.4 Grade 4

Loud murmur but not accompanied by a palpable thrill (vibration)

55.3.1.1.5 Grade 5

Loud murmur accompanied by a palpable thrill

55.3.1.1.6 Grade 6

Very loud murmur that produces a palpable thrill still audible after stethoscope is removed from the chest

55.3.2 Tricuspid Insufficiency

The murmur of tricuspid insufficiency sounds similar to that of mitral insufficiency but is loudest over the right apex (tricuspid valve area). It is often difficult to distinguish tricuspid insufficiency from a radiating murmur of mitral insufficiency. Tricuspid murmurs might be a different pitch compared with a radiating mitral murmur and can be accompanied by jugular pulsations. Tricuspid insufficiency can result from congenital malformations of the valve, chronic degenerative valve disease, or any disorders that cause marked right heart enlargement and valve annulus distention, such as pulmonary hypertension, and arrhythmogenic right ventricular cardiomyopathy). Tricuspid valve endocarditis is extremely rare in dogs and cats.

55.3.3 Aortic Stenosis

Valvular and subvalvular aortic stenosis (SAS) produce a systolic ejection (crescendo-decrescendo) murmur that is usually best heard at the left heart base. The murmur is usually of mixed frequency and harsh, and it sometimes radiates towards the right cranial thorax and up the neck along the carotid arteries. Mild obstructions cause soft murmurs that are difficult to distinguish from innocent or functional murmurs. Murmurs that vary dramatically in intensity with exercise or excitement should prompt consideration of a dynamic left ventricular outflow tract obstruction. Dynamic outflow tract obstruction is the most common type of ejection murmurs in cats with hypertrophic cardiomyopathy and its onset and duration coincide with systolic anterior motion of the mitral valve. Dynamic left ventricular outflow tract obstruction occurs uncommonly in dogs as an isolated abnormality or in association with mitral valve dysplasia or hypertrophy of interventricular septum.

55.3.4 Pulmonic Stenosis

Pulmonic stenosis murmur is typically a high-frequency crescendo-decrescendo (ejection) holosystolic murmur, best heard at the left heart base over the pulmonic valve. The murmur can be very similar to aortic stenosis murmur described above but should not radiate along the carotid arteries. As the pressure gradient between the right ventricle and pulmonary artery increases, the murmur intensity becomes louder and peaks later in systole.

55.3.5 Ventricular Septal Defect

Ventricular septal defects (VSDs) produce murmurs that vary tremendously in shape and quality. Most often the murmur is a harsh, mid-to high-frequency holosystolic murmur best heard on the right cranial thorax. Murmur intensity may be reduced when the VSD is large and as pulmonary hypertension develops. With severe pulmonary hypertension, the murmur may be entirely absent and splitting of the second heart sound is noted.

55.3.6 Atrial Septal Defect

Heart murmurs in dogs and cats with an atrial septal defect (ASD) result from increased flow across the pulmonic valve as a result of the left to right shunting. This murmur resembles that of mild pulmonic stenosis but is often accompanied by a fixed splitting of the second heart sound. Flow across the atrial septal defect is usually not audible.

55.3.7 Physiologic and Innocent Murmurs

Functional (physiologic) murmurs are usually caused by decreased blood viscosity or increased cardiac output. Physiologic murmurs are most often noted in animals with anemia, fever, pregnancy, hyperthyroidism, and increased sympathetic tone. These murmurs usually are proto to mesosystolic, soft to moderate intensity (grade 1/6 to 3/6), and loudest at the left heart base. They tend not to radiate extensively.

Innocent murmurs should disappear as the dog matures and appear to be the result of larger stroke volumes in puppies for the size of their great vessels in comparison with adult dogs. In some cats, turbulent blood flow can be noted in the region of the right ventricular outflow tract, often causing a soft systolic apical sternal murmur ranging in grades from 1 to 3/6, with no evidence of structural heart disease and little clinical consequence.

55.4 DIASTOLIC HEART MURMURS

55.4.1 Aortic Insufficiency

The murmur of isolated aortic insufficiency is typically a decrescendo murmur starting at the time of S_2 and extending variably into diastole. In young dogs, aortic insufficiency can occur as an isolated defect or in combination with subaortic stenosis or a ventricular septal defect. Detection of aortic insufficiency in an adult dog or cat should prompt consideration of bacterial endocarditis.

When the regurgitant volume is large, the diastolic murmur is often accompanied by a soft mesosystolic ejection murmur, creating a distinct *"to-and-fro"* murmur. The systolic ejection component tapers off in late systole and allows recognition of S_2 and differentiation from a continuous murmur. Other causes of "to-and-fro" murmurs include ventricular septal defects that cause loss of aortic root support and pulmonic valve stenosis and significant pulmonic insufficiency (rare). Occasionally massive aortic regurgitation causes premature closure of the mitral valve producing functional mitral stenosis and a diastolic murmur referred to as an *Austin Flint murmur*.

55.4.2 Pulmonic Insufficiency

The murmur of pulmonic insufficiency is similar to that of aortic insufficiency; however, clinically significant pulmonic insufficiency is uncommon. It is sometimes detected in animals with pulmonary hypertension, pulmonic valve dysplasia, or idiopathic dilation of the pulmonary artery.

55.4.3 Mitral Stenosis

The diastolic murmur of mitral stenosis is difficult to recognize in dogs and cats. This low-frequency murmur begins in mesodiastole and has presystolic accentuation due to atrial contraction. Mitral stenosis might be

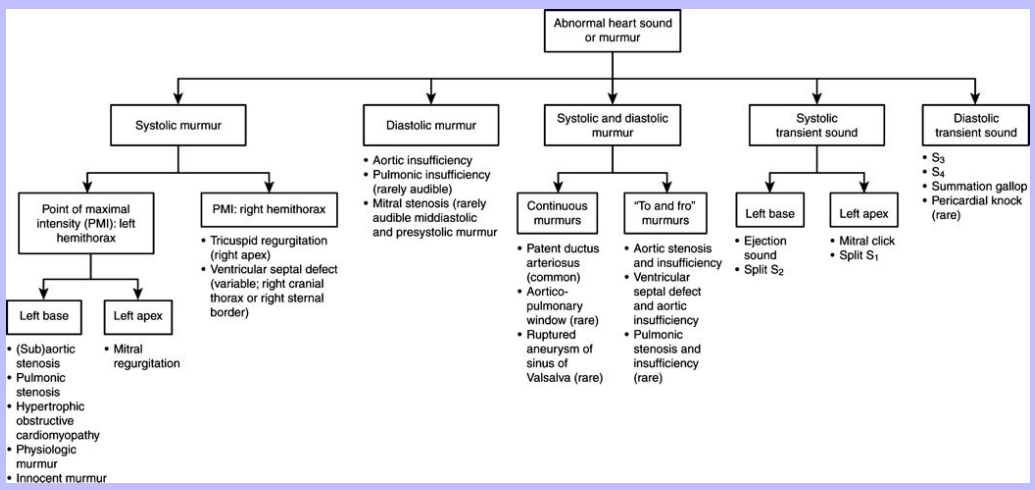
accompanied by other cardiac malformations, which causes murmurs such as valvular or subvalvular aortic stenosis. In dogs, mitral stenosis may be more common in breeds that are prone to congenital mitral valve malformations such as the bull terrier breed, in which it is often associated with aortic stenosis.

55.5 CONTINUOUS MURMURS

The most common cause of a continuous murmur at the left heart base is patent ductus arteriosus (PDA). This classic "machinery-like" murmur of a PDA is usually audible throughout the cardiac cycle with peak intensity near S_2. The intensity of the murmur is diminished in late diastole in dogs with very slow heart rates and the diastolic component can also disappear with the development of pulmonary hypertension. Less common causes of continuous murmurs include aorticopulmonary windows, ruptured aneurysms of sinus of Valsalva, and coronary arteriovenous fistulas.

198 200

Figure 55-2 Algorithm for differentiating causes of abnormal heart sounds and murmurs. *PMI,* Point of maximal intensity; *PDA,* patent ductus arteriosus; *AP,* aorticopulmonary.



55.6 AUSCULTATION AND BEYOND

Historical findings may suggest underlying heart disease; however, a thorough auscultation with identification and understanding of abnormal heart sounds and their genesis will permit recognition of the most likely cause (see Figure 55-2). As important a tool as cardiac auscultation is, it should be one part of a complete physical exam that integrates evaluation of lung fields, jugular veins, arterial pulses, and peripheral circulation. Increasingly the affordability and availability of next generation electronic stethoscopes will allow the clinician to pick up difficult-to-hear heart sounds and other body sounds.

Additionally, other diagnostic tests might be needed to further classify and define the animal's abnormality, and in some cases differentiate a pathologic from a physiologic murmur (especially cats).

56 CHAPTER • 56 Pulse Alterations

Richard Kienle

Assessment of arterial and venous pulse characteristics is an integral component of the physical examination. However, the findings from these exams should not be used in isolation but integrated with findings from other exams and diagnostic tests. Arterial pulse qualities (rate, rhythm, symmetry, and strength) provide important information regarding the status of the cardiovascular system, specifically cardiac output and perfusion. Evaluation of venous pulse qualities (distention or pulsation) provides insight regarding right-sided cardiac pressures and the status of venous return. Abnormalities of arterial and/or venous pulse characteristics may be present in any cardiovascular disease state and may also be present in other systemic and metabolic states that affect cardiac output and systemic pressure or venous return. Detection of these changes often facilitates selection of additional diagnostics and allows for monitoring of patient status and response to therapy. The clinician should be familiar with the common abnormalities detected and their significance (Figure 56-1).

56.1 THE ARTERIAL PULSE

56.1.1 Genesis of the Arterial Pulse

Systolic arterial blood flow and pressure are generated by the contractile force of the left ventricle and to a lesser extent by elastic recoil of the aorta. During systole, aortic pressure rises rapidly as left ventricular pressure exceeds aortic pressure and ventricular ejection begins. Later in systole, as ventricular pressure declines and the blood flows into the distal vasculature, aortic pressure decreases. During ventricular diastole, when left ventricular pressure drops below aortic pressure and the aortic valve closes, diastolic blood pressure is maintained by elastic recoil of the aorta. Diastolic blood pressure gradually decreases as elastic recoil is consumed and blood continues to flow distally.

56.1.2 Assessment of the Arterial Pulse

The femoral pulse should be evaluated carefully in every patient (Figure 56-2). This evaluation is performed preferably with the patient standing but may also be done in recumbent patients. The femoral arteries should be palpated high on the limb so that the artery is palpated within or just below the femoral triangle, where the least amount of fat and muscle overlie the artery. The index finger, the middle finger, or both should be placed over the artery lightly to start. Digital pressure should then be applied with sufficient strength to occlude arterial flow so that no pulsation directly beneath the fingers is identified. Digital pressure should then be gradually decreased until the maximum pulsation is felt. The maximum pulsation occurs when digital pressure is equal to mean arterial blood pressure.

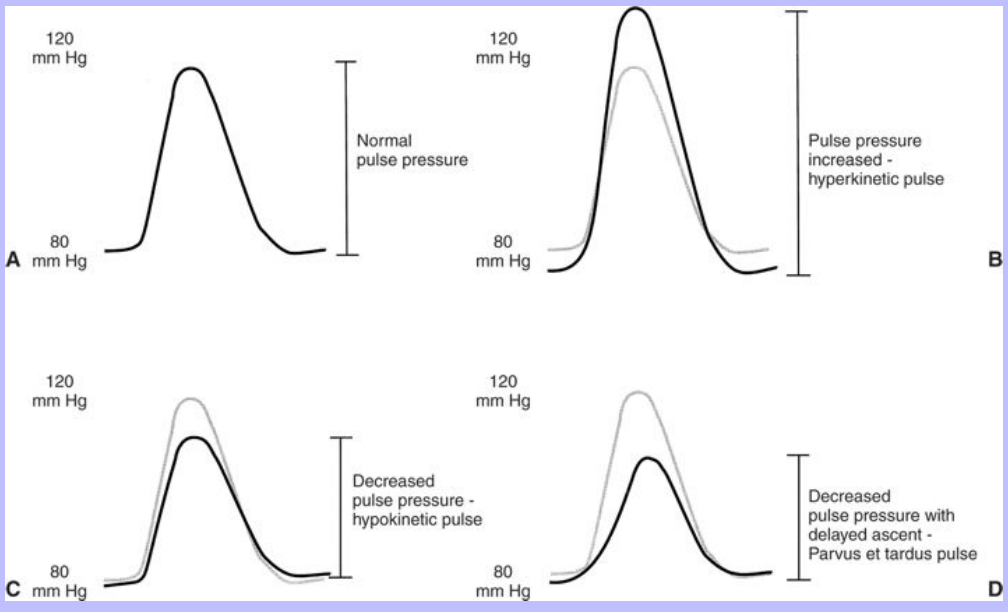
The intensity of the peripheral arterial pulse is determined by the difference between the systolic blood pressure and the diastolic blood pressure, termed the *pulse pressure*. Consequently, absolute blood pressure cannot be determined by digital palpation of artery. In addition to pulse pressure, body condition affects the perceived strength of the arterial pulse. Arterial pulses are usually more prominent in thin animals, whereas they may be difficult to palpate in obese animals. The clinician should take into account the animal's body condition when pulse strength is assessed.

56.1.3 Arterial Pulse Alterations

Pulse pressure can be decreased or increased or it can have an altered configuration (see Figure 56-1). Three physiologic factors are important in determining arterial pulse pressure: (1) heart rate, (2) stroke volume, and (3) peripheral vascular resistance. An increase in heart rate may result in a mild increase in diastolic arterial pressure, as there is less time for diastolic pressure to decline. This will result in a decrease in pulse pressure and an increase in mean arterial pressure generally leading to what is perceived as a weak peripheral pulse. Bradycardias, on the other hand, may lead to excessive run off during diastole as well as a greater strength of contraction due to greater diastolic filling, leading to a stronger than normal pulse.

A decrease in pulse pressure can occur if stroke volume is decreased, as in patients with heart failure or hypovolemia. This is termed a *hypokinetic* pulse. In most patients with a decreased stroke volume, arterial resistance increases and arterial compliance decreases to keep systemic blood pressure within the normal range. Patients with a decreased stroke volume commonly have normal pulses until the stroke volume becomes markedly reduced.

Figure 56-1 Schematic illustration of femoral artery pulse contours. **A,** Normal pulse. There is a rapid rise in pressure followed by a more gradual descent to diastolic pressure. The pulse pressure is indicated by the bar. **B,** Hyperkinetic pulse. Elevation in systolic pressure and decrease in diastolic pressure have widened the pulse pressure, resulting in a strong or hyperkinetic pulse. **C,** Hypokinetic pulse. Pulse pressure is reduced because of decreased systolic pressure. **D,** Parvus et tardus pulse. This is a type of hypokinetic pulse characterized by a slow ascent and is typical for subaortic stenosis.



Pulse pressure may also decrease if peripheral vascular resistance (PVR) is decreased or if arterial compliance is increased. Peripheral vascular resistance is a function of vessel tone and arterial wall compliance. When PVR is increased, there is an increase in diastolic blood pressure and a corresponding decrease in pulse pressure. PVR is increased in older animals as a result of loss of arterial wall compliance and in some animals with heart failure.

An increase in pulse pressure, known as a *hyperkinetic* pulse, can occur because of an increase in systolic blood pressure, a decrease in diastolic blood pressure, or both. In cardiovascular disease, an increase in systolic blood pressure is usually caused by an increase in stroke volume. A decrease in diastolic blood pressure is usually due to excessive runoff of blood into some other portion of the cardiovascular system during diastole. Consequently, dogs with shunting lesions such as a patent ductus arteriousus or dogs with aortic insufficiency commonly have a significant increase in pulse pressure, leading to a "bounding" pulse. Bounding pulses can also be felt in patients with arteriovenous fistula, severe bradycardia, thyrotoxicosis, fever, and anemia.

Alterations in pulse conformation may also occur. Dogs with severe subaortic stenosis may have a "weak" pulse or may have a pulse pressure that increases more slowly and peaks later during systole (pulsus parvus et tardus) (see Figure 56-1). This occurs because the velocity of shortening and the ejection time may be longer in severe subaortic stenosis. Dogs with mitral regurgitation, conversely, commonly have a brisk pulse that rises more rapidly in systole and lasts a shorter time because the left ventricle ejects blood at a higher velocity and the ejection time is shorter.

Other pulse abnormalities include pulsus paradoxus, pulse deficits, and pulsus alternans. Pulsus paradoxus is an increase in pulse pressure on expiration and a decrease on inspiration. This occurs normally but is exaggerated in pericardial tamponade. Pulse deficits occur with cardiac tachyarrhythmias in which beats occur so rapidly that the ventricle does not have time to fill enough to result in ejection of blood. Pulsus alternans is alternating strong and weak pulses and is rare. In patients with atrial fibrillation, pulse pressure alternates erratically and pulse deficits are also present.

Systemic thromboembolism, a complication of feline cardiomyopathy, is often characterized by a complete loss of arterial pulsations of the femoral arteries. Systemic thromboembolism may also occur in dogs and cats secondary to hypercoagulable sates such as renal amyloidosis, hyperadrenocorticism, and infective endocarditis.

56.2 VENOUS PULSES

Jugular venous pressures correlate with right atrial and ventricular pressures. Because the tricuspid valve is open in diastole and because the tricuspid valve annulus provides very little resistance, right ventricular diastolic pressure and right atrial pressures are approximately equal. Whatever pressure is present in the right atrium is also present in the systemic veins that are at the same height as the right atrium. The pressure in the vessels higher than the RA will have lesser pressure and the veins will be less distended. Because of this, as right atrial pressure increases, the jugular veins become distended farther and farther up the neck.

Figure 56-2 Algorithm for arterial pulse evaluation.

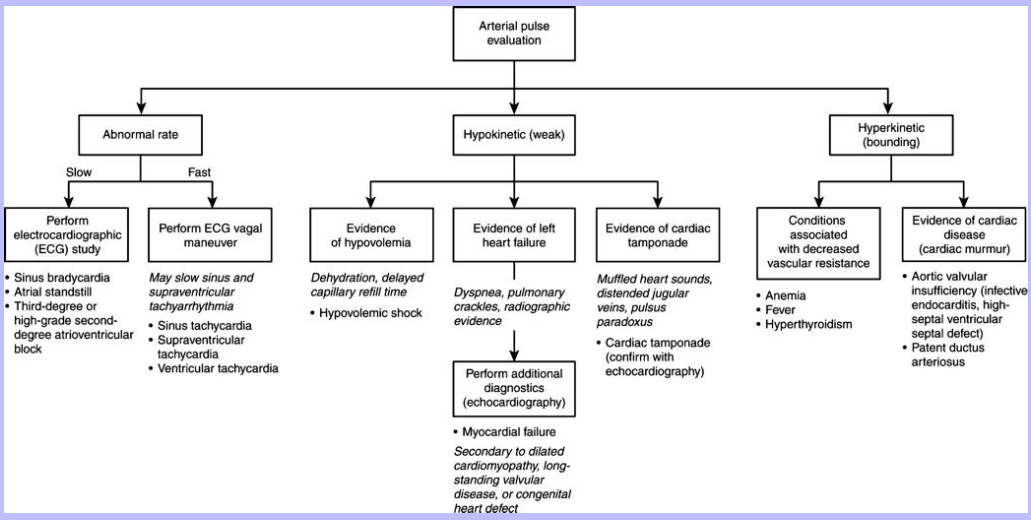


Figure 56-3 Algorithm for venous pulse evaluation.

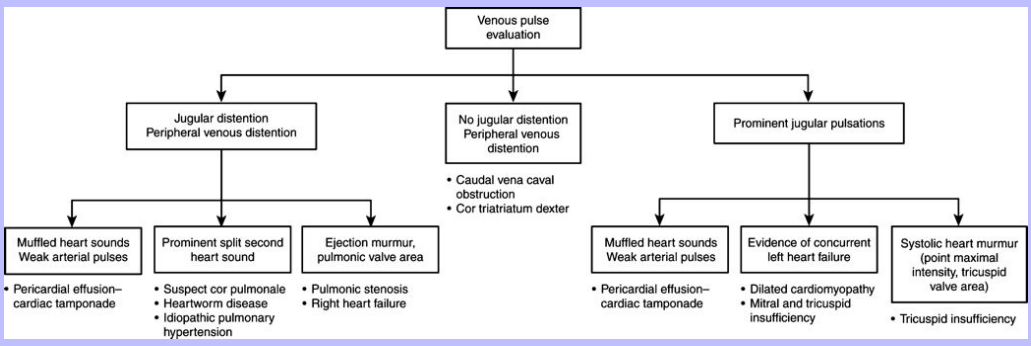


56.2.1 Components of the Normal Venous Pulse

When jugular waveforms are analyzed, several components can be detected. The most prominent deflection is the A wave corresponding to right atrial contraction. During right atrial relaxation, a slight dip in pressure is noted (Z point). Immediately following the Z point, a second wave (C wave) corresponding to right ventricular isovolumetric contraction occurs. This wave is produced by bulging of the tricuspid valve into the right atrium and transmission of this pressure into the jugular veins. During right ventricular ejection, the tricuspid valve is displaced downward producing a prominent negative deflection, the X descent. Late in systole, a third positive deflection, the V wave, occurs resulting from increased blood volume and pressure within the right atrium. Immediately following the V wave, right atrial emptying occurs as a result of relaxation of the right ventricle producing a second prominent dip in jugular venous pressure, the Y descent.

56.2.2 Assessment of the Venous (Jugular) Pulse

The jugular veins should be examined carefully in any case suspected of having cardiac disease (Figure 56-3). Neck hair may need to be clipped or wetted to identify the jugular veins in dogs and cats with thick or long neck hair (see Figure 56-3). A jugular vein should be initially identified with the animal in a sitting or standing position with the head moderately extended. In a normal animal the vein should be distended by placement of enough pressure at the thoracic inlet to occlude jugular vein flow, which results in jugular vein distension. Thoracic inlet pressure should then be released and the vein observed to determine the rate of vein collapse. In normal animals, jugular pulsations should not extend more than one third the distance up the neck from the thoracic inlet. Pulsations from the underlying carotid arteries may mimic jugular venous pulsations. If pulsations continue despite occlusion of jugular vein, they are arterial in origin. In an animal with cardiac disease, the vein may be distended or pulsating, in which case the vein should be observed with-out occlusion. More subtle jugular vein alterations may be detected by performing the hepatojugular or abdominojugular reflux test. This test is performed by application of sustained pressure to the abdomen with one or both hands for 30 to 60 seconds during observation of the jugular veins. This technique results in increased venous return (increased right ventricular preload), which in the presence of underlying right heart disease will elevate right atrial pressure and impede jugular venous return, which leads to distention or pulsation of the jugular veins. This technique is generally accepted as a test for detecting right heart failure. Most likely this test is an indication of increased blood volume in the peripheral venous system and can be positive with either left or right heart failure.

56.3 VENOUS (JUGULAR) PULSE ALTERATIONS

Distended jugular veins indicate increased systemic venous pressure or occlusion of the venous system between the jugular veins and the right heart. An increase in systemic venous pressure is most commonly secondary to an increase in right ventricular diastolic pressure.

Jugular vein pulsation may also be observed. Jugular vein pulsation may be due to exaggerated “a” waves, cannon “a” waves, or prominent “v” waves. Exaggerated “a” waves may occur secondary to decreased right ventricular compliance. A decrease in right ventricular compliance may occur with such conditions as right ventricular hypertrophy, restrictive right ventricular disease, and constrictive pericarditis. The deceased right ventricular compliance must be severe to result in jugular vein pulsations and a severe decrease in right ventricular compliance generally results in an overall increase in right ventricular diastolic pressure with resultant jugular vein distension. Cannon “a” waves may occur with A-V dissociation when the atria contract against a closed tricuspid valve, as in third degree A-V block. Prominent “v” waves occur secondary to tricuspid regurgitation. The “v” wave occurs during ventricular systole and is increased in tricuspid regurgitation when the atrial volume is increased by the regurgitation of blood into the right atrium. Patients with overt right heart failure from any cause may have obviously distended jugular veins.

57 CHAPTER • 57 Pleural Effusion

O. Lynne Nelson

57.1 DEFINITION OF PLEURAL EFFUSION

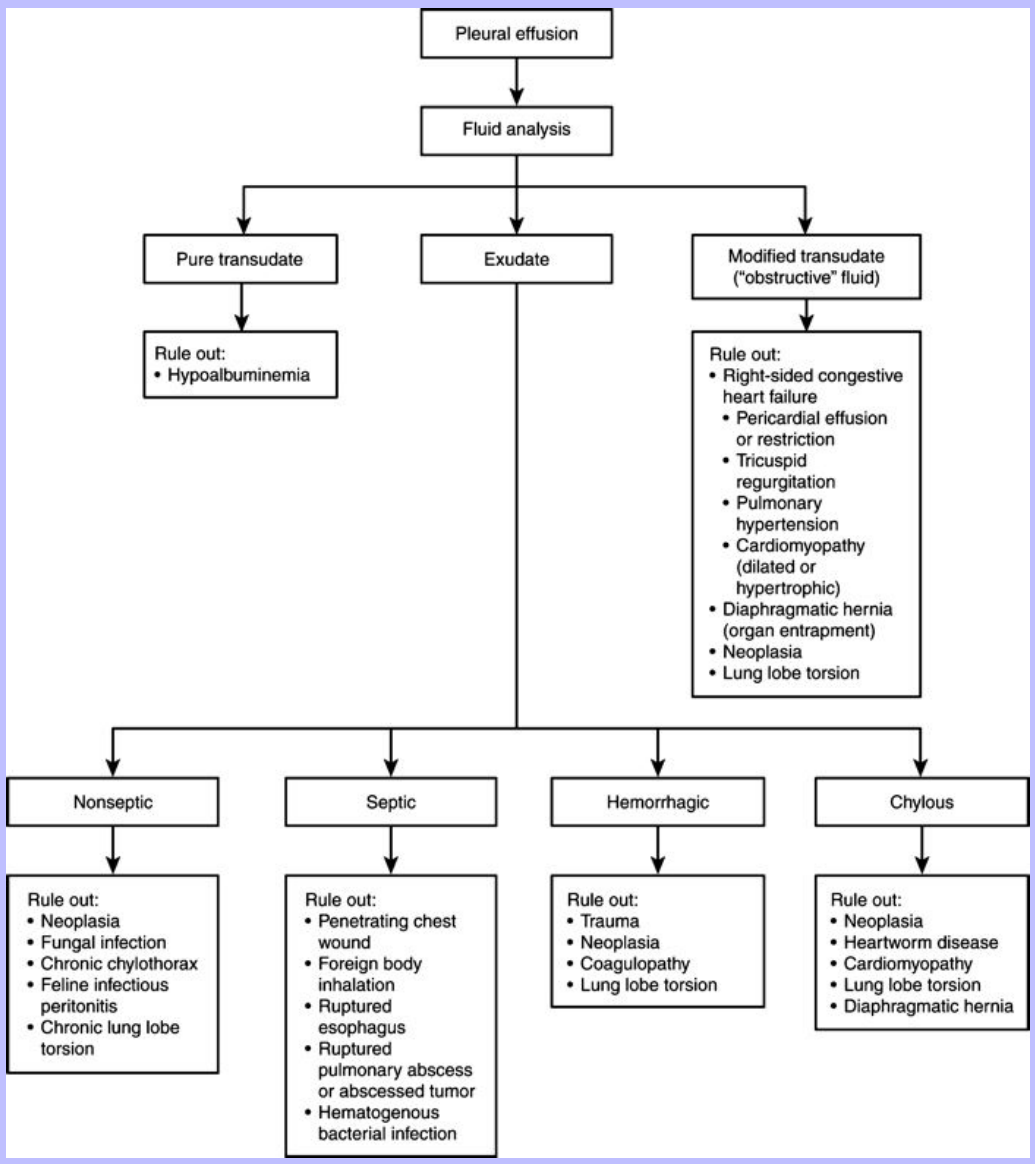
The pleura surround the lung lobes (visceral pleura) and line the thoracic cavity (parietal pleura). Normally, the pleural space contains 3 to 5 mL of a low-protein fluid that lubricates the pulmonary tissue for respiratory motion. Normal pleural fluid is in a constant state of flux much like fluid flow across capillary membranes. The same Starling forces that determine fluid movement across capillary walls are responsible for fluid movement in and out of the pleural space. Abnormal accumulations of pleural fluid may occur due to increased capillary hydrostatic pressure or permeability, decreased intravascular oncotic pressure, or impaired lymphatic drainage. The mediastinum of the dog and cat is fenestrated or incomplete, therefore pleural effusions are usually bilateral.

Pleural effusion is typically a secondary phenomenon; therefore recognition of pleural effusion is not analogous to diagnosis of a dog or cat's underlying condition. A thorough investigation should reveal the primary disease (Figure 57-1). 205

57.2 CLINICAL SIGNS OF PLEURAL EFFUSION

Clinical signs associated with pleural effusion are most often related to the respiratory system. Severity of signs is determined by the amount of the effusion and how quickly the effusion developed. The respiratory pattern caused by pleural effusion results from the interference of normal lung expansion. This observed pattern of ventilation is often called *restrictive respiration*. The respiratory effort is characterized by a labored inspiratory phase, often with a pronounced abdominal component, and an easy expiratory phase. The increased inspiratory effort associated with pleural effusion can be difficult to differentiate from the inspiratory effort of airway disease by observation alone. As a general rule, dogs and cats with pleural effusion will have decreased lung sounds, particularly ventrally, on thoracic auscultation. The presence of a fluid line may be determined by auscultation of a definitive point on the chest wall, where respiratory sounds shift from muffled to normal or slightly increased. By contrast, dogs and cats with airway disease often have abnormal inspiratory airway sounds such as crackles and wheezes. Most animals with significant pleural effusion are tachypneic as a compensatory measure because total lung capacity is reduced (secondary to reduced inspiratory capacity). Coughing is occasionally noted. 205 206

Figure 57-1 Algorithm of differential diagnosis of pleural effusion.



57.3 DIAGNOSTIC EVALUATION OF PLEURAL EFFUSION

A thorough physical examination often provides clues to the underlying cause of pleural effusion. For example, the presence of uveitis may alert the clinician to possible systemic inflammatory conditions such as viral disease (e.g., feline infectious peritonitis), rickettsial disease, fungal infection, or sepsis or systemic neoplasia (e.g., lymphosarcoma). Lymphadenopathy may suggest systemic inflammatory process or lymphosarcoma. Jugular distension and pulsation suggests increased right heart filling pressures that may be associated with

cardiomyopathy, pericardial effusion, tricuspid regurgitation, pulmonic stenosis, or any of the many causes of pulmonary hypertension (e.g., heartworm disease, thromboembolic disease). Jugular distension without pulsation is more likely to be associated with occlusion of right heart inflow, due to mediastinal masses or severely increased intrapericardial pressues. Many cats with large mediastinal masses will have decreased compressibility of the anterior thorax. A thorough palpation of the skeleton and the abdomen may uncover masses or painful regions associated with inflammatory disease.

Dogs and cats with severe respiratory distress from pleural effusion may be quite fragile. Unnecessary handling should be avoided until the animal is sufficiently stable. In these cases, oxygen therapy may be provided and thoracocentesis should be performed before additional diagnostics are planned. Although thoracocentesis is invasive, the potential therapeutic benefit far outweighs the small chance of complications. Patients that present in stable condition may have chest radiographs taken to confirm presence of pleural effusion before thoracocentesis.

Thoracic radiography can confirm pleural effusion and often identifies the underlying cause (i.e., cardiac disease, mediastinal mass). In many cases, critical evaluation of the chest cannot be performed because the fluid silhouettes with the normal thoracic structures, which obscures their borders. Repeating chest radiographs after thoracocentesis may aid in identification of thoracic pathology.

Fifty to 100 milliliters of fluid must be present for pleural effusion to be recognized radiographically. A minute amount of effusion may be detected as pleural fissure lines on the radiograph. These radio-opaque lines arc from the periphery toward the hilar region and outline individual lung margins. As effusions progress, lung lobes retract from the chest wall and lung borders become rounded. With large volumes of effusion, the lungs appear to float on the fluid line and the trachea is displaced dorsally, which mimics cardiomegaly or cranial mediastinal mass. The fluid often obscures cardiac margins interfering with cardiac size interpretation. The cardiac silhouette may not be visualized at all on the dorsoventral radiograph. Lung lobes may appear abnormally dense due to incomplete expansion, collapse, or lung lobe torsion. Pockets of fluid accumulation or unilateral effusions should alert the clinician to the possibility of inflammatory lesions and pleural adhesions.

Analysis of the pleural fluid obtained by thoracocentesis provides important clues in determination of the cause. The thoracocentesis technique is described in detail elsewhere in this text. Samples should be placed into anticoagulant tubes (EDTA) for cell counts, clot tubes for possible biochemical analysis, and culture devices in the event septic processes are identified by cytologic evaluation. Measurement of protein concentration, a total cell count, and cytologic analysis may reveal a specific diagnosis or at minimum, assist in formulating a diagnostic plan. Pleural effusions can generally be categorized as transudates and modified transudates; septic and nonseptic exudates; or chylous, hemorrhagic, or neoplastic effusions.

57.4 TRANSUDATES AND MODIFIED TRANSUDATES

Pure transudates are fluids characterized by low protein concentration (less than 3 gm/dl) and low nucleated cell counts (less than 1000/µl). Macrophages, lymphocytes, and mesothelial cells are the primary cell types. Modified transudates have slightly higher protein concentration of up to 3.5 gm/dL and cell counts of up to 5000/µl. In addition to the above cell types, neutrophils are a common finding. Pure transudates are classically transparent, whereas modified transudates may have very slight turbidity.

The most common cause of a pure transudate is decreased oncotic pressure from hypoalbuminemia. The finding of a pure transudate should alert the clinician to assess serum albumin concentration and to screen for underlying causes of hypoalbuminemia (impaired hepatic production, or albumin loss via gastrointestinal or renal lesions). Occasionally, pleural effusions of hypoalbuminemia will be modified transudates in long-standing cases.

The most common cause of modified transudates is increased hydrostatic pressure of the vascular system or lymphatics. Pleural effusion due to increased intravascular hydrostatic pressure is typically referred to as *right-sided congestive heart failure*. Cardiomyopathy (dilated and hypertrophic), severe tricuspid regurgitation, pulmonary hypertension, and pericardial effusion or restriction are some common examples of diseases that may result in right heart failure. Pleural effusion from lymphatic obstruction can be caused by neoplasia or strangulation of intrathoracic tissue such as with diaphragmatic hernia or lung lobe torsion.

57.5 SEPTIC AND NONSEPTIC EXUDATES

Exudates are usually the result of inflammation and increased vascular permeability. Exudates have a higher protein content and cell count than transudates. Protein concentrations are classically greater than 3 gm/dL and cell counts are greater than 5000/µl. These fluids appear turbid as a result of the higher cellular content. The cell types are similar for septic and nonseptic exudates (neutrophils, macrophages, eosinophils, lymphocytes), but septic processes usually have extremely high nucleated cell counts, that is, greater than 50,000/µl. In septic exudates, degenerate neutrophils predominate and bacteria can also be observed within the neutrophils or free fluid. However, the absence of bacteria does not rule out an infectious process and all exudative fluids should be submitted for gram stain and aerobic/anaerobic culture. Prior antibiotic therapy can alter the cellular concentration of the pleural fluid and diminish bacterial numbers; therefore cytology (and culture) should ideally be performed prior to initiation of treatment. In some cases the septic exudates will have a foul odor. Septic pleural effusions are also called *pyothorax*. Penetrating chest wounds, penetrating esophageal or airway lesions, migrating foreign material such as grass awns, and extension of bacterial pneumonia are relatively common causes of pyothorax in the dog and cat.

Nonseptic exudates may be difficult to differentiate from septic processes. The cell count is usually lower for nonseptic effusions. Although macrophages and lymphocytes may appear activated, neutrophils are typically nondegenerate. As stated earlier, the absence of obvious bacteria in fluid does not guarantee a nonseptic process. Culture and sensitivity testing should be performed. Differential diagnoses for patients with nonseptic exudates include neoplasia, resolving sepsis, chronic diaphragmatic hernia and lung lobe torsion, fungal infection, feline infectious peritonitis, and long-standing chylothorax.

206

207

57.6 HEMORRHAGIC EFFUSIONS

Hemorrhagic effusions are grossly red with red blood cells and may appear similar to frank blood. A packed cell volume (PCV) should be determined on the fluid and compared with a peripheral blood sample. PCV of similar values suggest active bleeding into the chest cavity, whereas effusions with lower PCV than the peripheral blood suggest other factors are responsible for the bloody effusion. Hemorrhagic effusions due to active inflammatory causes often have increased numbers of neutrophils and macophages compared with the peripheral blood sample, and erythorphagocytosis is commonly present. Hemorrhagic effusions may result from trauma, neoplasia, lung lobe torsion, and systemic coagulopathies such as rodenticide ingestion.

57.7 CHYLOUS EFFUSIONS

Chylous pleural effusion (chylothorax) results from leakage of material from the thoracic duct. These effusions may occur from increased lymphatic hydrostatic pressure or obstruction. Common causes include cardiac disease, pericardial disease, dirofilariasis and pulmonary hypertension, lung lobe torsion, diaphragmatic hernia, neoplasia, and trauma. Idiopathic cases of chylothorax are suspected to be secondary congenital or acquired defects of the thoracic duct.

Chylous effusion is usually milky white due to the presence of chylomicrons, but it may be clear if the animal has fasted. Occasionally, the effusions are blood-tinged and resemble tomato soup. These fluids must be differentiated from exudative processes, as protein concentration and cell counts are similar. The predominant cell type in chylous effusion is the mature lymphocyte. With chronic effusions, increasing numbers of nondegenerate neutrophils and macrophages may be seen. A definitive diagnosis of chylothorax may also be made by comparing the triglyceride content of the effusion to that of serum. The triglyceride content of chyle is classically greater. Occasionally, this test may need to be repeated if an animal has been anorectic.

57.8 NEOPLASTIC EFFUSIONS

Thoracic neoplasia can cause any type of pleural effusion with the possible exception of pure transudates. Neoplastic cells may or may not exfoliate into the effusion for cytologic identification. Repeat thoracic radiography after thoracocentesis (particularly with mediastinal neoplasia), thoracic ultrasonography or computed tomography may uncover masses, but definitive diagnosis requires fine needle aspiration or biopsy.

57.9 TREATMENT AND PROGNOSIS OF PLEURAL EFFUSION

Recognition of pleural effusion is not analogous to diagnosis of the patient's underlying condition. A thorough investigation should reveal the primary disease process. Initial treatment for patients with respiratory distress from pleural effusion is thoracocentesis. Thoracocentesis provides therapeutic as well as diagnostic benefit. The prognosis for pleural effusion is directly related to the underlying condition.

58 CHAPTER • 58 Sneezing and Nasal Discharge

Kirsten Cooke

Sneezing and nasal discharge are common problems in companion animals. Nasal discharge may result from nasal or paranasal (sinus) disorders or from systemic disease (Box 58-1). Sneezing and reverse sneezing localize the problem to the nasal cavity or nasopharynx. Although increased frequency of sneezing is often readily apparent, many owners may not notice nasal discharge immediately because most animals clear these secretions by licking. However, clients may report other clinical signs associated with nasal disease, including increased respiratory sounds, increased respiratory effort, gagging, epiphora, and/or nasal deformity. Alternatively, they may notice signs of systemic disease such as lethargy and weight loss.

Signalment, history, and physical exam including characterization of the nasal discharge can help narrow the list of differential diagnoses and thus the diagnostic focus.

58.1 DIAGNOSTIC APPROACH

58.1.1 Signalment

Younger animals are more likely to have congenital, infectious, or toxicity-related disorders, whereas nasal discharge in older animals is more likely to be due to neoplasia, metabolic, or dental disease.

58.1.2 History

Acute disease results most commonly from trauma, foreign body, acute viral infections, and coagulopathies. If other pets in the household are affected, an infectious process should be suspected. Chronic disease is usually caused by neoplasia, fungal infection, dental disease, or chronic foreign bodies. Outdoor pets are prone to trauma and foreign bodies in addition to parasitic and fungal infections. Owners should also be questioned about clinical signs such as polyuria, polydipsia, or melena that may support systemic disease. Environment and travel history should be determined as both rickettsial and fungal infections have regional predilections.

58.1.3 Physical Exam

A complete physical exam should be performed to try to differentiate nasal disease from systemic disease (Table 58-1). Patency of each nostril should be evaluated with the use of a glass slide to look for condensation or a wisp of cotton and looking for movement with respiration. Cats with polyps may have a head tilt, nystagmus, or otic discharge. Systemic disease is associated with clinical signs that involve other organs such as ocular lesions (hypertension) or petechia (coagulopathy).

58.1.3.1 Box • 58-1 Causes Of Sneezing And Nasal Discharge

58.1.3.1.1 Nasal and Paranasal Diseases

Congenital

- Cleft palate
- Ciliary dyskinesia
- Foreign body
- Dental disease
  - Tooth root abscess
  - Oronasal fistula
- Neoplasia
  - Carcinoma (adeno-, squamous cell)
  - Sarcoma (fibro-, osteo-, chondro-)
  - Round cell (lymphoma, transmissible venereal tumor)
- Infectious
  - Viral
    - Herpesvirus (C)
    - Calicivirus (C)
  - Fungal
    - *Aspergillus* (D)
    - *Penicillium* (D)
    - *Rhinosporidium* (D)
    - *Cryptococcus* (C)

Parasites

Pneumonyssus caninum (nasal mite) (C)

Eucoleus böehmi (formerly *Capillaria* sp.) (C, D)

Cuterebra sp. (C, D)

Inflammatory

Lymphocytic-plasmacytic rhinitis

Allergic rhinitis

Acquired nasopharyngeal stenosis

Nasopharyngeal polyps (C)

Trauma

58.1.3.1.2

Systemic Disease

Hypertension

Hyperthyroidism

Hyperadrenocorticism

Renal disease

Pheochromocytoma

Infectious

Canine infectious tracheobronchitis (kennel cough)

Canine distemper

	Pneumonia
Coagulopathy	
	Thrombocytopenia
	Vitamin K rodenticide toxicity
	DIC
Vasculitis	
	Ehrlichia
	Rocky Mountain spotted fever
Hyperviscosity	
	Multiple myeloma
	Lymphoma

D, Dogs; *C,* cats.

A thorough oral exam to evaluate the teeth, gums, palate, and tonsils is essential. However, this may be difficult or impossible in the conscious animal. A cursory exam may be done during the initial physical and a more complete exam done under sedation or anesthesia prior to other, more invasive, diagnostics.

58.1.4 Characterization of Nasal Discharge

Unilateral nasal discharge is usually indicative of intranasal rather than systemic disease. Neoplasia, fungal infection, foreign bodies, and dental disease often present with unilateral nasal discharge. However, the discharge may become bilateral as the disease progresses. Therefore establishing whether bilateral nasal discharge began as unilateral discharge can be an important piece of historical information.

Bilateral nasal discharge can be due to lymphocytic-plasmacytic rhinitis, allergic rhinitis, and chronic fungal or neoplastic diseases. Systemic diseases such as hypertension, coagulopathy, or infectious diseases usually result in bilateral nasal discharge as well. However, systemic diseases such as coagulopathies can occasionally be associated with unilateral nasal discharge.

Nasal discharge can be characterized as serous, mucoid, purulent, or hemorrhagic (or a combination of types). The character of the discharge may change as acute disease becomes chronic. For example, a serous discharge may become purulent as the result of a secondary bacterial infection.

Serous discharge is clear and often intermittent. It is most commonly associated with allergic rhinitis, lymphocytic-plasmacytic rhinitis, nasal parasites, foreign bodies, and early viral infections. If the disease is associated with paroxysmal sneezing, the discharge may become blood-tinged.

Purulent nasal discharge is thick, opaque, and yellow to green and is associated with bacterial infection. However, bacterial infections are almost always secondary to some other disease that has damaged the nasal mucosa. Mucopurulent nasal discharge can also be seen in patients with bacterial pneumonia. As with a serous discharge, it is not uncommon for purulent discharge to be tinged with blood due to mucosal irritation.

Systemic diseases, including coagulopathies or vasculitis, can lead to epistaxis or hemorrhagic nasal discharge. Intranasal diseases that erode major blood vessels (neoplasia, fungal disease) should also be included on the list of differential diagnoses for epistaxis. Hemorrhagic nasal discharge can be differentiated from blood-tinged nasal discharge by the volume. Epistaxis is generally copious and has a hematocrit similar to peripheral blood.

Mucoid nasal discharge is clear and gel-like. It may be copious and may be blood tinged. It is uncommon but when seen, is most commonly associated with nasal adenocarcinoma.

208

209

Table • 58-1 Physical Exam Findings Associated with Sneezing

LOCATION	FINDINGS	DIFFERENTIAL DIAGNOSIS
Face	Asymmetry (swelling, deformity)	Neoplasia
		Fungal rhinitis
		Tooth root abscess
Nose	↓Air movement	Neoplasia
	Depigmentation Mass	Fungal rhinitis
Submandibular lymph nodes	Enlargement	Neoplasia
		Infection
		Dental disease
Oral cavity	Dental disease	Oronasal fistula
	Cleft palate	Tooth root abscess
	Swelling	Neoplasia
Eyes	Exophthalmos	Neoplasia
		Trauma
		Abscess
	Retinal hemorrhage/detachment	Vasculitis
	Tortuous vessels	Hypertension
		Coagulopathy
	Ocular discharge	Viral infection
		Lacrimal duct obstruction (neoplasia)
Skin	Petechia	Vasculitis
Mucous membranes	Ecchymoses	Coagulopathy
Thoracic auscultation	Crackles	Pneumonia

The presence of food particles in nasal discharge suggests a cleft palate in a young animal or an oronasal fistula in an adult.

58.2 DIAGNOSTIC PLAN

Evaluation of the signalment, history and physical exam findings should allow initial prioritization of differential diagnoses and selection of the most appropriate diagnostic tests (Figure 58-1).

Routine laboratory evaluation (CBC, chemistry profile, urinalysis) is unlikely to establish a diagnosis for intranasal disease. However, these tests may support a systemic cause of nasal discharge and prompt investigation along these lines. Additionally, these values may provide information on the patient's overall health prior to general anesthesia, which may be required to arrive at a definitive diagnosis.

Indirect blood pressure can be measured to determine if the patient is hypertensive. If vasculitis is suspected, serology for *Ehrlichia* species and Rocky Mountain spotted fever should be done. A platelet count, buccal mucosal bleeding time, prothrombin time, and partial thromboplastin time are indicated to rule out a coagulopathy in a patient with epistaxis. It is also a good idea to assess coagulation parameters prior to nasal biopsy.

Fungal serology for aspergillosis, penicilliosis, and cryptococcosis may be evaluated. Both false positive and false negative results occur. Results are interpreted in light of other findings, including imaging, rhinoscopy, histopathology, and fungal culture.

Cytology of nasal secretions or tissue specimens is of limited value. Neutrophils, bacteria, and even fungal elements may be present in normal animals or as part of a secondary infection and are not diagnostic of a primary bacterial or fungal rhinitis. Cytology can be useful in the diagnosis of cryptococcal rhinitis as well as nasal lymphoma.

58.2.1 Imaging

Imaging of the nasal cavity, whether via conventional radiography, computed tomography, or magnetic resonance imaging, requires general anesthesia to provide the most accurate study. Imaging should be done *prior* to invasive diagnostic procedures such as rhinoscopy, nasal flushing, or nasal biopsy. These procedures can lead to hemorrhage in addition to alterations in bony and soft tissue structures, which can obscure subtle pathologic lesions and make it difficult to determine if abnormalities are pathologic or iatrogenic.

Immediately following induction of anesthesia for imaging studies is the perfect time to complete the oral exam. Palpation of the hard and soft palate and evaluation of the tonsils, teeth, and gums, including periodontal probing, should be done at this time.

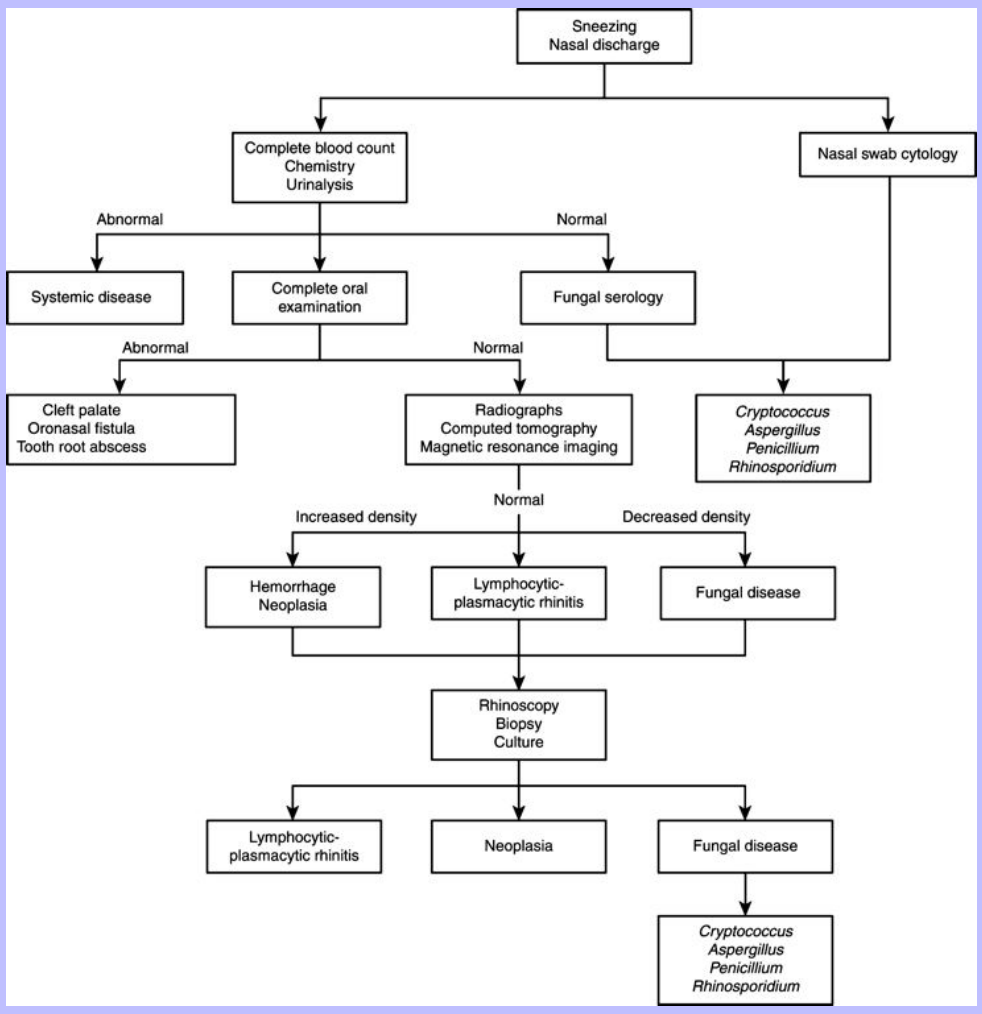
58.2.1.1 Radiography

Radiography of the nasal cavity and sinuses can be useful for determining the location and extent of disease. Radiographs should be evaluated for changes in soft tissue opacity in addition to osteolytic or osteoproductive changes. Nasal and sinus films can be challenging to interpret under the best of circumstances due to the complexity of the anatomy as well as superimposition of overlying structures. Proper positioning requires general anesthesia and is critical to obtaining diagnostic films.

58.2.1.2 Computed Tomography

Computed tomography (CT) allows a more complete examination of the nasal cavity and sinuses than conventional radiography. Because cross-sectional images are obtained, superimposition of structures is eliminated. Where available, it has largely replaced radiography for evaluation of nasal disease. The use of contrast agents can help to distinguish vascularized tumors from mucous accumulation. The ability of CT to localize nasal lesions can help direct other procedures, including rhinoscopy and biopsy.

Figure 58-1 Algorithm for sneezing and nasal discharge.



Although imaging provides information regarding the location, extent, and character of a nasal lesion, it generally does not provide a definitive diagnosis.

58.2.1.3 Rhinoscopy

Rhinoscopy provides direct visualization of the anterior nasal cavity, the nasopharynx, and the choanae. It allows sample collection directly from visible lesions and foreign body removal in addition to diagnosis of nasal mites and nasopharyngeal polyps. Tissue samples should be submitted for histopathology and fungal culture.

58.2.2 Histopathology

Histopathology remains the gold standard in the diagnosis of most cases of nasal disease. Biopsies are obtained rhinoscopically. Alternatively, “blind” biopsies can be obtained with or without the use of radiography or CT to localize the lesion. It is extremely important that the biopsy instrument be passed no further than the distance from the tip of the nose to the medial canthus of the eye to avoid penetration of the cribriform plate.

58.2.3 Treatment and Outcome

Successful treatment of sneezing and nasal discharge hinges on the determination of a definitive diagnosis. Although antibiotic therapy may lead to some improvement, clinical signs will return unless the underlying problem can be resolved.

59 CHAPTER • 59 Hematologic/Chemical: Pallor

Wallace B. Morrison

The term *pallor* is defined as the absence of skin color. Clinically, the term *pallor* is most associated with paleness of mucous membranes. Pale mucous membranes originate from either shock or anemia (Figure 59-1). A severely anemic patient may progress to shock as an end-stage event. A patient experiencing shock will be anemic only if blood loss is a part of the clinical disorder. However, severe blood loss may lead to both shock and anemia. Neutrophil and platelet counts are unaffected by shock and many causes of anemia. Anemia with other and concurrent cytopenias is common. Anemic patients that are not in shock should have a normal capillary refill time (CRT) of 1 to 2 seconds. Patients in shock will have a prolonged CRT; however, unless blood loss is also present, they should have a normal packed cell volume (PCV). Evaluation of mucous membrane color and CRT becomes progressively more difficult as the PCV falls below about 20% because not enough hemoglobin is present to impart any color through mucous membranes to make evaluation of these parameters possible.

Metabolically and biochemically, shock is a complex event characterized by poor tissue perfusion that leads to decreased or uneven O_2 delivery to tissues, altered cell metabolism that may in turn result in cell death, organ failure, or a combination. Shock usually has a readily apparent cause and either responds to intervention or results in death. Shock is a peracute state. It is not a chronic condition, although the primary disorder that ultimately culminated in shock may itself have been chronic in duration.

Causes of shock include hypovolemia and disruptions in blood flow (noncardiogenic shock), as well as poor cardiac activity (cardiogenic shock). The primary causes of shock are trauma, hypovolemia, hypotension, severe acute blood loss (internal or external), severe chronic blood loss (flea infestation, gastrointestinal loss), severe heart disease causing underperfusion of peripheral tissues, and sepsis. Most cardiac conditions that result in shock are secondary to decreased myodynamic ventricular function, conditions that compromise ventricular filling, disruption of valve structures that result in severe regurgitation of blood, severe arrhythmias, or conditions that block outflow of blood from the heart (Table 59-1). The physical consequences of inadequate tissue perfusion relate directly to the production of proinflammatory mediators as a result of cellular ischemia and inadequate oxygen delivery to tissues. The origins and clinical consequences of proinflammatory mediators in shock are listed in Table 59-2.

Anemia has many origins and is initially classified as either being regenerative or nonregenerative (see Figure 59-1). Anemia can be further characterized with erythrocyte indices. The terms *normocytic*, *microcytic*, and *macrocytic* characterize the size of red blood cells (RBCs). The terms *normochromic* and *hypochromic* characterize the hemoglobin-related properties of RBCs.

Nonregenerative anemia lacks a normal reticulocyte response (reticulocyte count <60,000/μL). It occurs when selective erythropoietic depression, decreased RBC survival time from an extramarrow chronic disease, or insufficient erythropoietin release (or a combination of these factors) exist, as well as if the bone marrow fails to respond to normal or increased amounts of erythropoietin. Simple, nonregenerative anemia that is due to hyporesponsiveness of bone marrow to erythropoietin alone will have normal platelet and leukocyte production. Bone marrow disorders affecting more than erythrocytes will have other and concurrent cytopenias (Table 59-3). Nonregenerative anemias are usually normocytic and normochromic.

A regenerative anemia is usually the result of blood loss (bleeding) or hemolytic disease (Table 59-4). A regenerative anemia has a normal bone marrow response to erythropoietin in an effort to replace the lost red cells. A regenerative anemia is characterized by a reticulocytosis (reticulocyte count >60,000/μL), polychromasia, and perhaps the

presence of nucleated RBCs. It takes 5 to 7 days from the time of the blood loss for the maturation process of red cells to develop such that polychromasia and reticulocytosis is detectable.

Table • 59-1 Classification and Examples of Causes of Shock

CARDIOGENIC	NONCARDIOGENIC
Decreased myodynamic ventricular function	Trauma
Dilated cardiomyopathy	
Myocarditis	
Myocardial infarction	
Compromised ventricular filling	Hypovolemia
Cardiac tamponade	Severe blood loss
Hypertrophic cardiomyopathy	Severe dehydration
	Hypoadrenocorticism
Disruption in valvular function	Disruptions in blood flow
Severe endocardiosis	Sepsis and endotoxemia
	Hypotension
Outflow obstruction	
Intracardiac tumors	
Aortic stenosis	
Hypertrophic obstructive cardiomyopathy	
Heartworm disease	
Thrombosis	
Severe arrhythmia	

Figure 59-1 Algorithm for pallor.

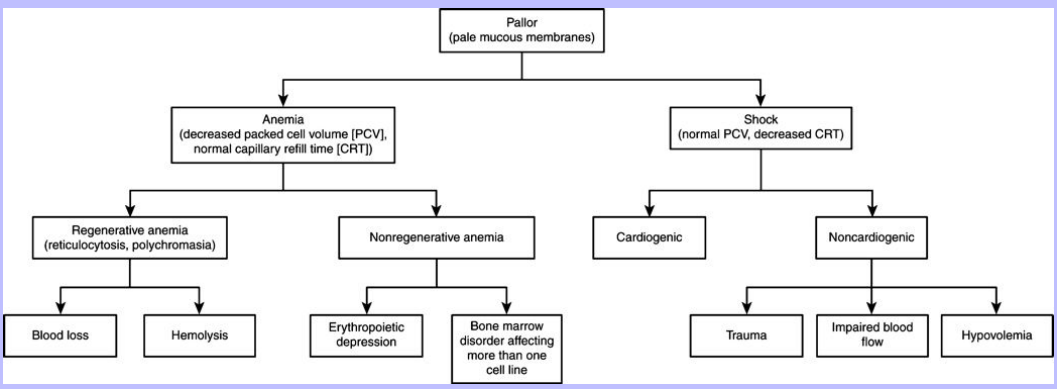


Table • 59-2 Cytokine and Chemical Mediators of Shock

CYTOKINE OR CHEMICAL MEDIATOR	CLINICAL CONSEQUENCES
Histamine	Released from mast cells and results in vasodilation, increased capillary permeability, and bronchoconstriction
Bradykinin	Released from many cells and kallikrein; it causes pain, vasodilation, and edema; it also stimulates prostacyclin production
Serotonin	Causes bronchoconstriction, platelet aggregation, and increased vascular permeability
Prostaglandins	Prostaglandin E_2 results in vasodilation, erythema, hyperalgesia, and edema; prostaglandin F_2 results in vasoconstriction
Thromboxane A_2	Causes vasoconstriction, platelet aggregation, and leakage of lysosomal enzymes
Leukotrienes C_4, D_4, and E_4	Causes bronchoconstriction, vasodilation, increased vascular permeability, and cardiodepression
Tumor necrosis factor	Stimulates the production of many inflammatory mediators and cytokines; it promotes the production of adrenomedullin, vasodilation, myocardial depression, increased capillary permeability, edema and disseminated intravascular coagulation
Platelet-activating factor	Produced by most inflammatory cells, the endothelium, and platelets; it can result in vasodilation and increased capillary permeability
Endothelins	Causes vasoconstriction and increased capillary permeability
Nitric oxide	Causes vasodilation, increased capillary permeability, hypotension, and the production of oxygen free radicals
Oxygen free radicals (O_2^-, H_2O_2, OH^-)	Free radicals promote production of peroxynitrite and peroxynitrous acid, destroy cell membranes, and cause cell lysis

Modified from Muir WW: Shock, *Compend Cont Ed* 20:549, 1998.

Table • 59-3 Nonregenerative Anemia

CAUSE	KEY POINTS
Erythropoietic Depression	
Anemia of chronic disease	This is a poorly understood disorder that accompanies many chronic diseases. It is normochromic and normocytic, the survival time of red blood cells (RBCs) is decreased, increased tissue iron stores exist, and apparent bone marrow hyporesponsiveness to erythropoietin occurs. Packed cell volume (PCV) is usually only mildly depressed and rarely requires treatment. Neutrophil and platelet counts are unaffected.
Anemia with renal failure	Common in dogs and cats in chronic renal failure. It is due to inadequate renal erythropoietin release and a shortened survival of RBCs. It may be mild to severe in magnitude. Neutrophil and platelet counts are unaffected.
Feline leukemia virus (FeLV)–associated	Approximately 70% of anemic cats will test positive for FeLV. Nonregenerative anemia may be due to simple erythropoietic depression and/or associated hemolysis, but concurrent neutropenia and/or thrombocytopenia often result from the myelodysplasic, myeloproliferative, or myeloaplastic effects of infection with FeLV.
Endocrine	Mild anemia is often associated with hypothyroidism and hypoadrenocorticism in dogs, but the mechanisms are poorly characterized.
Bone Marrow Disorders	
Myeloaplasia (aplastic anemia)	Characterized by severe bone marrow cell depopulation and peripheral cytopenias. Because bone marrow aspirates are often diluted with blood and therefore difficult to interpret, it is advisable to collect a bone marrow core biopsy for histologic examination to establish a diagnosis. Myeloaplasia can be associated with FeLV infection, ehrlichiosis, trimethoprim-sulfadiazine use, estrogen toxicity, phenylbutazone toxicity, chemotherapy, and chloramphenicol toxicity. It occasionally occurs without a known cause.
Myelodysplasia	Bone marrow of affected individuals is often normal or hypercellular, but associated maturation defects result in cytopenias. Myelodysplasic anemia is most recognized in cats where the anemia is attributed to maturation defects in RBCs.
Myeloproliferative and lymphoproliferative disorders	This disorder is characterized by the proliferation of abnormal cells within bone marrow at the expense of normal hematopoiesis. If the anemia appears to be regenerative, a low-grade hemolytic process may be occurring concurrently.
Myelofibrosis and osteosclerosis	These disorders may be terminal lesions in myeloproliferative disorders or a response to bone marrow injury. Myelofibrosis can be a consequence of pyruvate kinase (PK) deficiency in dogs.

Table • 59-4 Regenerative Anemia

CAUSE	KEY POINTS
Hemolysis	An absolute reticulocytosis is not present in up to 30% of cases. Spherocytosis is expected in dogs. Cats rarely show spherocytosis with immune-mediated hemolytic anemia because they have relatively small red blood cells (RBCs) and lack central pallor when compared with dogs.
Immune mediated	
Extravascular	
Intravascular	
Parasites of Erythrocytes	These organisms are known to cause hemolytic disease and include *Hemobartonella*, *Babesia*, and *Cytauxzoon* spp.
Fragmentation (Microangiopathic)	Fragmentation anemia may occur with disorders like disseminated intravascular coagulation, heartworm disease, hemangiosarcoma, vasculitis, hemolytic-uremic syndrome, and diabetes mellitus. Anemia results from mechanical shearing of red cells by intravascular strands of fibrin across small vessel lumina. Often the rate of hemolysis is subclinical. RBC fragments are called schistocytes.
Hereditary Nonspherocytic Hemolytic Anemia	Hereditary nonspherocytic hemolytic anemia has been reported in poodle and beagle dogs, but it may not be the same disease in each breed. It is very rare.
Pyruvate Kinase (PK) Deficiency	Lack of normal red cell PK activity impairs normal adenosine triphosphate (ATP) generation from glucose. The result is chronic, severe hemolysis without spherocytosis. PK deficiency affects basenjis and beagles and is very rare.
Phosphofructokinase (PFK) Deficiency	This is intravascular hemolysis as a result of vigorous exercise or panting from overheating. It involves erythrocyte fragility to alkaline pH caused by impaired synthesis of 2, 3, diphosphoglycerate (2, 3, DPG). Spherocytosis is absent. It is very rare.
Feline Porphyria	This is a rare autosomal dominant disorder of Siamese cats that is characterized by porphyrin accumulation that causes reddish discoloration of teeth and bones, fluorescence with ultraviolet light, and mild-to-severe anemia.
Hemolysis in Abyssinian and Somali Cats	This is a very rare hereditary hemolytic anemia secondary to severe increased osmotic fragility of erythrocytes.
Copper Toxicity	Intravascular hemolysis has been rarely associated with hepatic necrosis in Bedlington terriers.
Neonatal Isoerythrolysis	Although rare in dogs and cats, this results from colostrum passage of an antibody capable of lysing RBCs.
Oxidative Injury (Heinz Body)	A variety of agents will cause oxidative injury to hemoglobin. Exposure to oxidants can denature hemoglobin into aggregates known as *Heinz bodies*. Cats are more sensitive to Heinz body formation than are dogs. Eccentrocytes may form in dog RBCs after oxidant-induced membrane fusion that causes hemoglobin to shift to one side of the cell, lack of central pallor, and a clear zone outlined by a membrane. They are associated with Heinz body formation in dogs. Oxidant damage to hemoglobin can also result in methemoglobin formation.
Onion ingestion (usually dogs)	
Acetaminophen ingestion(usually cats)	
Zinc ingestion (pennies mintedpost-1982, zinc oxide ointment, zinc-plated bolts and screws)	
Benzocaine ingestion vitamin K3(dogs)	
D-L methionine ingestion (cats)	
Phenolic compounds (moth balls)	
Phenazopyridine (cats)	

Blood Loss Anemia External blood loss Blood loss to a body cavity Coagulopathy (factors, platelets, disseminated intravascularcoagulopathy [DIC]) Endoparasites GI loss	Occult GI loss of blood may not be obvious. Body iron is stored as hemoglobin, and iron deficiency anemia is a late feature of chronic blood loss. Iron deficiency anemia is usually characterized as being microcytic and hypochromic. Red cell fragmentation may be seen after microcytosis is well established owing to increased stiffness of the RBC membrane and increased membrane fragility to normal intravascular trauma.

Hemolysis can be triggered by immune-mediated and nonimmune-mediated mechanisms. Immune-mediated hemolytic anemia is often highly regenerative. However, in up to 30% of cases, the anemia is not regenerative because it is either too acute and the bone marrow has not yet had time to respond or because there may be antibodies also directed at bone marrow stem cells that inhibit the normal regenerative response. Primary immune-mediated hemolytic anemia occurs when immunoglobulins (usually IgG or IgM) develop against normal or altered RBC membrane antigens. Primary immune-mediated hemolytic anemia is common in dogs but rare in cats. Infectious agents like *Ehrlichia, Hemobartonella*, *Babesia*, and *Leptospira* organisms and feline leukemia virus (FeLV) can alter normal surface antigens on RBCs and result in secondary immune-mediated hemolytic disease. Adsorbed immunoglobulins on RBC membranes cause intravascular hemolysis, extravascular hemolysis, or both. Extravascular hemolysis occurs when RBCs are removed by macrophages of the reticuloendothelial system (primarily in the spleen and liver) at an accelerated rate. Intravascular hemolysis occurs when adsorbed immunoglobulins activate complement and the cells spontaneously lyse. Some immunoglobulins (IgM) have greatest activity below normal body temperature and cause intravascular agglutination at cold temperatures (cold-agglutinin disease). Clinical effects may first be noticed in devitalized areas of the ear tips, feet, and tip of the tail after exposure to cold temperatures has caused plugging of small vessels and capillaries with agglutinated RBCs.

Nonimmune-mediated mechanisms of hemolysis include Heinz body formation after oxidative damage to hemoglobin, congenital defects in erythrocyte metabolism, intracellular parasites of erythrocytes, fragmentation across intravascular strands of fibrin, and copper toxicity. Common causes of blood loss include trauma, external blood loss, blood loss to a body cavity, coagulopathy, endoparasites and ectoparasites that suck blood, and gastrointestinal loss from nonparasite causes.

Clinical signs of severe anemia and shock may be similar and may include pallor (pale mucous membranes), cool mucous membranes, polypnea, tachycardia, weakness, and signs referable to the primary disease. Distinguishing shock from anemia should be uncomplicated. A patient in shock will usually have a history of trauma or a preexisting and serious systemic disease. Previously nonanemic patients with shock from any acute cause (including acute bleeding) should have a normal PCV. A time delay exists for acute blood loss to be reflected as a lower PCV because it takes several hours to complete fluid shifting from the extravascular space to the intravascular space to compensate for lost blood volume. Patients with shock and anemia will have a low PCV, but a careful history and physical examination and other diagnostic texts should reveal the underlying disorder.

Table • 59-5 Guidelines for Interpreting Anemia

CRITERIA	PCV DOG	PCV CAT
Normal	40%–50%	30%–40%
Mild anemia	35%–39%	25%–29%
Moderate anemia	20%–34%	20%–24%
Severe anemia	<20%	<20%

PCV, Packed cell volume.

An anemic patient will have a PCV below the reference range and will either be unstable if the blood loss is acute and severe or stable if the blood loss is mild, moderate, or of slow onset over a prolonged period of time (up to a critical end point). Patients with sudden blood loss will become unstable because of hypovolemia and the reduced oxygen carrying capacity of blood. Anemia that develops slowly over time allows for each red cell to increase the relative amounts of oxygen it carries in hemoglobin through increases in intracellular 2, 3, diphosphoglycerate (2, 3, DPG). Increases in 2, 3, DPG increases the amount of oxygen that hemoglobin can carry so that the clinical manifestations of a decreased red cell mass are minimized. The speed of the blood loss will in part determine how stable the anemic patient is relative to the degree of anemia present (Table 59-5). The detection of anemia after acute blood loss cannot be done until several hours has passed and the normal circulating blood volume is reestablished.

60 CHAPTER • 60 Polycythemia

Andreas H. Hasler

60.1 DEFINITIONS AND PATHOPHYSIOLOGY

Polycythemia denotes the finding of an elevated cell count in the blood and is a medical composite term of the Greek words *polys* (many), *cytos* (cell), and *haima* (blood). In veterinary medicine most often only the erythrocyte number is increased, whereas the other cell lines (leukocytes, thrombocytes) are not. Some authors prefer the term *erythrocytosis*, but the term *polycythemia* is historically well established.

It is important to recognize that normal upper values of erythrocyte parameters for dogs are different from those for cats. Upper limits for dogs versus cats are packed cell volume (PCV) of 55% versus 45%, red blood cell (RBC) count of $8.5 \times 10^6/\mu L$ versus $10 \times 10^6/\mu L$, and hemoglobin concentration (Hb) of 18 versus 14 g/dl. Certain breeds such as greyhounds and dachshunds generally have higher PCV values than other breeds.

60.2 PATHOPHYSIOLOGY

Polycythemia is classified as relative or absolute (Figure 60-1). Relative polycythemia is defined as an increased PCV with a normal total RBC mass resulting from a decrease in plasma volume. The most common causes of relative polycythemia are external losses of body fluids such as in diarrhea or burns. Less common causes are shifting of body fluids from the vascular space into the interstitial space or inadequate fluid intake (water deprivation). Signs of dehydration are usually present. Splenic contraction can lead to a temporary increase of circulating red cells in dogs but not in cats.

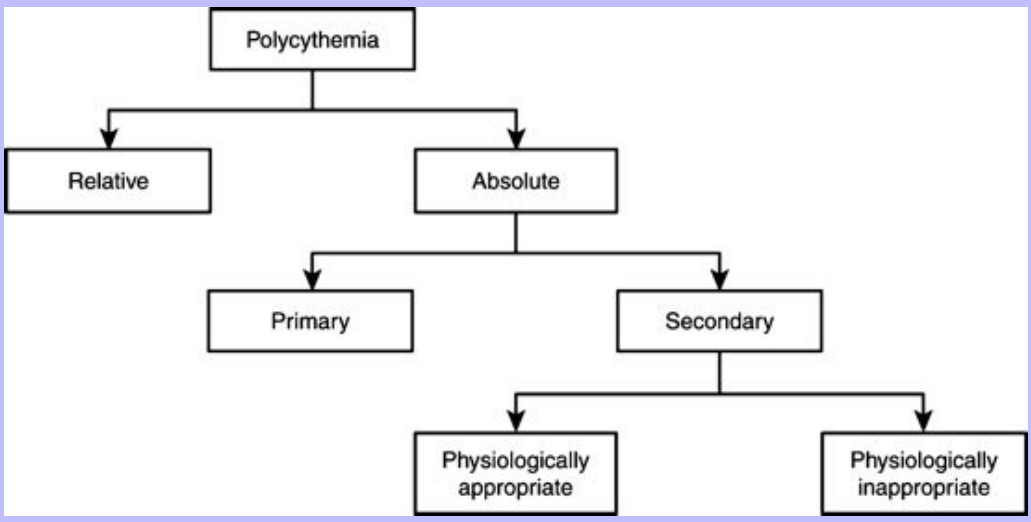
An increase in total RBC mass defines the absolute polycythemias. Absolute polycythemia is further divided into primary and secondary polycythemia, and the latter is further classified as physiologically appropriate or inappropriate (see Figure 60-1).

Under normal circumstances, the erythropoiesis and hence red cell mass is tightly regulated. The principal hormone that regulates erythropoiesis is erythropoietin (EPO). Renal hypoxia, but not the number or mass of circulating red cells, mediates the production of the hypoxia-inducible factor-1 (HIF-1). HIF-1 is a physiologic factor and the major factor of EPO gene transcriptional activation. The cellular site of EPO production in the kidney has been localized to interstitial renal cells in the inner cortex lying in immediate proximity to the proximal tubules. The number of cells that are recruited parallels the degree of hypoxia. As a consequence, EPO is released and its plasma level increases. The interaction of EPO with the EPO receptor results in stimulation of mitosis, differentiation, and prevention of apoptosis of erythroid progenitor cells. The resulting increase in circulating red cells enhances the oxygen-carrying capacity and, as a consequence, improves renal oxygenation. The oxygen sensor is turned off, HIF-1 and EPO levels decrease, and the regulatory loop is complete. The classification of absolute polycythemia is based on this physiology. In primary polycythemia an autonomous (i.e., EPO independent) production of red cells takes place, whereas in secondary polycythemia the red cell production is EPO dependent.

In veterinary medicine the term *primary polycythemia* is used synonymously with polycythemia vera. To the author's knowledge no attempts have been published to further characterize primary polycythemia in dogs or cats. Conversely, in human medicine polycythemia vera is one of several forms of primary polycythemia. The

underlying molecular basis of polycythemia vera has yet to be determined. Despite being considered a myeloproliferative disorder, the erythroid precursors mature into normal RBCs.

Figure 60-1 Classification of polycythemia.



Secondary appropriate polycythemia is a consequence of persistent hypoxia. This may be a physiologic response to living at high altitude. The most common cause of appropriate polycythemia is congenital heart defect with right-to-left shunting of blood. The mixing of venous and arterial blood causes systemic hypoxemia and activation of EPO production. Lung disease may cause hypoxia due to abnormal ventilation or ventilation-perfusion mismatch. The author is aware of one case of eosinophilic bronchitis in a cat with a PCV of 55% and mildly elevated serum EPO levels, but in general, respiratory disease causes mild polycythemia.

Hemoglobin function abnormalities that cause polycythemia are extremely rare in cats and in dogs. One cat with methemoglobinemia due to methemoglobin-reductase deficiency was noted to have moderate polycythemia (PCV 55%). Alterations of hemoglobin structure or decreases in 2,3-biphosphoglycerol that lead to polycythemia have been described in humans but not in cats or dogs.

Secondary inappropriate polycythemia refers to disease processes leading to elevated serum EPO levels without systemic hypoxia. Malignancies can produce EPO as a paraneoplastic syndrome; in a case of cecal leiomyosarcoma, immunohistochemistry and mRNA assays found the neoplastic cells to be the source of EPO origin. Renal disease (e.g., renal neoplasia, amyloidosis, infection, inflammation) may cause local hypoxia and trigger EPO synthesis.

Regardless of the cause, the consequence of an increased PCV is an increase in viscosity. As the red cells occupy the largest fraction of volume, hematocrit is a major determinant of blood viscosity. The rise in viscosity is not linear and becomes more pronounced above a PCV value of 50% to 60% (for dogs). Viscosity is elevated about twofold at a PCV of 70%. Depending on the degree of viscosity and local or systemic vascular hindrance, microcirculation decreases and may lead to local hypoxia or thrombosis. Most likely the neurologic symptoms seen in patients with absolute polycythemia are caused by impaired microcirculation in the brain. Thrombosis of cortical arteries associated with seizures and secondary polycythemia has been reported in a dog.

60.3 PRESENTING COMPLAINT AND PHYSICAL FINDINGS

The signs of relative polycythemia are usually obvious and depend on the severity of dehydration and the underlying disease process. The hematocrit generally is mildly increased (i.e., in dogs 55% to 65%) and returns to normal with fluid therapy. Depending on the amount of concomitant protein loss or shift, the plasma protein concentration will be low, normal, or high. Patients with absolute primary polycythemia have mainly signs related to hyperviscosity. More than half of the cases with primary polycythemia are presented for neurologic complaints such as seizures, ataxia, blindness, tremor, or behavior changes.

Animals with secondary polycythemia can have signs referable to hyperviscosity, to the underlying disease process, or both. Mucous membranes are typically hyperemic, and differentiation from cyanosis can be difficult.

60.4 DIAGNOSTIC PLAN

Treatment of a polycythemic animal is dependent on the cause; hence the type of polycythemia should be determined. Primary polycythemia is a diagnosis by exclusion; therefore all diagnostic steps are used to identify a relative or secondary cause of polycythemia (Figure 60-2).

60.4.1 Minimal Data Base

A complete blood count (CBC), a chemistry panel, and urinalysis are the minimal data base. This enables the clinician to distinguish absolute from relative polycythemia, to assess the degree of polycythemia, and to determine therapeutic success. In clinical practice it is rarely necessary or feasible to determine total red cell mass. On the other a hand, an absolute reticulocyte count is an inexpensive method to gauge the erythropoietic activity.

Appropriate polycythemia will show signs of dyspnea or cyanosis. In the latter case, signs might be restricted to caudal body parts, as seen with reversed patent ductus arteriosus (rPDA). Although an arterial blood gas (ABG) value should detect systemic hypoxia, the high viscosity can hamper sampling and reading. Hence it is recommended to stabilize the patient first (phlebotomy). Normal values are expected in all but appropriate polycythemia (exception: hemoglobinopathies where pO_2 is normal). If hypoxia is the cause of polycythemia, the changes are usually marked. Pulse oximetry can be used if ABG determination is not available. A low saturation (<80%) with a reliable recording and repeatability suggests hypoxia.

Abdominal ultrasound is used to detect renal disease, abdominal neoplasia, or both. Unspecific signs such as hyperechoic kidneys may be found in primary polycythemia. Splenomegaly is detected in up to 25% of cats and about 10% of dogs with primary polycythemia and might suggest primary polycythemia.

Thoracic radiographs and cardiac ultrasound examinations are directed toward identifying pulmonary and cardiac abnormalities. Mild changes such as myocardial hypertrophy or bronchointerstitial changes can be found in primary polycythemia and may be the result of hyperviscosity.

Routine bone marrow examination cannot distinguish primary from secondary polycythemia and hence are not useful. In either case the myeloid-erythroid ratio is normal or decreased. Growth performance of erythroid precursors in EPO-free culture medium can be helpful because erythroid cells of patients with polycythemia vera show normal growth, whereas erythropoiesis in secondary polycythemia is EPO dependent. However, this method is restricted to research laboratories, and few cases have been published in veterinary medicine.

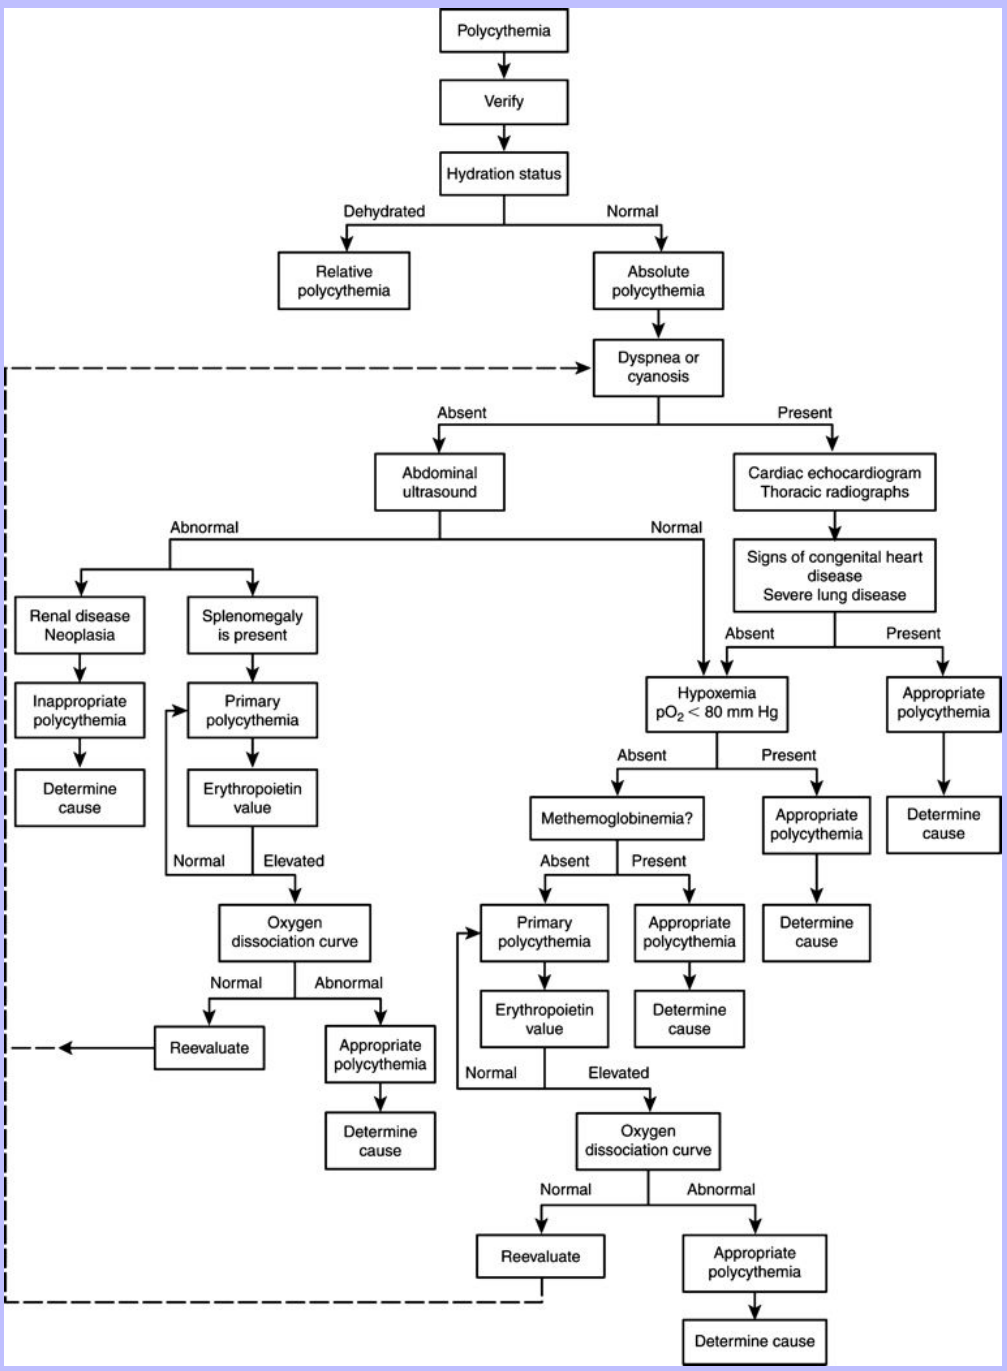
As primary and secondary polycythemia are EPO independent and EPO dependent respectively, it would appear that measurement of serum EPO levels is an appropriate test to differentiate the two forms. Several human test kits using either an enzyme-linked immunosorbent assay (ELISA) or radioimmune assay (RIA) method have been validated for animals. Although an increased serum EPO level is diagnostic for secondary polycythemia and values up to fiftyfold elevation have been found in secondary polycythemia, a low or normal serum EPO value occurs in about 50% of secondary polycythemia. This finding reduces the diagnostic accuracy of serum EPO level's determination.

60.4.2 Treatment and Prognosis

Relative polycythemia is treated with intravenous fluids and addressing the underlying cause. Phlebotomy is contraindicated in cases of relative polycythemia. Independent of the cause, absolute polycythemia is treated initially with blood-letting. This can be done by phlebotomy or by leeching. The latter has been used successfully in a cat as initial treatment when phlebotomy was not feasible. Four leeches reduced the hematocrit from 79% to 56% within 48 hours. Serial phlebotomies of 10 to 20 mL/kg blood are withdrawn until clinical symptoms have resolved or the target hematocrit is reached. In primary polycythemia the target hematocrit is below 55% for dogs and below 50% for cats. In cases of secondary appropriate polycythemia such as in rPDA the aim of treatment is resolving clinical signs of polycythemia and a higher hematocrit (60% to 70%) can be acceptable. A higher hematocrit might provide higher oxygen carrying capacity without causing hyperviscosity problems. If blood letting is inadequate, the myelosuppressing drug hydroxyurea is the treatment of choice. Multiple-dose regimens have been suggested in the literature. Some regimens use a loading dose starting with 30 to 50 mg/kg orally once a day; after 1 week the dose is reduced to 15 mg/kg/d, then titrated to effect. Other regimens propose using a maintenance dose such as 50 mg/kg every other day and titrating to effect. Side effects are reversible and include myelosuppression (thrombocytopenia), hair loss, and gastrointestinal (GI) upsets.

The prognosis for primary polycythemia is guarded, but survival for more than 6 years has been achieved in treated animals. The prognosis for secondary polycythemia depends on the cause. In cases of rPDA, survival of more than 4 years has been reported.

Figure 60-2 Algorithm for diagnostic approach to polycythemia.



61 CHAPTER • 61 Cyanosis

Jean-Paul Petrie

Cyanosis is a bluish discoloration of the skin and mucous membranes. It occurs due to an increased amount of reduced hemoglobin (RHb) within the erythrocytes and can be broken down into *central* and *peripheral* causes. In central cyanosis an unsaturation of arterial blood or the presence of a hemoglobin (Hb) derivative is seen. Peripheral cyanosis is a desaturation of blood due to a regional reduction in blood flow. It is not a sensitive indicator of the state of oxygenation, often not being recognized until the percent saturation of Hb in arterial blood (SaO_2) falls below 80%. Cyanosis is an emergency condition necessitating early recognition and careful diagnostic planning.

61.1 PATHOPHYSIOLOGY

Cyanosis can usually be detected when the mean capillary concentration of RHb is greater than 5 g/100 mL. An animal with a normal packed cell volume (PCV) must have an SaO_2 between 73% and 78%, or an arterial oxygen tension (PaO_2) of 39 to 44 mm Hg to have clinically detectable cyanosis. In general, the lower the total Hb concentration, the more SaO_2 may fall before the detection of cyanosis. An animal with a PCV of 18% (total Hb 6 g/dl) must have a PaO_2 of less than 30 mm Hg before cyanosis is detectable. This degree of arterial saturation is not compatible with life; therefore cyanosis is only detectable in this patient after death!

Secondary polycythemia is frequently seen with chronic arterial unsaturation contributing to the development of cyanosis at a higher SaO_2 compared with animals with a normal PCV. An animal with a PCV of 60% may appear cyanotic when their SaO_2 falls below about 87% or a PaO_2 of 55 mm Hg. Cyanosis can also be observed when nonfunctional Hb such as methemoglobin (MetHb) is present within the blood.

Peripheral cyanosis is due to a slowing of blood flow and a relative increased oxygen extraction from normally saturated arterial blood. Vasoconstriction, diminished peripheral blood flow, peripheral vascular disease, or venous obstruction can result in cyanosis. Peripheral vasoconstriction occurs as a compensatory mechanism with decreased cardiac output secondary to congestive heart failure or shock. Blood is diverted from the skin to more vital organs such as the brain, lungs, and heart.

61.2 DIFFERENTIAL DIAGNOSIS

Cyanosis is a clinical sign with many possible causes. Box 61-1 lists the common causes and classifications of central and peripheral cyanosis. Peripheral cyanosis results when a regional reduction of blood flow or venous obstruction exists. Causes of reduced capillary arterial blood flow include vasoconstriction (e.g., hypothermia, shock, low cardiac output), arterial thromboembolism (e.g., saddle thrombus, neoplasia, hypercoagulant states, arteritis), and low cardiac output (e.g., cardiac disease, arrhythmias, hypovolemia). Obstruction of venous drainage can be seen secondary to a tourniquet, venous thrombosis, or right-sided heart failure.

Central cyanosis occurs when SaO_2 decreases due to a reduced PaO_2. Reduced PaO_2 is seen with right-to-left shunting congenital cardiac disease, pulmonary disease, and when nonoxygen carrying Hb (e.g., methemoglobinemia) is present. When cyanosis is present in younger animals, congenital cardiac disease should be strongly suspected. Right-to-left shunting cardiac defects result in unoxygenated venous blood bypassing the lungs into the systemic circulation. Systemic vascular resistance normally decreases with exercise augmenting the degree of right-to-left shunting. Right-to-left shunting patent ductus arteriosus (PDA) may occur in the presence of

pulmonary hypertension and is associated with *differential* cyanosis. *Differential* cyanosis occurs when unoxygenated blood is delivered to the caudal portion of the body and oxygenated blood is delivered to the cranial portion of the body due to the anatomic location of the ductus. Severely impaired pulmonary function secondary to hypoventilation, airway obstruction, or poorly ventilated portions of the lung results in central cyanosis. This may occur acutely as with pneumonia, pulmonary edema, pleural effusions, and pulmonary thromboembolism, or it may occur with chronic pulmonary disease. Cyanosis resulting from primary pulmonary disease may occur at any age.

Increased amounts of nonoxygen carrying MetHb can result in cyanosis. MetHb is a normal product of Hb oxidation and is maintained at a normal concentration, approximately 1% of the total Hb concentration, by the enzyme MetHb reductase within the erythrocytes. Congenital MetHb reductase deficiency can occur but is rare in dogs and cats. Methemoglobinemia more frequently results from exposure to oxidants. Common oxidants associated with the production of MetHb include acetaminophen, benzocaine, phenazopyridine, and nitrates. If the MetHb content increases to 10% or greater, the patient's blood should have a noticeably brown coloration compared with bright-red blood.

61.3 APPROACH TO THE PATIENT WITH CYANOSIS

Initial clinical differentiation of cyanosis into central or peripheral causes is based on history, physical examination, and diagnostic testing (Figure 61-1). Peripheral vasoconstriction can occur with primary pulmonary pathology (e.g., pulmonary edema), and a mixture of both types of cyanosis may be present. Therefore all animals with peripheral cyanosis should be closely evaluated for central cyanosis.

History can sometimes provide useful information leading to the cause of the cyanosis. Recent exposure to oxidants (e.g., acetaminophen) or other toxic agents should be determined. The duration of the cyanosis may be helpful. Chronic cyanosis in a young animal is more likely associated with congenital heart disease. Information related to either chronic cardiac disease or pulmonary disease should be determined (e.g., coughing, labored breathing, fatigue, syncope, medications). Peripheral cyanosis may be associated with a history of acute pain, paresis, or lameness in the affected area.

219

220

61.3.1 Box • 61-1 Causes of Central and Peripheral Cyanosis

61.3.1.1 Central Cyanosis

Cardiac (right-to-left shunting)

- Intracardiac
  - Fallot's tetralogy
  - Atrial or ventricular septal defect with pulmonic stenosis or pulmonary hypertension
- Extracardiac
  - Reversed patent ductus arteriosus (PDA) (differential cyanosis)

Pulmonary arteriovenous fistulas

Pulmonary

Hypoventilation

Pleural effusion, pneumothorax

Respiratory muscle failure (e.g., fatigue, myopathy, or neurologic abnormalities)

Toxicity (e.g., sedative or anesthetic overdose)

Primary neurologic disease (e.g., neoplasia, inflammatory)

Obstruction

Laryngeal paralysis

Foreign body (e.g., laryngeal, tracheal)

Mass lesion of large airways (e.g., neoplasia, parasitic, inflammatory)

Inadequate oxygen concentration of inspired gas (e.g., high-altitude, anesthetic complication)

Ventilation-perfusion mismatch

Pulmonary thromboembolism

Pulmonary infiltration

Edema

Inflammation

Neoplasia

Acute respiratory distress syndrome (ARDS)

Chronic obstructive pulmonary disease or pulmonary fibrosis

Nonoxygen carrying hemoglobin (Hg) (e.g., methemoglobinemia)

61.3.1.2 Peripheral Cyanosis

Central cyanosis (e.g., congestive heart failure)

Decreased arterial supply

Peripheral vasoconstriction (e.g., hypothermia, shock)

Arterial thromboembolism

Low cardiac output

Obstruction of venous drainage

Tourniquet or foreign object (i.e., rubber band)

Venous thrombosis

Right-sided heart failure

Peripheral versus central cyanosis is often determined based on physical examination. Typically, peripheral cyanosis involves the extremities and skin, and central cyanosis is most readily apparent in the mucous membranes and tongue. An exception to this rule is differential cyanosis seen with a right-to-left shunting PDA as described earlier in the chapter. Causes for peripheral cyanosis can frequently be determined by careful examination of affected areas. Generalized peripheral hypothermia may be secondary to vasoconstriction. Massaging or gentle warming of a cyanotic extremity will increase blood flow and may abolish the cyanosis. Mechanical venous obstructions or deformities (e.g., rubber band, tumor) may be readily apparent. Typical findings associated with arterial thromboembolism include pain, pulselessness, paresis, pallor, and palpable coolness of the affected area.

Other physical examination findings including respiratory pattern, lung sounds, murmurs, arrhythmias, jugular venous distension, ascites, weakness, and pulse quality may provide information that is useful in differentiating a cardiac or respiratory cause for the cyanosis.

Arterial blood gases (ABGs) or pulse oximetry can be a reliable method to evaluate central cyanosis, suggesting the type of altered physiology present (Table 61-1). Specimens for ABG analysis should be compared on room air and 100% oxygen. Pulse oximetry can be used in clinics where immediate blood gas analysis is not available. If a satisfactory signal is recorded, there can be a good correlation for SaO_2 between pulse oximetry and ABG.

Radiographic analysis provides valuable information in determining the extent of pulmonary disease if present. Radiographs can differentiate the presence of common respiratory abnormalities including pulmonary edema, pleural effusion, pneumonia, pneumothorax, neoplasia, bronchiole disease, and potentially pulmonary thromboembolism. The cardiac silhouette and pulmonary vasculature can also be evaluated. Animals suspected of having congenital cardiac disease should have an echocardiogram and electrocardiogram performed as soon as possible.

61.4 THERAPY

Successful therapy of cyanosis relies on understanding the cause. Peripheral cyanosis can be indicative of a very serious condition but is not itself life threatening. Therapy should be directed toward resolution of the underlying disease process and supportive care.

Central cyanosis is often a life-threatening emergency. Immediate determination of airway patency is critical. If airway obstruction is present, either removing the obstruction (e.g., foreign body) or intubation by means of a tracheostomy or endotracheal tube should be performed bypassing the obstruction. Oxygen administration should be instituted as soon as possible via an oxygen mask, nasal cannula, oxygen cage, or tracheal intubation. Significant pleural effusion and pneumothorax require thoracocentesis. If primary pulmonary parenchymal disease is present, direct treatment aimed at relieving the disease process is required (e.g., diuretics should be administered to animals assessed as having cardiogenic pulmonary edema). Chronic obstructive pulmonary disease and pulmonary fibrosis are chronic conditions with limited treatment options. Oxygen supplementation in the home environment is impractical, and chronic management includes weight loss, exercise restriction, and bronchodilators. Future vasodilator therapies (i.e., oral prostacyclins) may provide more hopeful outcomes in these patients.

Right-to-left shunting congenital cardiac disease does not respond well to oxygen administration. In some cases where severe pulmonary hypertension is present, oxygen administration can result in pulmonary artery vasodilation and improve pulmonary blood flow resulting in less ventilation-perfusion mismatch. Cage rest is recommended. Polycythemia can be treated by phlebotomy or medications (e.g., hydroxyurea). In some cases of cyanotic heart disease, surgical palliation may be an option.

Figure 61-1 Algorithm for the differential diagnosis of cyanosis. All tentative diagnoses should be confirmed with appropriate specific testing.

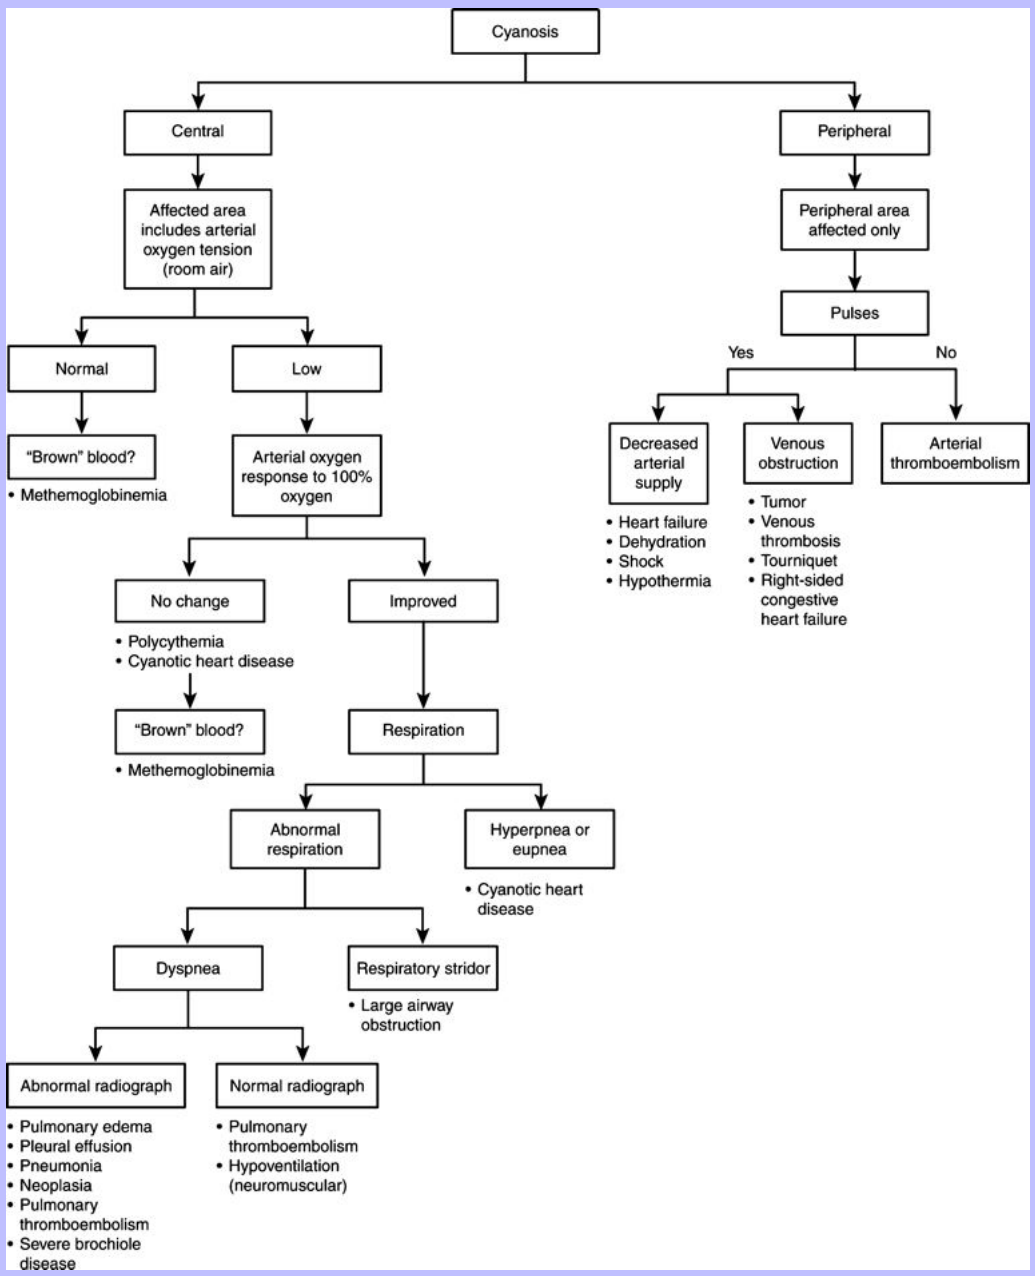


Table • 61-1 Arterial Blood Gas Patterns with Various Central Cyanotic Causes

PROBLEM	SaO_2 (ROOM AIR)*	PaO_2 (ROOM AIR)*	$PaCO_2$*	PaO_2 RESPONSE TO 100% O_2
Right-to-left shunting cardiac defect	↓↓	↓↓	Normal	–
Pulmonary parenchymal disease	↓↓	↓↓	↑	↑
Hypoventilation	↓	↓	↑↑↑	↑
Systemic hypoperfusion	↓	↓	Normal/↑	↑
Ventilation-perfusion mismatch	↓	↓	Normal/↓	↑
Methemoglobinemia	↓	Normal	Normal	–

* Normal SaO_2 (room air), ~97%; normal PaO_2 (room air),~100 mm Hg;normal $PaCO_2$ (room air), ~40 mm Hg.

Mild methemoglobinemia does not require specific therapy, but oxidant exposure should be eliminated. After elimination of oxidant exposure, erythrocytes can convert most of the MetHb back to Hb within 24 hours. MetHb cannot bind to oxygen; therefore supplementation with oxygen has limited value. In some cases where the exposure is more severe, the use of N-acetylcysteine or methylene blue may be indicated.

Neurologic or musculoskeletal causes of hypoventilation may require respiratory support including oxygen supplementation with or without mechanical ventilation. Temporary causes (e.g., sedative overdose, respiratory muscle fatigue) may only require short-term treatment. Therapy for pulmonary thromboembolism (PTE) includes oxygen supplementation and fluid therapy. Other more controversial therapies for PTE include anticoagulants and plasma.

In all causes of cyanosis, patients should be monitored for response to therapy by serial assessments of mucous membrane color, oxygen saturation, radiographs, blood gas values, and respiratory rate and effort.

62 CHAPTER • 62 Jaundice

Susan M. Eddlestone

***J**aundice* or icterus is a syndrome characterized by hyperbilirubinemia and deposition of bile pigment in the skin, mucous membranes, and sclera with resulting yellow appearance. Visually detectable jaundice may begin to occur when serum bilirubin exceeds 1.5 mg/dl, with most cases being clinically detectable closer to 2 mg/dl. Obvious jaundice is seen at serum bilirubin concentrations of 4 to 5 mg/dl or greater. Inspection of nonpigmented body surfaces including sclera, gingiva, sublingual tissues, soft palate, pinnae, periumbilical area, and mucosal surface of the penis or vagina allows easy recognition. Urine and feces may be a bright orange-gold to dark brown color due to increased excretion of bilirubin. The differential diagnoses of jaundice includes (1) prehepatic conditions such as hemolytic anemia, (2) hepatic diseases causing intrahepatic cholestasis, and (3) posthepatic causes such as biliary obstructive disease.

62.1 BILIRUBIN METABOLISM

Bilirubin is a waste product formed during the catabolism of hemoglobin (Hg) from aging or damaged erythrocytes or ineffective erythropoiesis, myoglobin, and a small portion of other hemoproteins in the body. Hg from erythrocytes contains more than 90% of all heme in the body. Aging erythrocytes are phagocytized by macrophages in the liver, spleen, bone marrow, and lymph nodes. Hg is released into the circulation and binds with haptoglobin, an $alpha_2$-globulin and acute-phase reactant that serves as a carrier protein. The Hb-haptoglobin complex is taken up by the reticuloendothelial (RE) system. Both Hg and the carrier proteins are degraded.

After degradation, heme is released from globin and transferred to heme oxygenase in the endoplasmic reticulum of the RE cell and in hepatocytes. Globin is degraded to amino acids and recycled by the body. Ferric (Fe^{3+}) heme is reduced to ferrous (Fe^{2+}) heme and then modified to a ferric iron-biliverdin complex. Released iron binds to iron-carrying proteins, transferritin, and ferritin for storage or recycling. Biliverdin is converted to unconjugated bilirubin via biliverdin reductase available in most mammalian cells, with highest concentration in liver, spleen, and kidney. The lipid soluble unconjugated bilirubin is released into the circulation and must bind with albumin for circulatory transport.

Albumin-bound unconjugated bilirubin binds to receptors on hepatocytes and is taken up and converted to the water-soluble conjugated bilirubin diglucoronide. This occurs by the reaction of bilirubin and two UDPEA molecules catalyzed by glucoronyl transferase to form bilirubin diglucoronide. Approximately 70% of bilirubin in the liver is in the unconjugated form due to the rate-limiting factors of enzymatic activity and availability of glucuronic acid needed for bilirubin conjugation. Conjugated bilirubin is excreted from the hepatocyte into the canaliculi to enter the bile by an active transport process that occurs against a large concentration gradient. This is the rate-limiting step in bilirubin metabolism in the dog and probably the cat.

The liver has a large reserve capacity for bilirubin excretion and can accommodate a thirtyfold to sixtyfold increase above normal. Only a small percent of conjugated bilirubin is refluxed into the circulation, with only a small percentage (<2%) filtered through the glomerulus. Conjugated bilirubin is carried in bile via the common bile duct and emptied into the duodenum. Colonic bacteria deconjugate and hydrogenate the conjugated bilirubin to unconjugated bilirubin. This produces the colorless pigment mesobilirubinogen that is oxidized to a group of colorless tetrapyrolles called *urobilinogens*. Urobilinogens are oxidized to urobilin, which has a yellow-orange color and stercobilin that gives the brown fecal pigment. Small amounts (10% to 20%) of urobilinogen are absorbed from the intestine, with 95% circulating back to the liver for hepatic uptake and 5% excreted through the

kidneys. Conjugation of bilirubin inhibits small intestinal absorption, thus impeding the enterohepatic circulation. Increased deconjugation occurs during bacterial overgrowth of the small bowel with colonic anaerobes, leading to increased enterohepatic turnover of bilirubin pigments. Feces lacking brown pigment are referred to as *acholic* and may be caused by decreased bile flow or deficient intestinal bacterial activity. Complete biliary obstruction would be required for development of acholic stools due to the small amount of bile pigments necessary to impart normal color. Absence of fecal pigment develops 7 to 10 days after complete bile duct occlusion by which time clinical jaundice is obvious.

62.2 DIFFERENTIAL DIAGNOSIS

Prehepatic jaundice is caused by intravascular or extravascular hemolysis (see Figure 62-1). The greatly increased rate of erythrocyte destruction and subsequent catabolism of Hg causes an increased production of bilirubin. Serum unconjugated bilirubin is increased transiently, with both unconjugated and conjugated bilirubin increased by the time the dog or cat is clinically jaundiced. An increased production of bilirubin accompanied by reduced hepatic clearance has been shown to be present in dogs with severe Coomb's-positive hemolytic anemia. In general, hyperbilirubinemia due to hemolytic anemia without underlying hepatic disease is usually mild with serum bilirubin values below 10 mg/dl.

Hepatic causes of jaundice may occur when disruption takes place in any step of bilirubin hepatocellular transport. Inflammatory conditions of the liver can impede bile flow causing swelling and occlusion of canaliculi, bile ductules, and small bile ducts. Membrane permeability is increased with bilirubin refluxing into the sinusoidal space in conjunction with bilirubin back diffusing into hepatocytes. In addition, canalicular excretion of bilirubin may become compromised.

Chronic inflammation occurring in periportal areas (zone 1) can cause occlusion of smaller bile ducts. Chronic inflammation within bile ducts leading to bile duct hyperplasia or biliary cirrhosis may also cause mechanical obstruction. *Cholestasis* is the term applied to conditions in which bile flow is impaired. Paranchymal lesions occurring away from periportal areas (zone 3) tend not to cause hyperbilirubinemia until later in the disease, when hepatocellular transport of bilirubin fails as opposed to the mechanical occlusion of bile flow. Formation of regenerative nodules due to hepatic injury may cause hyperbilirubinemia in severe cases. Bile flow may be impaired due to compression by fibrotic tissue that results in disruption of normal hepatic architecture. Congenital portosystemic vascular anomalies causing hepatic atrophy do not usually cause hyperbilirubinemia even though other indicators of liver function may become affected (hypoalbuminemia, hypoglycemia, decreased blood urea nitrogen [BUN]).

Primary conditions associated with jaundice in the dog and cat include sepsis. Sepsis causes hyperbilirubinemia due to the production of cytokines that interfere with the transport of bilirubin across the canalicular membrane. Heritable disorders of bilirubin metabolism have not been reported in the dog or cat.

Posthepatic or obstructive jaundice may be caused by intraluminal or extraluminal mechanical occlusion of the larger ducts of the biliary tree. The most common causes are pancreatitis and neoplasia in and around the gallbladder, cystic duct, and common bile duct. Less frequent causes are primary disorders of the walls of the biliary system that obstruct the flow of bile. Inspissated bile and choleliths formed secondary to biliary wall inflammation can obstruct bile flow. Bile duct rupture with bile spillage into the peritoneal cavity can cause extrahepatic jaundice.

62.3 CLINICAL SIGNS

The canine or feline patient with prehepatic jaundice due to hemolytic anemia may have anorexia, pale mucous membranes, increased respiratory rate, lethargy, weakness, or collapse. Mucous membranes may be slightly yellow to orange in color due to the combination of pallor and hyperbilirubinemia. Early intravascular hemolysis may cause a port wine-colored urine due to hemoglobinuria if the presence of bilirubin in the urine has not yet occurred. Historical and clinical findings in canine and feline liver disease are nonspecific but may include anorexia, weight loss, vomiting, diarrhea, and abdominal pain. Severely affected animals may be dehydrated, hypovolemic, or have neurologic signs. Posthepatic diseases causing biliary obstruction may have anorexia, depression, weight loss, vomiting, or diarrhea occurring 1 to 3 weeks prior to presentation.

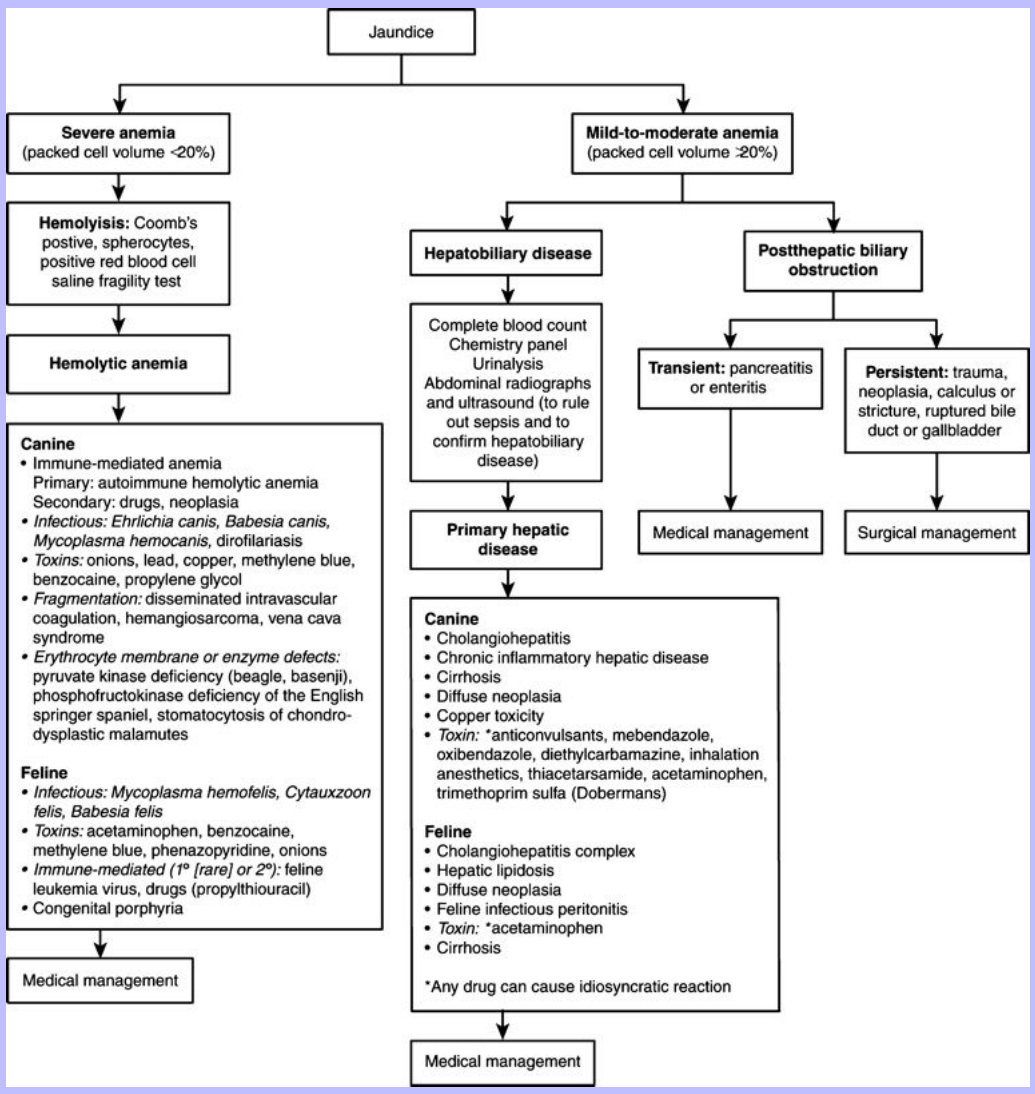
62.4 DIAGNOSTIC PLAN

Clinical assessment of the jaundiced dog or cat begins with historical and physical exam findings described previously. Laboratory analysis can distinguish prehepatic jaundice from hepatic and posthepatic jaundice by the presence of severe anemia (packed cell volume [PCV] <20%) and evidence of hemolysis. In the absence of blood loss, hemogram changes consistent with hemolysis and regenerative anemia include low PCV and hematocrit (HCT) (< 20%), low erythrocyte number, increased mean corpuscular volume (MCV), reticulocytosis, poikilocytosis, anisocytosis, regenerative leukocytosis, nucleated erythrocytes, and enlarged platelets. In primary immune-mediated disease causing erythrocyte destruction, spherocytes, and autoagglutination may be seen, as may a delayed regenerative response. Hepatocellular disease occasionally results in hemolysis associated with erythrocyte membrane alterations, but this rarely causes severe anemia or contributes significantly to increased serum bilirubin concentration.

Once hemolysis is ruled out, hepatic and posthepatic diseases need to be considered. Serum biochemical analysis allows evaluation of serum total bilirubin and liver enzymes. Increased liver enzymes (alanine aminotransferase [ALT], aspartate aminotransferase [AST], alkaline phosphatase [ALP], gamma-glutamyltransferase [GGT]) are found in primary hepatic disease, in secondary hepatic diseases (sepsis, pancreatitis), and in posthepatic diseases. Therefore these enzymes do not allow differentiation between these categories. Measurement of unconjugated (indirect) and conjugated (direct) bilirubin to distinguish between prehepatic, hepatic, and posthepatic causes of jaundice is not useful in dogs and cats. Serum bile acids will be simultaneously increased with bilirubin in jaundiced animals due to the interruption of the enterohepatic circulation of bile acids noted in hepatic and posthepatic diseases. Urinalysis can confirm the presence of bilirubinuria in discolored urine. Male dogs and occassionally female dogs may normally have small amounts of bilirubin present in urine; however, large amounts in conjunction with hyperbilirubinemia are diagnostic for jaundice. Bilirubinuria in the cat is always significant and indicates hyperbilirubinemia due to a higher renal threshold and an inability of the cat to conjugate bilirubin at the renal tubule, as compared with the dog. Hemoglobinuria may be seen in patients with intravascular hemolysis.

223
224

Figure 62-1 Algorithm for differential diagnoses of jaundice.



The initial diagnostic approach to differentiate hepatic from posthepatic disease is the noninvasive use of abdominal radiographs and abdominal ultrasound to identify any obvious structural changes in the biliary tract that may suggest posthepatic biliary obstruction such as an enlarged gallbladder or a tortuous, dilated common bile duct. Duodenal and pancreatic masses and pancreatitis may be suggested on ultrasound. Hepatomegaly, hepatic masses, or changes in hepatic echogenicity on ultrasound examination may indicate liver disease. Ultimately, exploratory celiotomy or laparotomy may be indicated to examine the liver and biliary tract and to biopsy the liver for histologic diagnosis of hepatic disease. Celiotomy may also be indicated when corrective surgery for obstructive masses or biliary reconstruction to preserve bile flow is needed.

62.5 TREATMENT AND PROGNOSIS

The specific treatment for jaundice is dependent on the underlying cause. Treatment for hemolytic anemia is directed at the primary initiator of hemolysis. Toxic, infectious, or immune-mediated causes are treated with specific therapies that include specific antidotes, antibiotics, and immunosuppressive therapies, respectively. Supportive care including red blood cell (RBC) or Hg transfusion may be needed in severe cases of anemia. Prognosis is good for toxic and infectious causes of hemolysis if treated appropriately. Prognosis for immune-mediated disease is guarded due to the resistant and relapsing nature of the disease in dogs.

Treatment of specific hepatic diseases requires a liver biopsy for definitive diagnosis. Infectious, toxic, canine copper storage disease; chronic immune-mediated liver disease; feline hepatic lipidosis; and cholangiohepatitis carry fair-to-good prognoses when treated with appropriate therapy. Hepatic neoplasia and cirrhosis carry a much poorer prognosis. Supportive therapy of liver disease may include intravenous fluids to rehydrate the dog or cat and promote forward bile flow, vitamin K1 to replace deficiencies due to cholestasis, vitamin E for antioxidant properties, vitamin B complex, and S-adenosyl for replacement of intrahepatic glutathione levels to restore mechanisms of hepatocyte metabolism.

Treatment of chronic cholestasis associated with chronic hepatic or posthepatic disease may include the use of the cholerectic, ursodeoxycholic acid, a hydrophilic bile acid that displaces the more toxic hydrophobic bile acids from the bile acid pool that can cause hepatocyte membrane damage. Posthepatic obstructive disease is almost always surgically managed except for pancreatitis, which is usually responsive to medical therapy. Prognosis of postobstructive diseases is good if appropriately managed, except for necrotizing pancreatitis and neoplasia that carry a poorer prognosis.

63 CHAPTER • 63 Bleeding Disorders: Epistaxis and Hemoptysis

Tracy Gieger

63.1 EPISTAXIS

Epistaxis is defined as hemorrhage originating from the nose. The following areas should be emphasized when evaluating a patient with epistaxis (Figure 63-1).

63.1.1 Signalment

Young animals that roam are susceptible to trauma, infections, and foreign body (FB) inhalation. Intact dogs that roam are susceptible to transmissible venereal tumors. Purebred dogs may be affected with von Willebrand's disease (vWD) or coagulation factor deficiencies. Immune-mediated diseases occur most commonly in middle-aged animals. Nasal tumors are more common in animals over 8 years of age, although nasal lymphoma may occur in younger cats. Nasopharyngeal polyps occur more often in young cats. Brachycephalic cats are more susceptible to chronic viral respiratory infections.

63.1.2 Environment

Outdoor pets are more susceptible to nasal trauma, parasitic and fungal infections, rodenticide toxicity, and FB inhalation. The owner should be questioned about travel to areas endemic for fungal and rickettsial organisms, leishmaniasis, and hepatozoonosis.

63.1.3 Time Course

Nasal trauma results in acute-onset and often severe bleeding that resolves with supportive measures and does not recur. FB inhalation, most commonly wood splinters or grass awns, often causes an acute onset of epistaxis, sneezing, and pawing at the face; however, if foreign objects remain lodged in the nasal cavity, chronic nasal discharge secondary to granuloma formation may result. Chronic or intermittent epistaxis is more common with oronasal fistulas, fungal rhinitis, and nasal tumors; often these diseases begin with mucoid nasal discharge that progresses to epistaxis later in the course of disease. Allergic rhinitis may cause seasonal epistaxis.

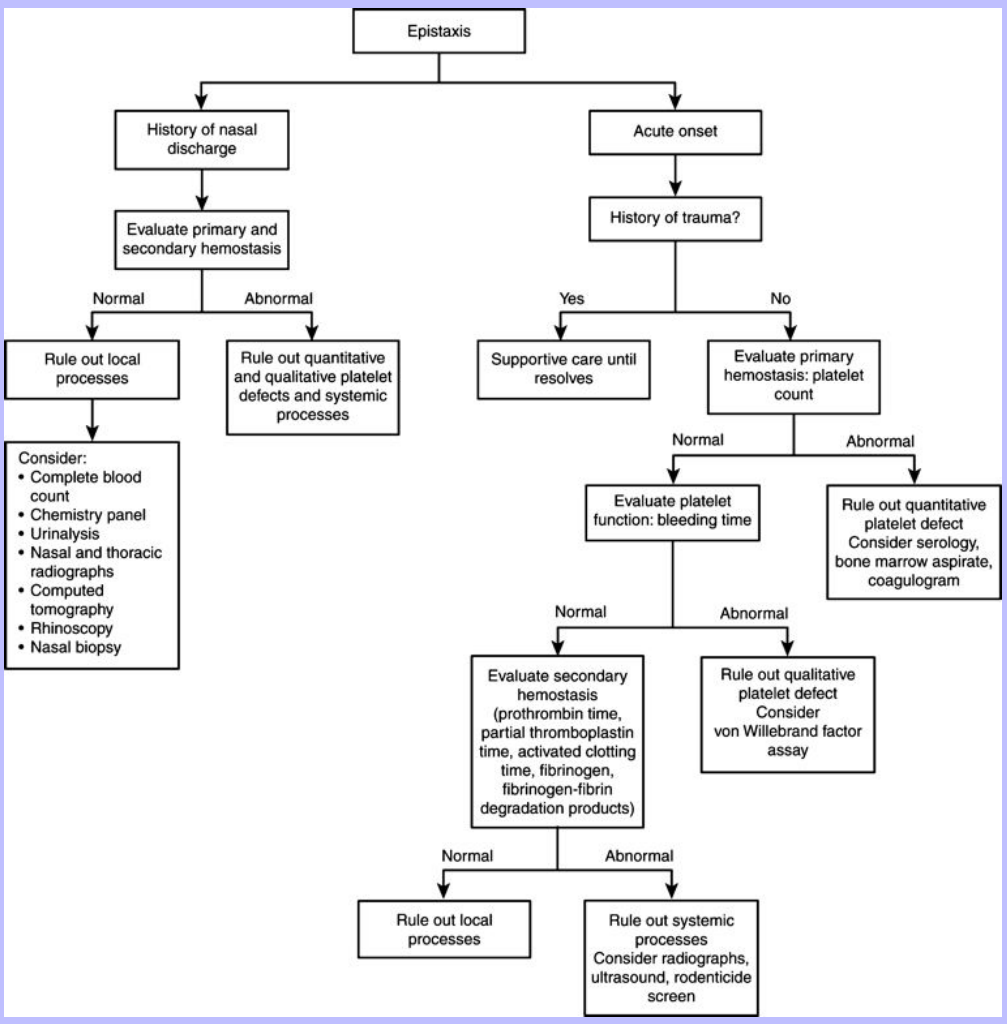
63.1.4 Characterization of Epistaxis

Many intranasal diseases such as nasal tumors begin with unilateral epistaxis that becomes bilateral as the disease progresses, disrupting the nasal septum. Bilateral epistaxis often indicates “extranasal” causes such as coagulopathies, hypertension, thrombocytopenia, and thrombocytopathia (a defect in platelet function).

63.1.5 History of Bleeding from Other Sites

Historical bleeding after tooth loss or elective neutering may indicate a congenital coagulation factor defect or platelet disorder. Animals with petechia, mucosal bleeding, melena or fundic hemorrhages are likely to have a defect of primary hemostasis (platelets), whereas those with hemarthrosis, hematomas, or bleeding into body cavities are likely to have a defect of secondary hemostasis (coagulation factors). Melena and hematemesis may occur when blood from the nasopharynx is swallowed.

Figure 63-1 Algorithm for epistaxis.



63.1.6 Concurrent Problems Not Related to the Nasal Cavity

Central nervous system (CNS) dysfunction may occur with hyperviscosity syndromes or nasal tumors invading the brain. Polyuria and polydipsia are seen with hyperadrenocorticism, chronic renal failure, and hyperthyroidism which uncommonly cause epistaxis secondary to hypertension. A history of dental disease may support oronasal fistula formation as a cause of epistaxis.

63.1.7 History of Drug and Vaccine Administration

Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit platelet function; trimethoprim sulfa and other antibiotics may induce an immune-mediated platelet destruction, whereas chemotherapeutic agents, estrogens,

and phenylbutazone may cause myelosuppression and thrombocytopenia. Immune-mediated thrombocytopenia is an uncommon sequela to vaccination.

226

227

63.2 PHYSICAL EXAMINATION

The clinician should examine the face for visual or palpable asymmetry, which is most commonly secondary to neoplasia. A glass slide may be held up to the nose to document airflow through the nostrils by the presence of condensation on the slide. Ulceration and depigmentation of the nasal planum may be seen with aspergillosis or squamous cell carcinoma. Polypoid masses extending from the nares are seen with rhinosporidiosis and cryptococcosis. Cats with nasal cryptococcosis often have a characteristic convexity of the nose ("Roman nose"). The mouth should be examined for palate deformity, masses, oronasal fistulas, or loose teeth. Nasal tumors often cause facial or hard palate deformity, inability to retropulse the globe, or epiphora. A fundic examination may reveal chorioretinitis, signs of hypertensive retinopathy, or hyperviscosity. Regional lymph nodes should be examined for enlargement secondary to infectious organisms, inflammation, or metastatic neoplasia. Evaluation of the skin, body cavities, and joints will help to eliminate evidence of a coagulopathy.

63.3 DIFFERENTIAL DIAGNOSIS

The differential diagnosis for epistaxis can be divided into *systemic* and *local* causes (Box 63-1). Local diseases may progress and develop systemic complications that can exacerbate bleeding.

63.4 SYSTEMIC PROCESSES

Hemostatic defects or increased capillary fragility are mechanisms of epistaxis. Primary hemostatic defects (platelet plug formation) include thrombocytopenia or thrombocytopathia. Mechanisms of thrombocytopenia include decreased production, increased destruction, sequestration, and increased consumption. Spontaneous bleeding is uncommon unless the platelet count is less than or equal to 50,000/μL. Decreased production of platelets can occur secondary to viral, rickettsial, protozoal, parasitic, or bacterial infections; to neoplastic conditions resulting in myelophthisis; to drug administration; or to immune-mediated phenomena. Increased destruction of platelets may be immune mediated (primary or secondary) or related to microangiopathy (seen with hemangiosarcoma). Sequestration of platelets in the spleen, liver, or large vascular tumors results in thrombocytopenia. Increased platelet consumption is seen with disseminated intravascular coagulopathy (DIC), vasculitis, and hemorrhage. Thrombocytopathia may be primary, such as in vWD, or secondary to uremia, dysproteinemias (associated with ehrlichiosis, multiple myeloma, among others), or drugs such as NSAIDs. Secondary coagulation (coagulation factor) defects such as Hemophilia A and B are uncommon congenital abnormalities that vary in severity. Acquired coagulopathies include anticoagulant rodenticide toxicity and hepatic failure (with decreased coagulation factor production). Increased capillary fragility with subsequent rupture can result from hypertension, neoplasia invading blood vessels, hyperviscosity syndromes, hyperlipidemia, and thromboembolic disease.

63.5 LOCAL PROCESSES

Local processes ("intranasal" causes) are the most common cause of epistaxis. Nasal adenocarcinomas are more common in dogs, whereas cats are more often affected with nasal lymphoma and benign polyps. Bacterial rhinitis is almost always secondary to inflammation or damage to the nasal mucosa, although *Bordetella, Pasteurella,* and *Mycoplasma* spp. may be primary pathogens. Aspergillosis is more common in dogs, and nasal cryptococcosis is seen more frequently in the cat. Animals with oronasal fistulas may have nasal discharge or epistaxis. Nasal

parasites are highly irritating and can cause severe epistaxis and intractable head rubbing and itching. Viral diseases rarely result in epistaxis in dogs, and cats with upper respiratory infections uncommonly develop chronic nasal discharge and sneezing that results in intermittent epistaxis. Allergic (eosinophilic) and lymphoplasmacytic rhinitis are uncommon immune-mediated phenomena that are often steroid responsive. Arteriovenous malformations can rupture, causing sudden-onset epistaxis.

63.6 DIAGNOSTIC PLAN

63.6.1 Complete Blood Count Including Platelet Count

Regenerative anemia indicates a bone marrow response to bleeding, but with chronic epistaxis, iron deficiency and a nonregenerative anemia may occur. Schistocytes are observed with microangiopathies that occur with hemangiosarcoma and DIC. Leukocytosis is anticipated with chronic inflammation or infection, and leukopenia suggests chronic ehrlichiosis, cytotoxic drug administration, or sepsis. Thrombocytopenia is the result of increased destruction or consumption, sequestration, or decreased production of platelets. Evaluation of a blood smear may be useful while awaiting laboratory results: normal dogs and cats have 8 to 29 platelets/100X oil immersion field. If the platelet count is 20,000/μL, approximately one platelet per oil immersion field is present. Macroplatelets suggest regeneration associated with peripheral platelet destruction or consumption; these platelets may be more functional than normal, explaining why dogs with platelet counts less than 10,000/μL often do not bleed.

63.6.2 Chemistry Profile

Panhypoproteinemia may develop with chronic blood loss. Hyperglobulinemia is associated with neoplasia or chronic infections, and serum protein electrophoresis helps to dis-tinguish between monoclonal or polyclonal gammopathy. Monoclonal gammopathies occur with multiple myeloma, chronic ehrlichiosis, lymphoma, leukemias, and macro-globulinemia. Evidence of renal, hepatic, or endocrine disease identifies general causes of disease that can cause or exacerbate epistaxis.

63.6.3 Urinalysis

Indirectly, the urine samples provide clues to potential causes of epestosis, such as bladder mucosal bleeding, and hematuria or glomerulonephropathies may be seen with thrombocytopenia and thrombocytopathia.

63.6.4 Hemostatic Studies

Buccal mucosal bleeding time (BMBT) is a useful in-hospital test of platelet function and is reliable if the platelet count is >100,000/μL. If this test is abnormal, searching for a cause of thrombocytopathia is indicated, including a von Willebrand's titer and evaluation for secondary causes of platelet function defects. Coagulation studies such as partial thromboplastin time (PTT), prothrombin time (PT), and activated clotting time (ACT) can be abnormal if the platelet count is <10,000/μL and should be considered in cases of epistaxis in which platelet abnormalities have been ruled out. If these coagulograms are abnormal, tests for specific clotting factors and a PIVKA (proteins inhibited by vitamin K antagonists) should be considered. A coagulogram should also include fibrinogen, fibrin degredation products (FDPs), and an antithrombin III level to examine for evidence of DIC.

63.6.4.1

Box • 63-1 Causes of Epistaxis

63.6.4.1.1

Systemic Processes ("Extranasal" Disease)

Thrombocytopenia (quantitative platelet abnormality)

- Decreased production
  - Infectious: Ehrlichiosis, feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), Rocky Mountain spotted fever, hepatozoonosis, septicemia, endotoxemia, leishmaniasis
  - Drugs: Cytotoxic drugs, modified live virus vaccines, estrogens
  - Neoplasia: Myelophthisis secondary to myeloproliferative or lymphoproliferative diseases
  - Immune-mediated: Antibodies against megakaryocytes
  - Other: Bone marrow aplasia, cyclic thrombocytopenia, myelofibrosis, hyperestrogenism (secondary to Sertoli cell and granulosa cell tumors), myelodysplasia, toxins, osteosclerosis, idiopathic
- Increased destruction
  - Immune mediated: Idiopathic or secondary to drugs, neoplasia, infection
  - Microangiopathy: Shearing of platelets; associated with hemangioma/hemangiosarcoma
- Sequestration
  - Neoplasia: Large vascular tumors
  - Splenomegaly or splenic torsion
  - Hepatomegaly
- Increased consumption

Disseminated intravascular coagulopathy (DIC)

Vasculitis: Rocky Mountain spotted fever, endotoxemia, neoplasia, heartworm disease, bacteremia

Hemorrhage-induced thrombocytopenia

Thrombocytopathia (qualitative platelet defect)

Congenital: von Willebrand's disease (vWD), platelet procoagulant activity deficiency in German shepherd dogs, Glanzmann's thrombasthenia in Great Pyrenees, Basset hound thrombopathia

Acquired: vWD (associated with hypothyroidism), uremia, dysproteinemia (associated with multiple myeloma, ehrlichiosis, leishmaniasis), drugs (NSAIDs)

Coagulation factor deficiency

Congenital: Hemophilia A and B, others

Acquired: Anticoagulant rodenticide toxicity, liver failure, DIC

Increased capillary fragility

Hypertension: Primary or secondary to chronic renal failure, glomerulonephropathies, pheochromocytoma, hyperadrenocorticism, hyperthyroidism, heart disease

Hyperviscosity syndrome: Secondary to multiple myeloma, ehrlichiosis, polycythemia (primary or secondary to hypoxia or neoplasia), leukemias

Hyperlipidemia

Thromboembolic disease

Neoplasia invading blood vessels

63.6.4.1.2 Local Processes (“Intranasal” Disease)

Trauma

Neoplasia

Epithelial: Adenocarcinoma, undifferentiated carcinoma, squamous cell carcinoma, polyps

Mesenchymal: Chondrosarcoma, fibrosarcoma, hemangiosarcoma, osteosarcoma, melanoma

Round cell: Lymphoma, transmissible venereal tumor, mast cell tumor

Infection

Fungal: *Cryptococcus*, *Aspergillus, Penicillium*, *Rhinosporidium*, *Exophiala jeanselmi*, phaeohyphomycosis

Parasitic: *Pneumonyssus, Eucoleus, Cuterebra*, *Linguatula*, *Capillaria*

Bacterial: Primary *(Bordetella, Pasteurella, Mycoplasma)* or secondary

Viral: Canine infectious tracheobronchitis, canine distemper, feline viral rhinotracheitis, calicivirus

Inflammation

Lymphoplasmacytic: Primary or secondary

Eosinophilic: Allergic rhinitis

Dental disease

Tooth root abscess

Oronasal fistula

Foreign body (FB)

Vascular malformation

228

229

63.6.5 Serology

Ehrlichiosis and Rocky Mountain spotted fever are diagnosed with serology. *Aspergillus* titers are nonspecific and seldom useful. Latex agglutination tests for *Cryptococcus* capsular antigen are useful for diagnosis and therapeutic monitoring. Feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) tests are indicated if the viral status is unknown. Thyroxine levels should be part of the minimal data base for cats over 6 years of age.

63.6.6 Imaging

Imaging studies are performed prior to rhinoscopy to avoid difficulties in interpreting iatrogenic lesions (i.e., bleeding induced by biopsy). Images should be examined for asymmetry and bone lysis, which can localize the disease, determine the severity of involvement, and guide biopsy procedures. Nasal radiographs should include lateral, oblique, open-mouth, ventrodorsal, intraoral, and frontal sinus views. Computed tomography (CT) is superior to radiographs for nasal disease because it allows visualization of bony and soft tissue lesions and it images all areas including turbinates, nasal septum, cribriform plate, and sinuses. Uptake of contrast material by tumors can distinguish them from mucus collections.

63.6.7 Rhinoscopy

If a coagulopathy has been ruled out as a cause for epistaxis, rhinoscopy is performed under general anesthesia (with a cuffed endotracheal tube in place) after imaging studies are completed. The least affected side should always be examined first, and the evaluation should begin ventrally and move dorsally in case of iatrogenic hemorrhage. Thorough evaluation of the oropharynx and oral cavity should be performed. Instruments including dental mirrors, spay hooks, and otoscopes provide limited visualization of the nasal cavity but may assist in the diagnosis of foreign bodies and large tumors. Rigid or flexible endoscopes are required for a full examination. The entire nasal cavity including the frontal sinuses (if possible) should be examined for masses, foreign bodies, fungal or inflammatory plaques, and polyps. The distance from the medial canthus to the end of the nostril should be marked on the instrument prior to entry into the nose to avoid penetrating the cribriform plate.

63.6.8 Nasal Swabs, Flushing, and Biopsy

Cryptococcus can be identified on cytology of nasal discharge with use of India ink. Flushing or biopsy of the nasal cavity is performed after the oropharynx has been packed with gauze sponges and the head is positioned ventrally to avoid aspiration of blood or fluid. A flexible endoscope or red rubber catheter retroflexed behind the soft palate may be used to flush saline through the nose. FBs may be retrieved, and parasitic ova may be evident on examination of the fluid. Biopsy should be performed after rhinoscopy, and it may be performed "blindly" if visualization of the nasal cavity is not possible. If lesions are not seen on imaging or rhinoscopy, multiple biopsies throughout the nose should be obtained. Biopsy instruments include alligator or pituitary-cup forceps, and should not be advanced past the medial canthus. Incisional biopsy or aspiration of hard palate defects or areas of facial deformity may be useful. Complications of nasal biopsy that should always be anticipated include life-threatening hemorrhage, aspiration of blood, and neurologic signs if the cribriform plate is violated.

63.6.9 Culture

Primary bacterial rhinitis is rare, but secondary infection is common. Nasal cultures may be obtained through nasal swabs, flush, or tissue culture; the latter is most likely to yield true representation of the nasal cavity flora. A superficial nasal swab is likely to yield growth of normal flora, including *Escherichia coli, Streptococcus* spp., *Pasteurella* spp., and others. The growth of only 1 to 2 species is more likely to represent an abnormality, whereas growth of multiple bacteria is usually normal flora; therefore, the laboratory should be advised to report all growth. Treatment with antibiotics may improve clinical signs and can give a false sense of disease resolution to the veterinarian. The growth of *Aspergillus* and *Penicillium* should be interpreted in light of other

findings such as fungal plaques and radiographic evidence of bony destruction to make a diagnosis of fungal rhinitis because these organisms may represent normal flora.

63.6.10 Blood Pressure

Blood pressure evaluation is indicated if hypertension is suspected as a contributing cause for epistaxis; it is commonly performed using indirect Doppler or oscillometric methods (see Chapter 28).

63.6.11 Exploratory Rhinotomy

If all other diagnostic procedures have failed to obtain a diagnosis or if an FB cannot be removed via rhinoscopy, exploratory rhinotomy may be indicated. Potential benefits of surgery must outweigh potential complications, including hemorrhage, subcutaneous emphysema, inadvertent entry into the brain, and recurrent nasal cavity infections.

63.7 TREATMENT

The goal of treatment is to control epistaxis until a definitive diagnosis and therapeutic plan can be determined. Treatments include cage rest, ice packs, and application of pressure. Sedation may aid in controlling hemorrhage. Sedatives such as diazepam and butorphanol at low doses may help to relieve anxiety, but caution should be used to avoid causing hypotension. In animals that have suffered trauma or are obtunded, suctioning blood from the oropharynx is indicated to prevent aspiration of blood. In severe cases, general anesthesia and packing the nasal cavity and oropharynx with dilute epinephrine-soaked (1:100,000) sponges or tampons, ligation of the external carotid artery on the affected side, or both might help to control bleeding. If a coagulopathy is suspected, transfusions are indicated. In thrombocytopenic animals, transfusions very rarely supply adequate platelet numbers to stop bleeding.

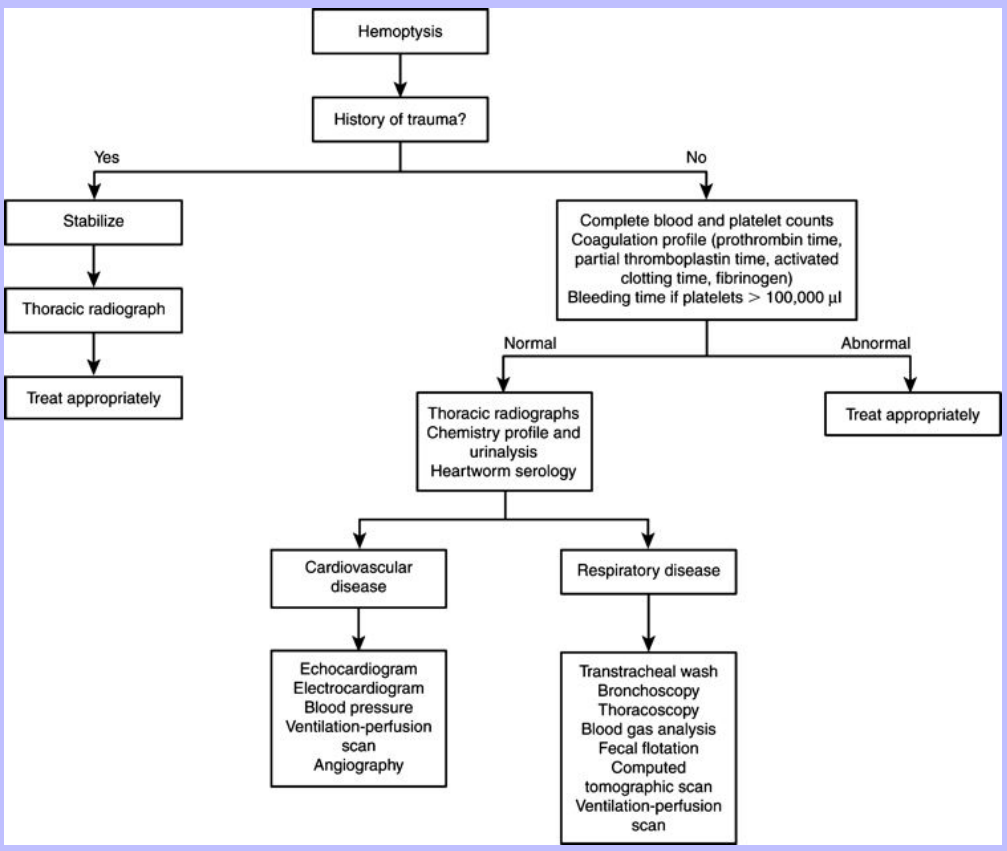
63.8 HEMOPTYSIS

Hemoptysis (from Greek *hamia,* "blood" + *ptysis,* "spitting") is defined as expectoration of blood or bloody mucus from the respiratory tract at or below the larynx. Detection and confirmation of hemoptysis may be difficult in dogs and cats because they do not expectorate after coughing. To direct the diagnostic and therapeutic process, it must be determined that the coughed up material is actually blood, the blood was coughed up and not regurgitated or vomited, and the blood originated from the lower respiratory tract. Hemoptysis is generally a serious condition that requires aggressive management. The following areas should be emphasized when evaluating a patient with hemoptysis (Figure 63-2).

63.8.1 History

Information regarding cardiac and pulmonary abnormalities, medications (including heartworm preventative), toxin exposure, and travel history are essential. The owner should be questioned regarding exercise intolerance, dyspnea, syncope, and cough in the patient. Animals that swallow blood from the upper gastrointestinal or respiratory tracts may experience hematemesis, which can be mistaken for hemoptysis. Prior bleeding episodes suggest a primary or secondary coagulopathy. Animals with a history of cough prior to onset of hemoptysis may have chronic diseases such as bronchitis, neoplasia, heartworm disease, or left-sided heart failure.

Figure 63-2 Algorithm for hemoptysis.



63.8.2 Signalment

Older dogs and cats are more likely to suffer from primary lung and metastatic neoplasia.

63.8.3 Environment

Dogs and cats in specific geographic areas are more susceptible to infections with heartworms and lungworms. Outdoor animals are more susceptible to trauma, anticoagulant rodenticide ingestion, and FB inhalation. Specific fungal diseases are endemic in limited regions.

63.8.4 Nature of the Expectorated Material

If the blood is mixed with sputum, suppurative lesions such as bronchopneumonia are likely; pulmonary edema often appears as blood mixed with pink frothy material; and bright-red blood is likely from an artery.

63.9 PHYSICAL EXAMINATION

A thorough evaluation of the cardiovascular and respiratory systems is essential to localize the condition. Care should be taken to avoid undue stress, and supportive measures such as oxygen therapy may need to be instituted prior to examination. Examination for coagulopathies should be performed as for epistaxis. Animals with systemic mycosis often have cutaneous or bony lesions.

63.10 DIFFERENTIAL DIAGNOSIS

Heartworm disease can cause hemoptysis in dogs and cats (Box 63-2). In dogs, exercise after adulticide therapy may result in worm embolization, inciting inflammatory lesions in the pulmonary vasculature and parenchyma and resulting in hemoptysis. Coagulopathies and platelet defects uncommonly result in airway mucosal bleeding. Cardiogenic pulmonary edema can result in expectoration of blood and pink froth. Pulmonary thromboembolism (PTE) (secondary to cardiac, endocrine, immune-mediated, gastrointestinal, and neoplastic disease) and 230
pulmonary hypertension (secondary to congenital or acquired cardiac malformations that result in abnormal 231
shunting of blood) uncommonly cause hemoptysis. Parasites including *Capillaria, Aelurostrongylus,* and *Paragonimus* species cause cavitated pulmonary lesions that rupture and bleed into airways. Chronic inflammatory conditions of the lung including heartworm disease, chronic bronchitis, bronchiectasis, and pulmonary infiltrate with eosinophils can result in inflamed and edematous mucosa that bleeds easily during coughing. Bacterial and fungal (*Blastomyces, Histoplasma, Coccidioides* spp.) pneumonia and lung abscesses may result in hemoptysis. Hemorrhage is a reported complication of transtracheal wash, lung biopsy, and bronchoscopy, and animals should be appropriately monitored after these procedures. Primary or metastatic neoplasia can result in erosion of pulmonary vessels. Blunt trauma or FB inhalation into the trachea or airways can result in hemoptysis. Rarely, ruptured arteriovenous malformations, bacterial endocarditis, and lung lobe torsions cause hemoptysis.

63.10.1 Box • 63-2 Causes of Hemoptysis

63.10.1.1 Pulmonary

Pulmonary thromboembolism: Secondary to neoplastic, endocrine, cardiac, metabolic disease

Pulmonary hypertension: Secondary to heartworm disease, congenital or acquired cardiac defects that result in shunting of blood

Chronic bronchitis/bronchiectasis

Bacterial pneumonia

Nocardiosis

Pulmonary abscess

Kennel cough (rare)

Fungal pneumonia: Blastomycosis, histoplasmosis, coccidiomycosis

Parasites: *Paragonimus kellicotti, Capillaria aerophila, Aelurostrongylus abstrusus*

Pulmonary infiltrate with eosinophils

Neoplasia: lung: Primary adenocarcinoma, undifferentiated carcinoma, squamous cell carcinoma, chondrosarcoma; metastatic; primary tracheal tumors

Lung lobe torsion

63.10.1.2 Cardiovascular

Heartworm disease

Cardiogenic pulmonary edema

Arteriovenous fistula

Bacterial endocarditis

63.10.1.3 Systemic

Coagulopathies: Primary (quantitative or qualitative platelet defects) or secondary hemostatic (factor deficiencies, anticoagulant rodenticide toxicity, disseminated intravascular coagulopathy [DIC]) abnormalities

Trauma: Pulmonary contusion, tracheal rupture, foreign body (FB)

Iatrogenic: Endotracheal intubation, complication of lung biopsy/aspirate, transtracheal wash, or bronchoscopy

63.11 DIAGNOSTIC PLAN

Measures must be taken to stabilize the animal and avoid undue stress during diagnostics. The minimum data base includes a complete blood count (CBC) with platelet count, chemistry profile, urinalysis, and three-view thoracic radiographs. The blood work should be evaluated for evidence of chronic bleeding, inflammation, infection, and systemic disease. Thoracic radiographs should be carefully evaluated for evidence of cardiac enlargement, pulmonary edema or contusions, pleural effusion, pneumonia, primary or metastatic neoplasia, signs of thoracic trauma such as broken ribs, foreign objects, and evidence of heartworm disease. A heartworm antigen test (and antibody test in cats) should be performed in animals not receiving heartworm preventative. Occasionally, malignant cells or fungal elements may be seen on microscopic evaluation of sputum. Examination of feces, sputum, or both for evidence of parasites may be indicated. Once the patient is as stable as possible, bronchoscopy may be performed if indicated to directly examine the upper airway, trachea, and bronchi, remove foreign objects, and perform bronchoalveolar lavage (BAL) and culture. Additional testing might include pulmonary arterial catheterization, ventilation-perfusion scan, arterial blood gas, coagulation giocardiogram fine needle aspiration or open biopsy of the lung, thoracoscopy, and CT scan of the thorax.

63.12 GOALS OF TREATMENT

Establishing a patent airway and intravenous fluid (once cardiogenic causes are ruled out), oxygen, or blood product administration should be instituted as needed until the underlying disease process can be identified. Most

commonly, hemoptysis is scant and self-limiting with cage rest and avoidance of stress. Antitussives may be indicated to decrease airway trauma from coughing, but sedation should be avoided because it increases the risk of aspiration of blood. If radiographs can localize bleeding to one lobe, the patient should be positioned with that side dependent. Broad-spectrum antibiotic therapy such as ampicillin and enrofloxacin or amoxicillin and clavulanic acid should be considered if bacterial infection is suspected (while cultures are pending) or as a prophylactic therapy to prevent pneumonia. If hemorrhage is uncontrollable, general anesthesia with suctioning of the airway, ventilatory support, or surgical intervention (or a combination of these treatments) may be indicated.

64 CHAPTER • 64 Petechiae and Ecchymoses

Mary Beth Callan

Superficial bleeding into the skin or mucous membranes is referred to as *purpura*. Purpura can be categorized as petechiae and ecchymoses. Petechiae are small pinpoint hemorrhages (<3 mm) resulting from extravasation of blood from capillaries, whereas ecchymoses are larger areas of hemorrhage resulting from leakage of blood from small arterioles and venules. Petechiae and ecchymoses are observed in primary hemostatic defects (i.e., platelet-vessel abnormalities). They represent a mild form of surface bleeding without external blood loss but may be associated with more serious hemorrhage. Both are commonly seen in dogs but rarely in cats.

64.1 PATHOPHYSIOLOGY

The vasculature is lined by a layer of endothelial cells that are linked by continuous and well-organized tight junctions varying in width from 0 to 4 nm. This provides a selectively impermeable membrane that prevents the passive transfer of blood into the extravascular space. The subendothelial matrix and additional layers of the vessels (media and adventitia) also act as barriers against extravasation of blood. Vascular integrity is influenced by many factors, one of which is platelets. Ultrastructural and functional changes develop in the vascular endothelium of thrombocytopenic animals, and these abnormalities are promptly reversed by a rise in the platelet count. However, the molecular basis for the observed changes remains unclear.

Thrombocytopenia (reduced platelet numbers), either as a sole hemostatic defect or as part of a combined hemostatic disorder, is the most common cause of petechiae and ecchymoses in dogs and cats. However, thrombopathias and vascular disorders may also cause capillary bleeding.

64.1.1 Thrombocytopenia

Thrombocytopenia may be a result of decreased platelet production by the bone marrow or increased platelet destruction, consumption, or sequestration. Frequently more than one mechanism is involved. For example, bone marrow suppression, consumption of platelets secondary to vasculitis, splenic sequestration, increased destruction of platelets by both immune-mediated and nonimmune-mediated mechanisms, virus-associated myelodysplasia, and myeloproliferative disorders may contribute to thrombocytopenia in dogs and cats with infectious diseases (e.g., ehrlichiosis, babesiosis, Rocky Mountain spotted fever, leishmaniasis, feline leukemia virus [FeLV], feline immunodeficiency virus [FIV]). In addition to infectious diseases, common underlying causes for thrombocytopenia include neoplasia, drug reactions, and immune-mediated disorders.

The most common cause of petechiae and ecchymoses in the dog is increased platelet destruction associated with immune-mediated thrombocytopenia (IMT), a disorder in which antibodies bound to the surface of the platelet results in premature removal by the reticuloendothelial system.

The bone marrow typically has normal to increased numbers of megakaryocytes. However, antibodies may also be directed against the megakaryocytes, resulting in decreased platelet production. Dogs suspected of having IMT should also be evaluated for hemolytic anemia, proteinuria, and polyarthritis. If any of these signs exist, systemic lupus erythematosus (SLE) should be considered. IMT occurs rarely in cats.

Increased sequestration of platelets resulting in thrombocytopenia has been observed in dogs with splenomegaly, hepatomegaly, and endotoxemia, as well as in experimental hypothermia. However, petechiae and ecchymoses are not typically observed as a result of sequestration of platelets.

64.1.2 Thrombopathia

Thrombopathias may be classified as inherited or acquired defects. Inherited disorders of platelet function have been identified in several breeds of dogs (e.g., Glanzmann's thrombasthenia of otter hounds and Great Pyrenees, δ-storage pool disease of American cocker spaniels) and a few cats. Spontaneous formation of petechiae and ecchymoses, mucosal surface bleeding, and excessive bleeding after surgery or trauma are common features of these disorders, and fatal hemorrhage has been observed in some affected dogs. Platelet function, as assessed by the bleeding-time test and various in vitro tests, may be affected by various systemic and hematologic disorders (e.g., uremia, liver disease, dysproteinemias) and by a large number of drugs. Although drugs of nearly every classification have been associated with acquired platelet dysfunction in humans, fewer drugs have been evaluated for adverse effects on platelet function in dogs and cats. Platelet dysfunction induced by aspirin, cephalothin, and acepromazine has been documented in vitro in the dog, but the in vivo effects of these drugs on platelet function are less clear. Nevertheless, it would seem prudent to avoid use of such drugs in dogs with known bleeding disorders.

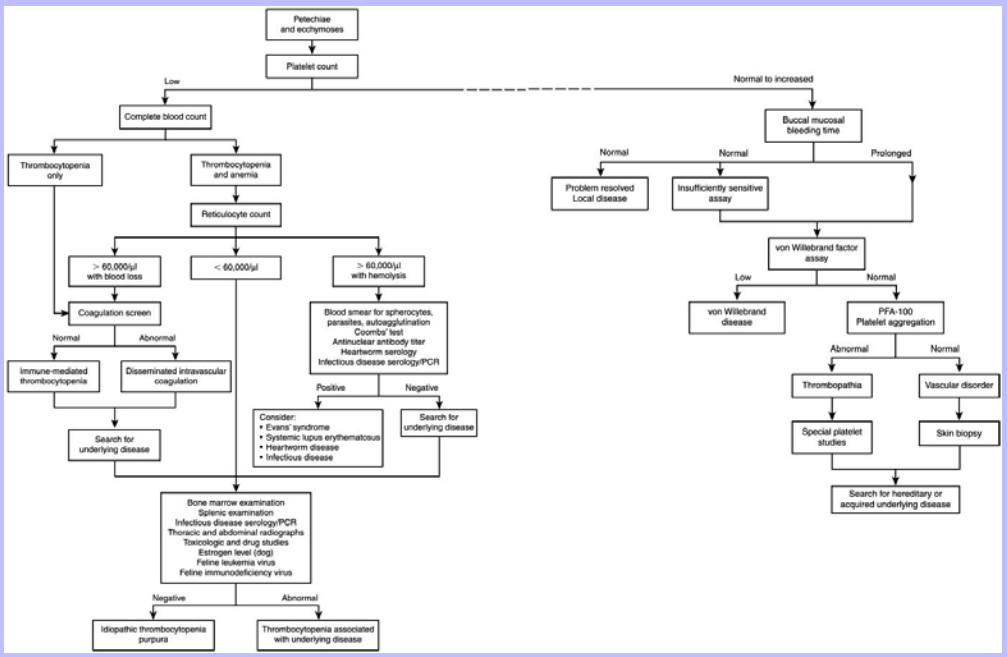
von Willebrand disease (vWD), the most common inherited bleeding disorder in the dog, results from a reduction in the amount of functional plasma von Willebrand factor (vWF), leading to impaired platelet-vessel adhesion. vWD rarely causes petechiae, although ecchymoses may be observed in some dogs with vWD after trauma and surgical procedures. As with other primary hemostatic defects, typical signs of vWD include bleeding from mucosal surfaces (e.g., epistaxis, melena, hematuria) and excessive bleeding after surgery or trauma.

64.1.3 Vascular Disorders

In the absence of a quantitative or qualitative platelet abnormality, the presence of purpura suggests a vascular disorder. Vasculitis, secondary to infectious, inflammatory, immune-mediated, or neoplastic diseases or drug reactions, is the most common cause of vascular purpura. Some dogs with Cushing's disease are also prone to develop ecchymoses after minor trauma (e.g., cystocentesis), possibly as a result of increased protein catabolism leading to dermal and connective tissue atrophy and thus altered dermal vascular support.

233

Figure 64-1 Algorithm for diagnostic approach to petechiae and ecchymoses.



64.2 PATIENT HISTORY AND PHYSICAL EXAMINATION

In a dog or cat with petechiae, ecchymoses, or both, the history may provide important clues as to the cause of the disorder. Given the many possible effects of various drugs on primary hemostasis (bone marrow suppression, immune-mediated thrombocytopenia, platelet dysfunction, and vasculitis), a complete medication history is imperative. Likewise, recent vaccinations, tick exposure, and previous or concurrent medical problems are relevant. A history of previous episodes of mucosal surface bleeding or purpura in an otherwise healthy animal or a family history of similar bleeding may be suggestive of an inherited thrombopathia.

233
234

Given that thrombocytopenia, thrombopathia, and vascular disorders may be associated with an underlying disease, a complete physical examination is essential. Peripheral lymphadenopathy, hepatomegaly, or splenomegaly (or a combination of these abnormalities) may indicate an underlying infectious, inflammatory, or neoplastic disease. Petechiae are most readily found on mucous membranes of the gingiva, prepuce, and vulva, as well as on sparsely haired skin of the ventral abdomen and pinnae. After phlebotomy, ecchymoses are commonly observed around the venipuncture site.

64.3 DIAGNOSTIC APPROACH

Because thrombocytopenia is the most common cause of petechiae and ecchymoses, the initial laboratory evaluation should always include a platelet count (Figure 64-1). Although electronic particle counters can quickly and accurately perform platelet counts in dogs, blood smears should also be evaluated. However, cell-counting instruments with a threshold function to separate platelets and red blood cells (RBCs) by volume may not be accurate in the cat (considerable overlap exists between erythrocyte and platelet volumes), resulting in spuriously

low platelet counts. In addition, feline platelets tend to clump. A manual platelet count and evaluation of a blood smear are recommended for all cats (although platelet clumping may also lead to inaccurate manual counts) and for dogs in which the automated platelet count is low. In an emergency situation, evaluation of a blood smear to obtain an estimate of platelet number is sufficient; 10 to 20 platelets per oil immersion field are deemed adequate. Platelet counts are often less than 10,000/μL in dogs with IMT. In addition to providing an estimate of platelet number, evaluation of a blood smear may reveal evidence of RBC regeneration (polychromasia, anisocytosis, and macrocytosis), blood parasites, RBC agglutination, spherocytosis, or RBC fragments.

If the dog or cat is thrombocytopenic, evaluation of the complete blood count (CBC) to determine if other cytopenias are present will aid in formulation of a list of differential diagnoses and a focused diagnostic plan. Pancytopenia is most suggestive of bone marrow disease, whereas concurrent anemia and thrombocytopenia may be the result of blood loss anemia due to thrombocytopenia, immune-mediated destruction of both RBC and platelets, or bone marrow disease. Newly synthesized or reticulated platelets can be identified using the ribonucleic acid (RNA)–binding fluorescent dye thiazole orange and flow cytometry. Reticulated platelets lose RNA within 24 hours after entering the peripheral circulation. The percentage of reticulated platelets is typically increased in dogs with IMT. However, the absolute numbers may be within reference range because of the low total number of platelets. The assay for measurement of reticulated platelets is rapid and less invasive than obtaining bone marrow samples to evaluate thrombopoiesis and may be readily available through commercial diagnostic laboratories in the future.

234

235

A bone marrow aspirate or biopsy is indicated in dogs and cats with pancytopenia, nonregenerative anemia and thrombocytopenia, persistent thrombocytopenia despite therapy, or atypical cells noted in the peripheral blood. A bone marrow aspirate is not necessary in all patients with IMT but should be considered when the platelet count has not increased within 5 to 7 days of initiating immunosuppressive therapy. Despite severe thrombocytopenia, excessive bleeding is rarely a complication of bone marrow aspiration or biopsy.

The buccal mucosal bleeding time (BMBT) evaluates only primary hemostasis or the platelet-vessel interaction. A BMBT is indicated in animals with petechiae and ecchymoses that are not thrombocytopenic. The BMBT is performed using a spring-loaded device that is standardized to produce uniform incisions. Simplate devices (Organon Tecknika Corp., Durham, NC) are available with one or two blades and produce incisions approximately 5 mm long and 1 mm deep (clinicians should not use blades with only 0.5 mm depth). Single-blade devices are recommended for cats and small dogs. Normal BMBT in the dog is less than 4 minutes and in the cat is less than 2 minutes. The effect of a low hematocrit (HCT) on bleeding time is often neglected, but ample evidence in the literature indicates an inverse relationship between HCT and bleeding time (the lower the HCT, the more prolonged the bleeding time) in humans with HCTs less than 25%. Altered rheologic properties of the blood and a reduced source of adenosine diphosphate (ADP) (RBCs release ADP) to activate platelets are mechanisms proposed for the prolongation of bleeding time in severely anemic patients. A prolongation of the BMBT in an animal with a normal platelet count and HCT suggests a thrombopathia, vWD, or a vascular disorder. Because vWD is much more common in the dog than intrinsic platelet function defects or vascular disorders, measurement of plasma vWF concentration is recommended before platelet function testing, particularly in dogs being evaluated for development of ecchymoses after surgery rather than for spontaneous formation of petechiae.

A point-of-care platelet function analyzer, the PFA-100 (Dade Behring, Miami, FL), assesses platelet adhesion and aggregation in citrated whole blood (800 μL per test sample) and provides results in less than 10 minutes. As with the BMBT, results of the PFA-100 are dependent on platelet count and HCT. This instrument, now available at a few veterinary teaching hospitals, has been useful in quickly identifying dogs with vWD and some thrombopathias, although measurement of plasma vWF concentration is necessary to differentiate these primary hemostatic disorders.

The cuticle bleeding time assesses both primary and secondary hemostasis and thus cannot differentiate between a thrombopathia and a coagulopathy. In addition, clipping the nail too short is painful. Finally, it is difficult to standardize this bleeding-time test, potentially providing misleading results. Therefore the BMBT is preferred to the cuticle bleeding time in the evaluation of animals with suspected disorders of primary hemostasis.

An activated clotting time (ACT), which assesses the intrinsic and common pathways of the coagulation cascade and thus provides similar information to the activated partial thromboplastin time (aPTT), is useful in ruling out a concurrent coagulopathy. Normal ACT in the dog is 60 to 110 seconds and in the cat is 50 to 75 seconds. In patients with severe thrombocytopenia (<10,000/μL), the ACT may be slightly prolonged by approximately 10 seconds because of decreased availability of platelet phospholipid to support coagulation.

64.4 TREATMENT

Medical management of patients with petechiae and ecchymoses varies widely. Treatment is aimed at the underlying disorder (e.g., rickettsial infections, neoplasia, immune-mediated diseases). Because IMT is the most common cause of severe thrombocytopenia in dogs with resultant formation of petechiae and ecchymoses, most thrombocytopenic dogs should be initially treated with doxycycline and prednisone pending results of diagnostic tests. In some cases, discontinuation of medications (e.g., methimazole, sulfonamides) may be all that is necessary to resolve the primary hemostatic disorder.

Dogs and cats with petechiae and ecchymoses as the sole form of bleeding rarely require blood transfusion support. However, if concurrent mucosal surface bleeding exists, particularly into the gastrointestinal tract, leading to anemia, transfusion of packed RBCs may be indicated to provide additional oxygen-carrying support. Platelet transfusions in the form of fresh whole blood, platelet-rich plasma, or platelet concentrate are indicated in life-threatening or uncontrolled bleeding. A small amount of bleeding into the brain, myocardium, lungs, or oropharynx could have devastating consequences without resulting in anemia. Platelet transfusions are generally not recommended in patients with IMT (unless uncontrolled or life-threatening bleeding occurs) because the transfused platelets have a short life span (typically destroyed within minutes to hours).

65 CHAPTER • 65 Electrolyte Disorders

David Church

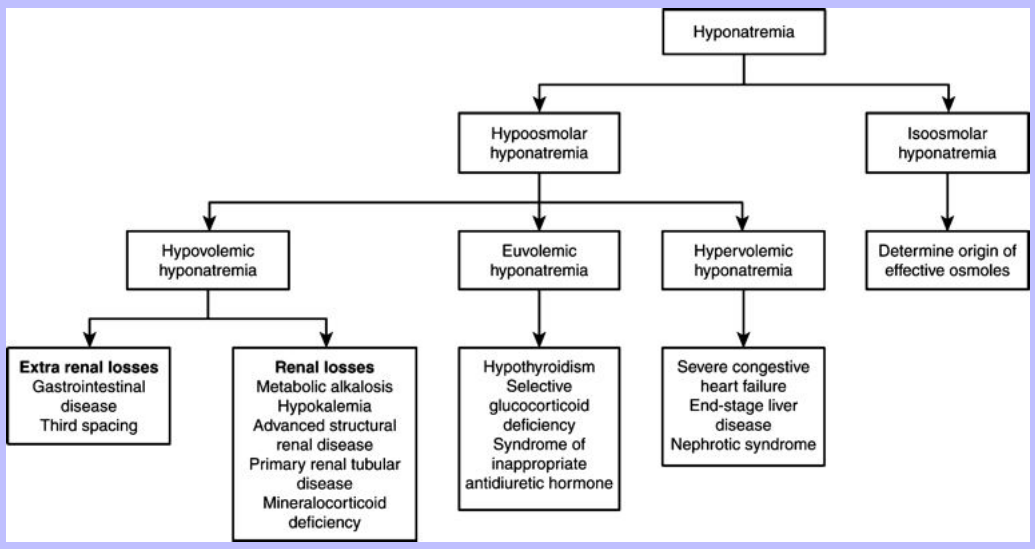
Disorders of electrolyte homeostasis are among the most frequently encountered challenges in small animal practice. An understanding of the underlying physiologic interactions is essential for a logical approach to their recognition and management (Figure 65-1).

65.1 DISORDERS OF CALCIUM METABOLISM

Only about 1% of total body calcium is freely exchangeable with the extracellular fluid (ECF). Maintenance of normal serum calcium concentration in the ECF is controlled by calcium itself through a specific receptor along with a number of hormones, the most influential of which are parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D_3 (1,25 D_3).

Calcium circulates in the ECF in three fractions. Approximately 50% exists in a biologically active, ionized form and 40% is protein bound, predominantly to albumin, although this proportion can be increased in alkalosis and decreased with acidosis. Additionally, factors that lower albumin can lower total serum calcium concentration without actually lowering the biologically active serum calcium concentration. For these reasons, measurement of serum ionized calcium is recommended in all patients suspected of having a clinically significant perturbation of serum calcium.

Figure 65-1 Algorithm for electrolyte disorders.



65.1.1 Hypercalcemic Disorders

The signs associated with hypercalcemia generally correlate with the magnitude and rate of change in serum calcium and include weakness, lethargy, polydipsia and polyuria, inappetence, and vomiting. Diarrhea, constipation, arrhythmias, seizures, and muscle fasciculations are uncommon.

Mild hypercalcemia can be present in young, large breed dogs and is a reflection of accelerated calcium turnover associated with rapid bone growth. Various degrees of hypercalcemia may occur artifactually (lipemia or sample contamination with detergent). It can be transiently associated with hemoconcentration, hyperproteinemia, hypoadrenocorticism, or severe hypothermia. Hypercalcemia can be a persistent, pathologic abnormality secondary to a number of diseases including malignant neoplasia, primary hyperparathyroidism, and renal failure. Other less frequently encountered associations include vitamin D intoxication, granulomatous inflammatory disease, and marked osteolysis. Over 50% of hypercalcemic cats reportedly have associated renal failure or malignancy; however, no explanation for the hypercalcemia could be found in 12% of these animals. Approximately 70% of hypercalcemic dogs are azotemic, with azotemia uncommon in those with primary hyperparathyroidism.

In cats and dogs with renal failure, hypocalcemia rather than hypercalcemia is generally observed. However, whenever hypercalcemia is present in a renal failure patient, one must determine if the impaired renal function is *due to* the hypercalcemia or the renal failure has *resulted in* the hypercalcemia. Hypercalcemia impairs renal function by reducing renal sensitivity to antidiuretic hormone (ADH). The reduction in ECF volume decreases glomerular filtration rate (GFR), which is exacerbated by calcium's direct vasoconstrictive effect on afferent glomerular arterioles. Furthermore, decreased renal tubular delivery of sodium increases tubular resorption of calcium and aggravates hypercalcemia. Consequently, any hypercalcemic scenario will tend to impair renal function by reversible processes that do not affect renal structure nor necessarily cause irreversible nephron loss.

236

237

Hypercalcemia does, however, result in nephron destruction through tubular calcium phosphate deposition (so called nephrocalcinosis). Once sufficient nephrons are destroyed, this loss of functional renal mass will further impair renal function. Consequently, persistent hypercalcemia will eventually lead to significant structural renal disease.

Malignancy may cause hypercalcemia through secretion of calcemic factors by malignant cells. Many tumors produce either PTH or parathyroid hormone–related peptide (PTH-rP), which binds to PTH receptors and has similar bioactivity to PTH. Primary hyperparathyroidism is another recognized cause of hypercalcemia and is generally diagnosed by finding a mild-to-moderate hypercalcemia in dogs and cats with normal renal function and an inappropriately increased (midreference range to increased) intact serum PTH concentration. Granulomatous diseases may produce hypercalcemia due to granulomatous tissue conversion of 25 D_3 to 1,25 D_3.

Vitamin D toxicosis and hypercalcemia may be observed in animals oversupplemented with vitamin D analogues. Vitamin D intoxication can also occur with ingestion of cholecalciferol rodenticides, calcipotriol-containing psoriasis preparations, or plants containing calcitriol glycosides.

Hypercalcemia may also result from exposure to aluminum salts, vitamin A intoxication, various nonmalignant skeletal lesions, hyperthyroidism, and the administration of thiazide diuretics.

65.1.2 Hypocalcemic Disorders

Hypocalcemia occurs when calcium is lost from the ECF, often through renal mechanisms, in greater quantities than can be replaced by accelerated absorption from the intestine or bone depots. As with hypercalcemic disorders, falsely low levels of serum calcium due to hypoalbuminemia should be excluded by measuring serum ionized calcium concentration.

The clinical signs of hypocalcemia generally correlate with the magnitude and rapidity of the fall in serum calcium concentration. Manifestations of neuromuscular irritability predominate and include generalized muscle weakness with or without muscle fasciculation, which in severe cases may progress to tetanic spasms and even seizures. Cardiac manifestations include a prolongation of the QT interval that may progress to ventricular tachydysrythmias or various degrees of heart block.

Causes for hypocalcemia are extensive. Because calcium phosphate has a low solubility quotient, any condition that increases serum phosphate concentration such as release of large amounts of cellular phosphorous or acute impairment of renal function may result in a reduction in serum calcium concentration. In idiopathic disease after removal of a PTH-secreting tumor, a deficiency of PTH leads to increased renal calcium excretion and decreased intestinal calcium absorption, the latter secondary to reduced 1,25 D_3 production.

Hypocalcemia and hypomagnesemia frequently coexist and are often due to decreased absorption of dietary divalent cations. Hypomagnesemia impairs both PTH secretion and activity. A loss of extracellular calcium leading to hypocalcemia can occur with pancreatitis through the release of pancreatic lipase, degradation of retroperitoneal and omental fat, and binding of calcium in the peritoneum. Hypomagnesemia and hypoalbuminemia may also contribute to the hypocalcemia associated with acute pancreatitis. Other infrequent causes of hypocalcemia include endotoxic shock and dietary deficiency of vitamin D.

65.1.3 Disorders of Phosphate Metabolism

Plasma phosphate concentrations are relatively increased in young animals, decreasing to adult values by approximately 1 year of age. Phosphorous is predominantly absorbed from the gut by passive transport processes, although active transporters are stimulated by 1,25 D_3. Phosphorous is freely filtered by the glomerulus and more than 80% of the filtered load is reabsorbed in the proximal tubule. Proximal reabsorption occurs by passive transport coupled to sodium and is regulated mainly by phosphorous intake and serum PTH. Acute adaptation to a low-or high-phosphorous diet involves the insertion or retrieval of Na-P transporters from the brush border membranes of the renal proximal tubules, whereas chronic adaptation involves the synthesis of new transport proteins. PTH induces phosphaturia by inhibition of the Na-P cotransporters, thus its phosphaturic effect is diminished in phosphate deficiency. In addition, the renal tubules respond to dietary phosphate intake, although this effect is independent of plasma phosphate and PTH levels. The precise nature of the dietary phosphate signal is uncertain. In parallel with the antiphosphaturic effect of reduced dietary phosphate, an increase in bone resorption takes place leading to mobilization of phosphate and calcium from the skeleton. This renal tubular response to dietary phosphate means dietary restriction of phosphorous rarely leads to hypophosphatemia. However, hypophosphatemia can occur through internal redistribution, increased urinary excretion, decreased intestinal absorption, or combinations of all three.

65.1.4 Alterations in Sodium Metabolism

Although characterized by an abnormal sodium concentration, hypo-and hypernatremia generally reflect abnormalities in water balance that may or may not be accompanied by changes in sodium balance. Despite marked fluctuations in water intake and excretion, stable plasma sodium concentration is maintained by a complex interplay between osmoreceptors and baroreceptors, both of which control secretion of ADH, the primary physiologic determinant of the rate of free water excretion. The major stimuli to ADH secretion are hyperosmolality and depletion of the effective circulating volume. ADH-induced water retention lowers plasma osmolality and raises effective circulating volume. It is important to remember the physiologic response to hyperosmolality includes a second mechanism for modifying free water—the sensation of thirst mediated through the satiety centre. Although thirst is regulated centrally, it is sensed peripherally through sensory oropharyngeal receptors. The cessation of thirst is also mediated initially in the periphery by oropharyngeal mechanoreceptors that are stimulated by swallowing relatively large volumes of fluid.

65.1.5 Modification Due to Altered Osmolality

The osmoreceptors that govern ADH release are located in the hypothalamus and are activated by changes in intracellular water content and consequent alterations in intracellular osmolality. These changes in intracellular water content are determined by the levels of so called effective osmoles in both the intracellular and 237
extracellular compartment. Effective osmoles are those determinants of serum osmolality that do not readily 238
cross cell membranes. Because sodium has poor cell membrane permeability and is by far the most abundant cation in the ECF, the serum sodium concentration with its accompanying anions generally accounts for nearly all of the effective osmotic activity of the plasma and is the primary osmotic determinant of ADH release. An increase in serum sodium invariably predicts a hyperosmolar state. However, a subnormal serum sodium concentration does not always reflect hypo-osmolar conditions because the presence of significant amounts of other osmotically active substances can modify osmolality with resultant variable effects on serum sodium concentration. In these situations the hyponatremia is a reflection of translocation of intracellular water rather than an indication of hypo-osmolality.

65.1.6 Modification Due to Altered Effective Circulating Volume

The carotid sinus baroreceptors are pressure receptors that induce secretion of ADH from cells in the paraventricular nuclei of the hypothalamus. The relationship between mean arterial blood pressure and plasma volume means they also function indirectly as volume receptors. They are much less sensitive than osmoreceptors, although once activated they produce marked increases in ADH secretion that exceed those induced by hyperosmolality. Potential exists for interaction between the osmoreceptors and volume receptors. Volume depletion will potentiate the ADH response to hyperosmolality but can also prevent inhibition of ADH release normally induced by a fall in the plasma osmolality. Volume depletion is also a potent stimulus to the thirst center, with hypovolemic patients having persistent activation of the thirst center even in the presence of hyponatremia. In other words, volume and tissue perfusion are maintained at the expense of plasma osmolality.

65.1.7 Hypo-Osmolar Hyponatremia

Underlying all hypo-osmolar hyponatremic states is a limitation of urinary water excretion due either to secretion of ADH through nonosmolar mechanisms despite serum hypo-osmolality or impaired renal diluting ability. Consequently in animals with hyponatremia, once hypo-osmolality has been established, assessment of

the extracellular fluid volume allows each pet to be classified as hypovolemic, hypervolemic, or euvolemic. This classification can provide possible explanation or explanations for the hyponatremia.

Hypovolemic hyponatremia occurs with concurrent deficits of both total body sodium and total body water, with the former exceeding the latter. This occurs as a result of persistent ADH secretion in response to marked volume depletion with continued oral or parenteral hypotonic fluid intake. The reasons for the sodium depletion can be broadly divided into *extrarenal* or *renal* sodium losses. Extrarenal sodium losses are invariably due to gastrointestinal (GI) or third-space losses and are characterized by concentrated urine with minimal natriuresis.

The causes for renal sodium losses are more extensive. Some individuals with GI disease resulting in vomiting and metabolic alkalosis may have both extrarenal and renal sodium loss. Renal sodium losses may occur in these animals for a number of reasons. In a proportion of cases there may be an appreciable bicarbonaturia that, despite severe volume depletion, leads to natriuresis through attempts to maintain tubular electroneutrality. Furthermore, these dogs and cats may have concurrent hypokalemia that will interfere with renal sodium resorption and reduce osmoreceptor and thirst receptor sensitivity. The mineralocorticoid deficiency of hypoadrenocorticism will result in hypovolemic hyponatremia with marked natriuresis along with moderate to marked hyperkalemia and azotemia. In primary hypoadrenocorticism both the hypovolemia and the markedly increased secretion of ACTH provide a dual stimulus for ADH release regardless of the serum sodium concentration. Animals with advanced renal disease, primary renal tubular disorders, and osmotic diuresis all may have hypovolemic hyponatremia.

In hypervolemic hyponatremia, although total body sodium is increased, total body water is increased even more. This is an unusual occurrence in veterinary medicine, although it may be associated with severe cardiac or hepatic failure, nephrotic syndrome, and oliguric and anuric renal failure.

Euvolemic hyponatremia is an uncommon finding in small animal medicine, although theoretically it may occur in dogs and cats with glucocorticoid deficiency through nonspecific cosecretion of ADH with ACTH, as well as ADH-independent, glucocorticoid-mediated disturbances in renal hemodynamics. In man, euvolemic hyponatremia has been associated with hypothyroidism, postsurgical stress with overzealous hypotonic fluid administration, and the syndrome of inappropriate ADH secretion (SIADH) in which defective osmoregulation of ADH secretion through heightened osmoreceptor sensitivity takes place. In the most common form of SIADH in man, ADH release varies appropriately with serum sodium concentration; however, the threshold for ADH secretion occurs at an abnormally low osmolality.

The clinical signs induced by hyponatremia depend upon its severity and the rate of development. Although sodium remains above 130 nmol/L clinical signs are rare. When the serum sodium concentration decreases to <130 m/q/L, animals may have inappetence, vomiting, muscular weakness, and ataxia, whereas severe or acute hyponatremia may result in seizures and irreversible central nervous system (CNS) damage. Animals with an acute hyponatremia are at risk of developing permanent CNS damage through marked cerebral edema, whereas those animals with chronic hyponatremia are at risk of osmotic demyelination if the hyponatremia is corrected too rapidly.

65.1.8 Hypernatremia

The presence of hypernatremia represents a hyperosmolar state and may develop when water loss exceeds loss of sodium and potassium. Free water can only be lost from one of three places: (1) through the skin and respiratory tract (so called insensible water loss), (2) through the urine, or (3) through the gut. Urinary water loss requires impairment of either ADH secretion or end-organ sensitivity. Water loss through diarrhea is more variable. With diseases resulting in secretory diarrhea the fluid that is lost is iso-osmotic with plasma and is

almost entirely composed of sodium and potassium salts. Although the animal may become profoundly volume depleted, the plasma sodium concentration will remain relatively unaffected. In conditions resulting in osmotic diarrhea the fluid lost is again iso-osmotic; however, the nonreabsorbed solute accounts for most of the osmolality. Consequently, water loss markedly exceeds sodium and potassium loss, and hypernatremia and volume depletion occurs. Similar considerations may apply to urinary water loss induced by osmotic diuretics such as glucose or mannitol, although the tendency for hypernatremia to develop will be offset by the translocational effect of these effective ECF osmoles.

As the thirst center will normally be concurrently activated by the increasing osmolality, any hypernatremic tendency should be offset by increased water consumption. Consequently, hypernatremia usually requires not only increased loss of free water but also reduced water consumption. The latter is generally due to either reduced availability of water to an appropriately thirsty animal or impaired activation of the thirst center through neurologic pathology or dysfunction in the hypothalamic region that may be either a primary problem or secondary to intercurrent illness.

238

239

65.2 DISORDERS OF POTASSIUM METABOLISM

Although sodium is primarily located extracellularly, roughly 98% of total body potassium is located within cells. Localization of sodium and potassium to the different fluid compartments is maintained by the Na-K ATPase cell membrane pump that actively pumps sodium from the cell and potassium into it in a ratio of two potassium ions for every three sodium ions.

65.2.1 Potassium Homeostasis

The plasma potassium concentration is predominantly determined by various homeostatic mechanisms controlling both internal and external balance, although total body potassium levels may have a modifying influence.

Internal potassium balance determines the ratio of intracellular to extracellular potassium and is influenced by many factors including extracellular pH, bicarbonate, insulin, glucagon, catecholamines, and osmolality. Acidosis and alkalosis are potentially potent influences on the internal balance of potassium. As H^+ ions move relatively freely across cell membranes, potassium tends to move in the opposite direction to maintain electrical neutrality. Consequently, ECF acidosis results in intracellular movement of H^+ ions and extracellular movement of K^+. The opposite occurs with alkalosis. Acidosis also inhibits Na-K ATPase activity, although this hyperkalemic effect is countered to some degree by an associated acidosis-induced reduction in the cell membrane's permeability to potassium.

Equally alkalemia, either metabolic or respiratory, promotes intracellular potassium entry although the effect tends to be relatively mild. A more potent hypokalemic effect may be seen with bicarbonate administration because plasma bicarbonate directly promotes intracellular potassium movement.

Various hormones including insulin, the catecholamines, and thyroxine may modify normal transcellular potassium balance. Insulin promotes potassium influx and sodium efflux from the cell through insulin's activation of the electroneutral Na^+/H^+ exchanger. Na-K ATPase then removes the resultant increase in intracellular sodium, with a consequent intracellular shift of potassium. In contrast, catecholamines lower plasma potassium by β_2 activation of membrane-bound adenylate cyclase and subsequent stimulation of Na-K

ATPase. Synthesis of Na-K ATPase is stimulated by thyroid hormone, and this effect can contribute to the hypokalemia of hyperthyroidism.

External potassium balance is predominantly determined by renal modification of kaliuresis based on a complex array of factors. Although the majority of filtered potassium is resorbed actively in the proximal tubule, regulation of potassium excretion predominantly occurs in the cortical collecting duct (CCD). The cells lining the CCD contain high numbers of Na-K ATPase pumps on their basolateral membranes and abundant numbers of potassium channels on their luminal surface. Altering the activity of the basolateral Na-K ATPase pumps or changing factors that encourage diffusion of intracellular potassium into the CCD through the luminal potassium channels can modify renal potassium excretion.

The most potent modifiers of renal potassium excretion include potassium intake, aldosterone, ADH, and the animal's acid-base status. In man, a chronic high potassium intake increases the number of basolateral Na-K ATPase pumps in the CCD (and in the colon), thereby facilitating increased renal and colonic potassium excretion. Aldosterone, ADH, and alkalosis increase kaliuresis by activation of both basolateral Na-K ATPase pumps and luminal potassium channels. Additionally the mechanism by which potassium and hydrogen may exchange for one another in the CCD favors renal potassium wasting in alkalosis and retention in acidosis. Luminal fluid flow rate and sodium content in the CCD will also influence renal potassium excretion. Sodium ions in the CCD tubular fluid are resorbed through luminal sodium channels down their concentration gradient, making the tubular fluid more electronegative and consequently increasing the tendency for intracellular potassium, through its luminal potassium channels, to move down both its concentration and electrical gradients into the CCD tubular fluid. This effect will be enhanced with increased tubular fluid delivery to the CCD.

65.2.2 Hypokalemia

Hypokalemia may develop as a postcollection artifact in some animals with a marked leukocytosis due to excess potassium uptake by the nucleated cells. Generally, however, hypokalemia reflects a breakdown in normal homeostatic mechanisms resulting in marked intracellular shifts or excessive losses of potassium.

A syndrome of fluctuating muscle weakness with concurrent hypokalemia has been reported in Burmese cats. The underlying cause for this condition is poorly understood, although it may be a result of dramatic intracellular shifts in potassium similar to the syndrome of familial hypokalemic periodic paralysis in man.

Insulin, catecholamines, and thyroxine all increase intracellular uptake of potassium, whereas accidental ingestion of barium compounds may cause hypokalemia by blocking potassium membrane channels and hence extracellular potassium movement. However, most commonly, hypokalemia is the result of either abnormal kaliuresis or GI losses associated with vomiting or diarrhea. As discussed previously, renal potassium loss will occur in any metabolic alkalosis, particularly if induced by selective chloride depletion due to vomiting, hypersecretory disorders of the upper GI tract, or both. The association is further enhanced because hypokalemia itself may play a role in the development and maintenance of metabolic alkalosis.

Additionally, primary hyperaldosteronism and various genetic abnormalities that influence the activity of renal ion transporters or activation and deactivation of cortisol in renal tubules may be rare causes of metabolic alkalosis and hypokalemia.

Increased urinary loss of potassium will also occur in several forms of metabolic acidosis in which concurrent increased distal tubular sodium delivery and flow takes place, as is seen with the osmotic diuresis associated with diabetes mellitus. The acidosis will tend to increase plasma potassium concentration and mask the tendency for depletion of total body potassium through kaliuresis. By increasing distal tubular sodium delivery,

the thiazide and loop diuretics, as well as larger doses of the intravenous penicillins, may cause hypokalemia. Aminoglycoside antibiotics, cisplatin, and amphotericin B all cause renal potassium loss through magnesium depletion. Hypomagnesemia can lead to potassium depletion and hypokalemia because it not only reduces intracellular potassium movement through impairment of Na-K ATPase activity but also leads to decreased potassium resorption in the loop of Henle and the CCD.

Hypokalemia can result in varying degrees of muscle weakness and enhanced myocardial excitability through activation of the normally inactive cell membrane sodium channels. Potassium depletion also may interfere with renal function. Diminished urinary concentrating capacity is a reversible consequence of hypokalemia and is due in part to impaired renal responsiveness to ADH through reduced expression of aquaporin-2 and decreased renal countercurrent function caused by impaired NaCl transport in the loop of Henle. In addition, these changes will result in an increased delivery of tubular fluid to the CCD and a consequent reduction in GFR.

239

240

65.2.3 Hyperkalemia

Hyperkalemia may occur as a postcollection artifact. This is a particular problem in the Japanese Akita breed, although rare changes in plasma potassium concentration occur in other dogs or cats. Although the presence of hyperkalemia is a common finding in many diseases, it invariably reflects impaired renal function together with varying degrees of nonspecific tissue damage, cell destruction, and intracellular potassium release into the ECF. Conditions characterized by hyperkalemia include hypoadrenocorticism, primary hypoaldosteronism, malignant hyperthermia, thromboembolic disorders resulting in marked myonecrosis, and idiosyncratic reactions to angiotensin converting enzyme inhibitors and nonsteroidal antiinflammatory agents. Hyperkalemia can be associated with any form of renal failure although it tends to be more profound in conditions resulting in either acutely impaired renal function, or urethral obstruction.

The clinical signs that are directly referable to hyperkalemia include varying degrees of muscular weakness and disturbances in cardiac conduction. These signs are due to changes in neuromuscular conduction caused by reduced membrane excitability, a result of further inactivation of cell membrane sodium channels.

The clinical consequences of hyperkalemia are uncommon unless plasma potassium exceeds 7.5 mmol/L. However, substantial interpatient variation occurs because factors such as the plasma calcium concentration and acid base status can modify the toxicity of hyperkalemia.

65.3 DISORDERS OF MAGNESIUM METABOLISM

Magnesium is predominantly an intracellular cation, with only 1% of total body magnesium found extracellularly. Although the majority of filtered magnesium is resorbed in the proximal tubule and loop of Henle, magnesium regulation occurs through variable resorption in the distal tubule. Many hormones can influence renal handling of magnesium; however, the major regulator of reabsorption is the plasma magnesium concentration itself.

Depletion of total body magnesium can occur through GI losses associated with acute or chronic diarrhea, malabsorption, and/or steatorrhea. Some evidence suggests that Yorkshire terriers, collies, and German shepherds are more prone to developing hypomagnesemia with these types of enteropathies, and a recent report suggested hypomagnesemia was a common finding in Cavalier King Charles spaniels. Many other factors may contribute to hypomagnesemia, including increased intracellular movement of magnesium induced by alkalosis or insulin, impaired renal resorption, and the pharmacologic actions of various drugs.

Urinary magnesium loss is often the basis for magnesium depletion. Tubular resorption is related to urine flow, so long-term parenteral fluid therapy and volume expansion may result in magnesium deficiency. Hypercalcemia and calciuria reduce tubular resorption of magnesium, as does glucosuria or any cause for osmotic diuresis.

A close link exists between magnesium and potassium concentrations. Potassium depletion is associated with reduced distal tubule resorption of magnesium, magnesuria, and hypomagnesemia. Furthermore, hypomagnesemia produces secondary cellular potassium depletion, kaliuresis, and hypokalemia as a result of increased potassium secretion in the loop of Henle and the CCD. Finally, reversible hypocalcemia due to impaired PTH secretion and target tissue PTH insensitivity is a consistent finding with hypomagnesemia. Consequently, otherwise unexplained hypocalcemia and hypokalemia is highly suggestive of underlying magnesium depletion.

66 CHAPTER • 66 Intoxication versus Acute, Nontoxicologic Illness: Differentiating the Two

Etienne Côté

Safdar A. Khan

Any acutely ill animal can present a diagnostic challenge if toxicosis is suspected but a clear recent history is not available. Common examples of such a situation include the pet that disappears and returns home with clinical signs or the found stray dog or cat that is ill. To address this challenge, this chapter presents common clinical problems that often are due to either intoxication or naturally occurring disease, and it highlights features of each to help elucidate the problem's cause in the absence of a medical history.

The categorization of toxicants and illnesses presented in this chapter is based solely on the patient's predominant clinical sign or abnormality. For management of suspected intoxications prior to the onset of overt signs or for details of specific diseases or intoxications, the reader is referred to the chapters indicated in each section and the references listed at the end of the chapter.

In general, intoxications probably are more likely in individuals known to be susceptible to ingestion (dogs or cats that are known to chew or swallow foreign material). Whether this behavior exists should be established as an initial part of the history whenever possible.

66.1 CENTRAL NERVOUS SYSTEM ALTERATIONS AND SEIZURES

Many intoxications are systemic and thus produce diffuse effects, such as central nervous system (CNS) alterations and seizures (see Chapter 48). Therefore in general, an interictal neurologic exam that reveals asymmetrical CNS deficits is inconsistent with ongoing toxicity.

With *lead* toxicity, such as from ingestion of paint chips, lead ornaments, or fishing weights, the onset of CNS signs and seizures may begin within a few days after the ingestion. Other signs of lead toxicity can include anorexia, vomiting, diarrhea, or constipation. Due to poor bioavailability, lead that is not ingested (e.g., gun pellets embedded in the tissues) almost never causes toxicity. In lead toxicity, basophilic stippling (25%) and nucleated red blood cells (RBCs) (54%) occur more often than anemia (8% of cases) and radiographic signs of metal in the gut (20%). Seizures that occur with *metaldehyde* (snail and slug bait) toxicity are distinctive in their speed of onset (30 minutes to 6 hours after ingestion) and in the prominent muscle tremors they generally produce, often resulting in marked hyperthermia (>106° F) that should be treated with cooling measures, not antipyretic drugs. A sweet, acetone-like smell of the vomitus or the whole animal may be apparent to some clinicians. Metaldehyde-induced seizures tend to respond well to antiseizure medications (high doses may be necessary). Clinical signs generally last 1 to 2 days, but acute hepatic damage can occur 24 to 48 hours later. Seizures induced by such *tremorgenic mycotoxins* as penitrem A or roquefortine occur within a few hours of consumption of moldy refrigerated foods or organic debris. Hypersalivation and vomiting commonly precede the seizures, and severe muscle tremors causing hyperthermia are also common. Uncomplicated cases resolve in 2 to 3 days. A similar syndrome occurs with ingestion of certain *blue-green algae* (see following discussion of acute hepatic damage). *Organophosphate*-and *carbamate*-induced of seizures very often occur with concurrent cholinergic signs, including vomiting, profuse diarrhea, hypersalivation, and increases or decreases in muscle tone, heart rate, or pupil size (though pupils remain symmetrical). Onset of signs is usually within minutes to a few hours of ingestion. Low blood cholinesterase levels (human or veterinary laboratory) are diagnostic. In dogs, *chocolate* toxicity that leads to seizures usually

does so within 12 hours of ingestion. Signs that precede the seizures commonly include polydipsia (PD), vomiting (brown color), tachycardia, and restlessness. *Marijuana* toxicity typically first produces CNS depression; vomiting, hypersalivation, and vocalization also occur. Rapid confirmation of toxicity is possible with over-the-counter (OTC) illicit drug test kits or by submitting a urine sample to a human hospital. The presence of anuria, azotemia, or a high osmole gap raises the possibility that seizures could be due to *ethylene glycol* toxicity (see discussion of acute renal failure that follows). Large ingestions of *ethanol* or *methanol* (distilled alcohol; fermented foods or grains) may terminally cause seizures, often preceded by vomiting, CNS depression, ataxia, disorientation, and coma.

Naturally-occurring illnesses that cause CNS alterations and seizures include *head trauma* (signs of blunt or penetrating injury should be present if trauma alone is causing seizures), *meningitis* (asymmetrical deficits during interictal period, neck pain, or papilledema on fundic exam would increase likelihood; cerebrospinal fluid [CSF] tap for diagnosis), *hydrocephalus* (persistent fontanelle may or may not be an indicator but allows transcranial ultrasound for diagnosis), *intracranial neoplasia* (more likely than intoxication if asymmetrical neurologic deficits are present during interictal period), *congenital portosystemic shunts* (PSS); (majority of symptomatic patients <6 months of age; concurrent cryptorchidism suggestive of PSS; liver commonly small on radiographs; pre-and post-prandial bile acid levels with or without skilled ultrasonography are most valuable for diagnosis, but if icterus, ascites, or very high liver enzyme elevations are present, PSS alone is unlikely), *rabies* (unvaccinated status, endemic area, and possible exposure to wildlife increase likelihood; fresh bite wounds are not usually relevant to seizures because rabies virus incubation period is at least 2 weeks), and *canine distemper* (fundic lesions, “hard pad disease” increase likelihood; if present, signs of conjunctivitis, rhinitis, or gastroenteritis are *not* usually from distemper once seizures are occurring; indirect fluorescent antibody [IFA] test for diagnosis). 242
Hypocalcemia (measure blood calcium) and *hypoglycemia* (measure blood glucose) should be ruled out 243
immediately in all seizuring patients because they are common, rapidly controllable causes of seizures. Sustained, profound *bradycardia* (e.g., <40 beats/minute for large dogs, <80 beats/minute for cats or small dogs) may cause syncope, progressing to cerebral hypoperfusion and seizures; heart rate should be measured during examination and on an electrocardiogram (ECG) if necessary. *Idiopathic epilepsy* remains the diagnosis of exclusion for recurrent seizures of unidentifiable cause.

66.2 MUSCLE WEAKNESS, PARESIS, AND FLACCID PARALYSIS

Weakness, paresis, and paralysis caused by intoxications tend to be symmetrical and diffuse, whereas a regional distribution may be observed with nontoxic causes. When it occurs, progression from weakness to paresis and paralysis is often quite rapid (hours) and uninterrupted with intoxications; it may be much slower or even chronic or malingering (e.g., wax-wane) with nontoxic causes. (For more on muscle weakness, paresis, and flaccid paralysis, the reader is referred to Chapter 46.)

Coral snakes (Southwestern, Southern United States and southward) can inflict a bite that produces paresis and paralysis within hours. Concurrent dysphagia and dyspnea are common, causing overlap in signs with botulism. However, coral snake bites usually cause swelling at the site of envenomation and may cause such additional signs as muscle fasciculations, vomiting, hypersalivation, and anemia with hemoglobinuria due to hemolysis. Bites of *black widow spiders* (*Latrodectus* spp.) throughout the United States typically cause an onset of signs within 8 hours of the bite. Muscle fasciculations, salivation, and generalized weakness, followed by flaccid paralysis can be observed. Such *phenoxy herbicides* as 2,4 D can cause muscle weakness and paresis within 24 hours of exposure. These common household herbicides can be absorbed by animals walking through wet, recently-treated lawns and usually cause other signs including vomiting, diarrhea, occasionally hepatic damage, and possibly may induce muscle rigidity. Dogs that ingest *macadamia nuts* (>1 to 2g/kg body weight) may show diffuse muscle weakness

and ataxia within 12 hours of ingestion and for 1 to 2 days' duration. Vomiting commonly occurs first, and depression, muscle fasciculations, and hyperthermia may occur concurrently.

Medical differential diagnoses for diffuse muscle weakness, paresis, and flaccid paralysis include *acute polyradiculoneuritis/coonhound paralysis* (diffuse muscle pain fairly common), *tick paralysis* (ticks may or may not be present [e.g., *Dermacentor* spp. in North America, *Ixodes* spp. in Australia]), *botulism*, and *myasthenia gravis* (acetylcholine receptor antibody test required for diagnosis; edrophonium test less commonly rewarding; weakness may classically be exercise induced and rest responsive, or it may be profound and continuous). Disorders not affecting the neuromuscular system directly, such as *joint pain* (suggested by joint swelling, resentment to manipulation of joints, and radiographic and cytologic abnormalities) or *aortic thromboembolism* (more likely if cyanosis of nail beds, absent pulse, cool extremity of affected limb, heart murmur, gallop sound, or cardiac arrhythmia are present) may also produce clinical signs appearing to suggest weakness. Such systemic disorders as *hyperviscosity* (evaluate hematocrit, serum globulins), marked *hyponatremia* (measure serum sodium), and *hypokalemia* (measure serum potassium) may also cause these signs. Diffuse muscle weakness can be caused by *profound anemia* (measure hematocrit) or such systemic disorders as *severe hypovolemia* (more likely if poor pulse quality, cool extremities, and tachycardia are present), or *marked hypo-* or *hyperthermia* (body temperature should be checked), all of which can alter mental alertness along with the weakness. Finally, degenerative spinal cord diseases such as *degenerative myelopathy* may cause ataxia and weakness; however, in most cases the hindlimbs are predominantly (or solely) affected and patients tend to be older, larger dogs, often with evidence of chronicity (e.g., worn dorsal toenails) if signs are severe.

66.3 ACUTE BLINDNESS

With massive ingestion of *salt,* severe mentation changes (profound mental depression, seizures) are expected simultaneously if blindness is present, as well as extreme hypernatremia (serum Na >180 mEq/L). Accidental ingestion of *horse dewormers* containing ivermectin or similar compounds (moxidectin) by dogs can cause acute blindness that is usually reversible, may last for a few days, and is accompanied by ataxia, tremors, shaking, CNS depression, or seizures. Differentiation from nontoxic causes is difficult and relies on the possibility of exposure (e.g., rural setting, horses in region); resolution is possible with supportive care. (For more on acute blindness, the reader is referred to Chapter 26.)

Medical differential diagnoses for acute blindness include *trauma* (more likely if signs of blunt or penetrating injury to the head or face, or obvious corneal, conjunctival, or scleral lesions are present); *retinal hemorrhage* or *detachment* (fundic exam; blood pressure measurement; assessment of coagulation if signs of coagulopathy); *glaucoma* (tortuous conjunctival vessels and corneal haze are common; intraocular pressure >30 mm Hg is diagnostic); acute onset of *cataracts* (presence of diabetes mellitus increases likelihood; ocular exam); *optic neuritis* (fundic examination; possibly CSF tap); *other disorders of the optic nerves, optic chiasm, optic radiation, or occipital cortex* (increased likelihood with other intracranial signs; CSF tap, imaging for diagnosis, or both); and *sudden acquired retinal degeneration* (electroretinogram for diagnosis).

66.4 ORAL MUCOSAL LESIONS

Ingestion of such substances as *corrosive acids* (e.g., some toilet cleaners, drain openers, antirust compounds), *alkalis* (e.g., alkaline batteries, bleaches, homemade soaps), *cationic detergents* (e.g., disinfectants, fabric softener sheets), *liquid potpourri* (more commonly in cats), or *formaldehyde* can cause mucosal injury and oral ulcers when ingested. Induction of vomiting is usually contraindicated, to avoid chemical esophagitis. (For more on oral mucosal lesions, the reader is referred to Chapter 219.)

Medical differential diagnoses for oral mucosal lesions include *uremic stomatitis* (more likely with abnormal kidneys on palpation, especially if azotemia and inadequately concentrated urine also are present), *periodontal disease* (usually concurrent with severe dental calculus; distribution of lesions more along gingivae and cheeks than tongue), *trauma* (e.g., persistence of foreign body such as porcupine quills), chewing on *electrical cord* (often including other signs of electrocution, such as mentation changes, dyspnea from noncardiogenic pulmonary edema; oral lesions commonly linear or regional, rather than multifocal), *systemic lupus erythematosus* or other autoimmune diseases (ulcerations most commonly at mucocutaneous junction; other cutaneous and systemic signs common), *feline calicivirus* infection (unvaccinated cats more susceptible; often, concurrent nasal congestion or purulent nasal with or without ocular discharge), *candidiasis* (cytology), or *feline leukemia virus* (FeLV) or *feline immunodeficiency* virus (FIV) infection (other signs possible; serologic tests).

243

244

66.5 ACUTE RENAL FAILURE

Ethylene glycol intoxication may first manifest with signs mimicking drunkenness, followed by weakness, ataxia, vomiting, recumbency, and seizures. Metabolic acidosis may be detectable within 1 to 2 hours of ingestion, hyperglycemia by 3 to 9 hours, and hyperkalemia and hypocalcemia by 6 to 9 hours. Serum urea and creatinine (CR) elevations are usually first apparent only 12 hours postingestion. Ethylene glycol intoxication can be suspected with an osmole gap greater than 15 mOsm/μL (osmole gap = measured serum osmolality – [2X (Na+K) + blood urea nitrogen (BUN)/2.8 + glucose/18]; for Système International Units [outside United States], osmole gap = measured serum osmolality – [2X (Na+K) + BUN + glucose]); an elevated osmole gap typically is detectable within 1 to 2 hours of ingestion of ethylene glycol. Confirmation is with a veterinary test kit or by submitting a urine or blood sample to a veterinary or human hospital laboratory for ethylene glycol analysis. In dogs, acute renal failure caused by ingestion of *grapes* or *raisins* typically manifests with vomiting within a few hours of ingestion, followed by polyuria (PU) and PD, depression, anorexia, and signs of abdominal pain. The vomitus can be informative (visible traces of grapes or raisins). Signs of renal failure occur in the subsequent 24 hours, and some have responded to supportive treatment (a few days to 3 weeks). Pancreatitis can occur concurrently. In cats, ingestion of *lilies* (Easter lily *[Lilium longiflorum]*, tiger lily *[L. tigrinum]*, *L. rubrum*, Japanese showy lilies *[L. speciosum*, *L. lancifolium]*, or day lily [*Hemerocallis* spp.]) can cause acute renal failure. Vomiting, anorexia, and depression occur 2 to 4 hours postingestion, and azotemia and isosthenuria occur 24 to 72 hours later.

Medical differential diagnoses for acute renal failure include *renal infiltration* as with lymphoma (kidneys often enlarged on palpation; ultrasound and cytology [and/or biopsy] for diagnosis), *renal thromboembolism* (more likely with procoagulant states; Doppler ultrasound of renal vessels to assess), *pyelonephritis* (urinalysis may reveal evidence of urinary tract infection; ultrasound, urine culture indicated), and *end-stage chronic renal failure* (azotemia, nonregenerative anemia, isosthenuria, and negative urine culture are needed to make this diagnosis). (For more on acute renal failure, the reader is referred to Chapter 258.)

66.6 ACUTE HEPATIC DAMAGE

Mushroom poisoning (e.g., *Amanita phalloides*) may cause acute hepatic damage in dogs 1 to 2 days postingestion; these signs usually follow acute vomiting, diarrhea, signs of abdominal pain, and anorexia that begin a few hours after ingestion. Similarly, ingestion of *blue-green algae*, usually from drinking pond water, produces acute vomiting, diarrhea, and signs of abdominal pain within 6 hours, progressing to intrahepatic hemorrhage, hypovolemic shock, and acute liver failure in hours to days depending on dose and type of algae. The patient's muzzle should be inspected because in some cases the exposure and diagnosis are strongly aided by the finding of algae around the lips or nose. *Iron* toxicity, most commonly from the ingestion of an overdose of

multivitamins, may first produce signs of gastrointestinal (GI) disturbance, followed by apparent recovery for a few hours, and then progressive weakness and possibly shock. Signs of liver failure occur 1 to 2 days later. The iron in vitamins is not radiographically detectable as metal. Iron toxicity produces elevated serum iron levels, usually more than the total serum iron–binding capacity. Ingestion of any part of the *sago palm* or *cycad palm* (*Cycas* spp.), native to the Southwestern United States, can cause acute GI disturbances, followed by signs of acute liver failure 1 to 3 days after ingestion. Some dogs also show such neurologic signs as weakness, ataxia, depression, or seizures. All parts of the plant are considered toxic, especially the seeds (1 to 2 of which can be lethal to an average-sized dog), and mortality in dogs in general is high (33%). (See also Chapters 227, 228, and 230.)

Medical differential diagnoses for liver failure include acute systemic processes such as *sepsis* (suggested by the presence of a focus of infection, elevated white blood cell [WBC] count, left shift and toxic changes on complete blood count [CBC]); *heat stroke* (elevated body temperature); *leptospirosis* (renal failure often concurrent; serology); *heartworm caval syndrome* of dogs (likelihood dependent in part on geographic location; heartworm antigen test positive; heartworms may be seen in right heart or cavae on echocardiogram); *trauma* (more likely with signs of trauma elsewhere on patient; hemoabdomen, fractures possible); and advanced cases of primary hepatobiliary disorders including *hepatic lipidosis* of cats (more common in obese cats; abdominal ultrasound shows diffusely hyperechoic liver; biopsy should be done to confirm); *cholangitis, cholangiohepatitis,* and *lymphocytic portal hepatitis* of cats; *chronic hepatitis* of dogs (in advanced stages, microhepatica possible on radiographs or ultrasound; ascites possible [pure transudate]; see previous discussion of CNS alterations.) In general, ultrasound evidence of marked microhepatica, a markedly nodular liver, or ascites that is a pure transudate (or a combination of these factors), are suggestive of chronic liver disorders or infiltrative liver disease rather than acute toxicity. Similarly, normal liver enzyme values (alanine aminotransferase [ALT], aspartate transaminase [AST], alkaline phosphatase [ALP]) may occur with liver failure originating from longstanding, naturally occurring liver disorders (e.g., PSS, chronic hepatitis) but are inconsistent with acute, toxic causes of liver failure. Ultimately, in the absence of a medical history, persistent signs of hepatopathy for more than several days despite supportive care warrant a liver biopsy to further pursue the diagnosis.

66.7 SEVERE ANEMIA

Ingestion by dogs of *onions* or *garlic* (as little as 3.5 oz of minced onions in a 25 lb [11 kg] dog), *zinc* (ingestion of U.S. pennies minted in 1983 or thereafter or galvanized nuts or cage wires), or *naphthalene mothballs* (one mothball for a medium-sized dog can cause signs; breath may smell like mothballs can all acutely produce GI signs), followed by Heinz body hemolytic anemia and hemoglobinuria within 1 to 2 days of ingestion. In cats, *acetaminophen* causes methemoglobinemia, Heinz body anemia, and hemolysis. Severe anemia of toxic origin may also come from blood loss caused by *anticoagulant rodenticide* ingestion, in which case overt signs of hemorrhage (e.g., melena, epistaxis, hematuria) may be present, or dyspnea (pulmonary hemorrhage, airway hematoma) or lethargy (hypovolemia, anemia) may be dominant features. Suspicion of the latter diagnosis comes from these signs together with failure of blood to clot in vitro or bruising after venipuncture or handling. Hematocrit may or may not be decreased depending on acuity and severity of blood loss. A markedly increased prothrombin time (PT) is highly suggestive of anticoagulant rodenticide toxicity. (For more on severe anemia, the reader is referred to Chapters 59, 270, and 271.)

Medical differential diagnoses for severe anemia include traumatic overt blood loss (physical exam); GI blood loss (more likely in presence of feces with melena; hematochezia; or vomitus with black flecks of digested blood or strong positive reaction on blood square of urine dipstick); bleeding abdominal mass (more common in larger breed, older dogs; palpable abdominal mass or abdominal fluid wave [or both]; ultrasound and abdominocentesis for confirmation); immune-mediated hemolytic anemia (IHA) (spherocytosis, positive Coombs' test, in-saline

autoagglutination are all more suggestive of IHA); immune-mediated thrombocytopenia (thrombocytopenia often marked [<30 k]); ehrlichiosis (anemia classically with neutropenia, thrombocytopenia, and hyperglobulinemia, but variable; titers or polymerase chain reaction [PCR] to pursue the diagnosis); *Mycoplasma hemofelis* infection in cats (formerly *Hemobartonella felis;* seen on blood smear; may be incidental finding only); feline leukemia (FeLV test); hookworms (fecal flotations; evidence of regeneration, iron loss; empiric deworming); chronic renal failure (often small kidneys; azotemia with isosthenuria); and other neoplasia (thoracic radiographs may reveal mass, effusion, or metastases; abdominal palpation or ultrasound may reveal intestinal thickening or mass; if present, biopsy should be considered to confirm). With the exception of intoxications causing aplastic anemia, anemias of toxic origin tend to be regenerative, whereas anemias of several days' duration or more that show no evidence of regeneration are unlikely to be caused solely by ingestion of the toxins listed previously.

66.8 CARDIAC ABNORMALITIES

Substances with toxic effects on the heart include the plants *foxglove* (*Digitalis* spp.), *lily of the valley* (*Convallaria* spp.), *oleander (Nerium oleander)*, *azalea* and other *Rhododendron* spp., *mistletoe (Phoradendron)*, and yew (*Taxus* spp.); as well as bufo toads (*Bufo* spp.). These toxins produce cardiac effects that manifest mainly as cardiac arrhythmias such as premature atrial or ventricular complex, as opposed to causing structural heart disease like valvular regurgitation. Therefore physical abnormalities from the previously listed intoxications commonly include lethargy or weakness associated with an irregular pulse and heart rhythm, perhaps a weak pulse, or syncope and collapse; monitoring of these patients begins with continuous ECG. Signs of structural heart disease such as valvular regurgitation (e.g., heart murmur) are almost never due to intoxication alone. (For more on cardiac abnormalities, the reader is referred to Chapter 202.)

Medical differential diagnosis for cardiac arrhythmia would include *automobile trauma* (physical exam or radiographic evidence of recent trauma); *gastric dilatation* and *volvulus* (physical examination; abdominal radiographs); such metabolic disturbances as *anemia*, *hypokalemia*, *acidosis*, or *hypoxia; abdominal mass* (palpation, radiographs, ultrasound), and *primary heart disease* including cardiomyopathy, advanced valvular heart disease, congenital heart disease, or heartworm (heart murmur, cardiomegaly on radiographs, or congestive heart failure would increase likelihood of primary heart disease as cause of arrhythmia).

66.9 GASTROINTESTINAL (GI) SIGNS

Many intoxications provoke vomiting as an initial manifestation before producing additional clinical signs. (The reader is referred to the previous sections of this chapter for information on GI signs occurring jointly with chief complaints or problems already discussed). In addition, ingestion of *arsenic* (in some ant baits and some herbicides; urinary arsenic concentration >1 ppm is diagnostic [human hospital laboratory]); *castor beans* (*Ricinus communis*: colorful, 6 mm seeds often incorporated into jewelry as beads; vomiting usually begins within 6 hours of ingestion); nitrogen-phosphorus potassium [NPK] *fertilizers; calcium oxalate-containing plants* (e.g., elephant's ear [*Caladium* spp.], dumb cane [*Dieffenbachia* spp.], and peace lily [*Spathiphyllum* spp.]; oral mucosal swelling a common occurrence with ingestion); *zinc oxide* (skin ointment either licked off the skin or eaten from a chewed tube); or *zinc phosphide* (gopher bait; concurrent pulmonary edema common; onset of signs within 15 minutes to 4 hours of ingestion; odor of rotting fish [phosphine gas] suggests hazard to veterinary personnel) may all initially produce GI abnormalities. (For more on GI signals, the reader is referred to Chapters 33, 35, 38, and 39.)

Medical differential diagnoses include *gastroenteritis* of unknown cause (self-resolving in 24 to 72 hours with minimal supportive care); *parvoviral enteritis* (fecal parvovirus test positive; leukopenia common; dog often unvaccinated); *small intestinal infiltration* (more likely if intestine is palpably thickened or with weight loss; abdominal lymph nodes may be enlarged; ultrasound may show bowel thickening; biopsy should be done for

diagnosis); *GI obstruction* such as with a foreign body, mass, or intussusception (palpable mass with or without discomfort; abdominal radiographs may suggest obstruction; *pancreatitis* (ultrasound can show abnormal pancreatic echogenicity with or without apparent abnormal size); *intestinal parasites* (serial fecal flotations; empiric deworming); *hypoadrenocorticism* (most dogs are young to middle-aged adults; usually hyperkalemia and hyponatremia are seen when GI signs are present; adrenocorticotropic hormone [ACTH] stimulation test for confirmation); *peritonitis* (ascites almost always present [may be small amount, only on radiographic or ultrasound]; cytology of fluid is diagnostic; penetrating injury around abdomen highly suggestive); *renal failure* (small kidneys on physical exam, uremic halitosis are suggestive; azotemia with isosthenuria highly consistent); *liver failure* (icterus with normal hematocrit very suggestive; liver enzymes, bile acids, hepatobiliary ultrasound abnormalities suggestive); *hypovolemic shock* (physical exam shows depression, recumbency, poor pulse, often tachycardia [or bradycardia in cats]); or *right-heart failure* (ascites, pleural effusion possible with normal serum albumin; echocardiogram shows right-heart disease or pericardial disease causing tamponade).

67 CHAPTER • 67 Venomous Bites and Stings

Patrick M. Burns

Venomous bites by snakes, spiders, and other species account for 1% to 1.3% of calls to poison information centers and approximately the same proportion of deaths in pets. The practitioner must know which venomous creatures inhabit the local area and the various treatments for envenomation.

A number of misconceptions exist about the treatment of envenomation, and new therapies are being developed for several of the conditions discussed here. In general, two important requirements are to keep the animal calm and quiet and to transport it quickly to the nearest veterinary facility. Administration of antivenin and supportive care are the mainstays of treatment for most envenomations, and this requires accurate identification of the toxin.

67.1 CROTALIDS (PIT VIPERS)

Nearly all snake bite envenomations in the United States are caused by snakes of the Crotalidae family. The three genera of crotalids in the United States are *Crotalus* (rattlesnakes) (Figures 67-1 67-3, 67-8), *Sistrurus* (pygmy rattlesnakes and massasauga) (Figure 67-7), and *Agkistrodon* (copperheads, cottonmouth water moccasins) (Figure 67-2). *Crotalus catalinensis* is the only rattlesnake that does not have a keratinized rattle on the end of the tail.

A single bite may produce as many as six puncture marks. The maxillary teeth are rotated forward at the time of the bite. Pit vipers have characteristic retractable rostral maxillary fangs (Figure 67-4). They can control the amount of venom delivered with each bite, and the first, defensive bite often is “dry.” Bites to the torso tend to develop more severe clinical signs, and bites are more serious during the spring and summer months.

Cats are more resistant than dogs to crotalid venom, but they often present with more severe clinical signs because of their small size relative to the amount of venom. Also, the interval between the occurrence of the bite and administration of medical therapy frequently is longer because of the hiding behavior of sick cats.

Crotalid venom is a mixture of enzymatic and nonenzymatic proteins. The enzymatic proteins (hyaluronidases and collagenases) cause local tissue injury and help the venom enter the systemic circulation. Different toxins found among the various species affect the clotting cascade through different mechanisms and result in impaired platelet function, thrombocytopenia, activation of clotting factors, fibrinolysis, and vasculitis. The venom of some crotalid species can cause neurologic signs, such as convulsions and alterations in mentation. The severity of the local reaction does not correlate with the severity of the systemic signs.

Clinical signs include localized pain, salivation, weakness, fasciculations, hypotension, alteration in respiratory pattern, regional lymphadenopathy, mucosal bleeding, prolonged bleeding times, echinocytosis of erythrocytes, obtundation, and convulsions.

Hematologic changes suggestive of envenomation include hemoconcentration followed by anemia, stress leukogram findings, and echinocytosis. The coagulation panel may show prolongation of the prothrombin time and partial thromboplastin time, with a reduction in fibrinogen and an increase in fibrin degradation products. Rhabdomyolysis may also be seen, especially with envenomation by Mojave, canebrake and tiger rattlesnakes. Urinalysis can reveal proteinuria, hemoglobinuria, and myoglobinuria. Electrocardiographic abnormalities occur in more severely affected victims.

Antivenin is indicated in moderate-to-severe cases of envenomation. Some first aid procedures are not efficacious, including application of ice or hot packs; incision and suction on the wound; the use of tourniquets; and electric shock therapy at the bite site. Most patients require one to two vials of the polyvalent antivenin given intravenously over 30 minutes. The antivenin reverses the coagulopathy, electrocardiographic findings, and neurologic changes. Tissue necrosis cannot be reversed by antivenin; however, the extent of the damage is limited. The practitioner should monitor the hemolysis and coagulation profile in order to judge the amount of venom required. Administration of blood products to reverse the coagulopathy without neutralization of the antivenin may result in further fibrinolysis.

Hypotension, hemolysis, and rhabdomyolysis are reasons for aggressive fluid therapy. Administration of antihistamines and corticosteroids usually is not necessary and tends to increase morbidity. Slow infusion of the antivenin reduces the chance of anaphylactoid reactions. Prior administration of an antivenin does not appear to increase the chance of a reaction. Broad-spectrum antibiotics and analgesics are indicated in patients with severe envenomation.

67.2 ELAPIDS (CORAL SNAKES)

Most elapids are found in the southern and southeastern United States (i.e., *Micrurus fulvius tenere* [Texas coral snake]; *M. fulvius fulvius* [Eastern coral snake]; *M. fulvius barbouri* [South Florida coral snake]; and *Micruroides euryxanthus euryxanthus* [Sonoran coral snake]). The incidence of elapid envenomation is extremely low compared with that from crotalids, and the percentage of dry bites is high because these snakes must “chew” on their victims to inject venom. Another difference between the elapids and crotalids is the lack of proteolytic enzymes in elapid venom (and therefore the lack of a local reaction). The neurotoxic venom of elapids affects the nervous system mainly by means of a nondepolarizing postsynaptic neuromuscular blocking activity, similar to the effect of curare. Some reports have mentioned an intravascular hemolysis, which is speculated to be mediated by phospholipase A.

The clinical onset of symptoms commonly is delayed 10 to 18 hours. In the dog, emesis, salivation, agitation, and central depression, followed by quadriplegia, hyporeflexia, intravascular hemolysis and, finally, respiratory paralysis, are seen. Cats show a loss of cutaneous nociception and hypothermia but not hemolytic anemia. Hematologic studies in dogs reveal erythrocyte membrane damage, such as burr cells and spherocytes.

246

247

Application of a compression bandage, where possible, has been shown to be helpful. The definitive treatment is with *Micrurus fulvius* antivenin (Wyeth Laboratories, Marietta, Pennsylvania). However, this antivenin is not effective against the Sonoran coral snake. Early administration of the antivenin produces the maximum effect. It should be administered slowly intravenously to help reduce the chances of anaphylactic and anaphylactoid reactions. (A new ovine Fab antivenin with fewer side effects may become available in the near future.) Subcutaneous injections at the bite site are ineffective. Initially, one to two vials of antivenin may be given, and the clinical signs are closely monitored to gauge the requirement for more antivenin. In severe cases of envenomation, respiratory support by means of artificial ventilation may be required for several days. Broad-spectrum antibiotics are recommended for local wound infections. Treatment of Sonoran coral snake envenomation is supportive at this stage. Tick paralysis, botulism, polyradiculoneuritis, myasthenia gravis, and certain drugs can have clinical signs similar to those of elapid envenomation.

67.3 *LATRODECTUS* spp. (WIDOW SPIDERS)

The widow spiders belong to the genus *Latrodectus. Latrodectus mactans* (black widow), *L. variolus, L. bishopi* (red widow), *L. hesperus* (western black widow), and *L. geometricus* (brown widow) are the five species found in all the U.S. states except Alaska. The cat seems more susceptible to *latrodectism,* or envenomation by a widow spider, than does the dog. Alpha latrotoxin is the major active component of the venom. The lethal dose (LD_{50}) of the venom varies, depending on the species of widow spider. The brown widow is the most potent, with an LD_{50} of 0.43 mg/kg body weight. The LD_{50} of the black widow is 1.39 mg/kg body weight. Alpha latrotoxin causes an initial release of neurotransmitters from nerve endings throughout the nervous system and ultimately causes depletion of these transmitters, resulting in a blockade. It affects both motor and sensory fibers.

Clinical signs are commonly detected within 8 hours of envenomation, with most occurring in the first hour. The toxin does not cause a significant local reaction at the bite site. Small, young, and geriatric patients are most susceptible to the venom. Hyperesthesia, muscle fasciculations, and cramping occur, and somatic abdominal pain is a characteristic clinical sign. The motor signs may give way to a flaccid paralysis within 24 hours of the bite. An acute abdomen, rabies, or intervertebral disk disease are differential diagnoses. Respiratory compromise, hypertension, tachycardia, and seizures may also occur. Cats also show vocalization, salivation, agitation, muscle cramping, and ataxia leading to paralysis. Severe bites tend to occur in the autumn.

The diagnosis is based on the clinical signs and historical exposure to the spider habitat. Occasionally cats may vomit up a spider. A stress leukogram with hyperglycemia is often seen. The muscle cramping may lead to a rise in creatinine phosphokinase. Urinalysis may reveal concentrated urine, casts, and an elevated albumin level. The reduction in urine output occurs secondary to dehydration and urinary retention.

The main treatment modality consists of administration of the antivenin (Lyovac antivenin, Merck, Sharpe & Dohme). This may be give intramuscularly or intravenously. One vial is usually enough, but at times a second is required. Relief of clinical signs is usually seen within 30 minutes. Slow administration reduces the risk of anaphylactoid reactions. Blood pressure monitoring is advantageous because of the hypertension that occurs. Intravenous fluids to correct dehydration and oliguria should be administered only after the hypertension has been corrected. Pulmonary edema has also been seen with latrodectism. In the early stages of the clinical signs, calcium gluconate 10% theoretically may help reduce muscle cramping and pain; however, the effect is short-lived, and this therapy is not a substitute for the antivenin. Muscle relaxants such as methocarbamol and diazepam may be of some help, but results from clinical trials have not been supportive of their efficacy.

67.4 LOXOSCELIDAE (RECLUSE OR BROWN SPIDERS)

Recluse spiders are members of the family Loxoscelidae, genus *Loxosceles*. Five species (*L. reclusa, L. refuscens, L. arizonica, L. unicolor,* and *L. laeta*) found in the south-central United States are capable of causing necrotic arachnidism. Two forms of *loxoscelism* (envenomation by recluse or brown spiders), cutaneous and viscerocutaneous, have been described. The cutaneous form, which is more common, starts with a bull's-eye lesion at the bite site. A pale center, caused by localized thrombosis, is surrounded by an area of erythema. Within 24 to 72 hours, a hemorrhagic bulla with an underlying eschar develops in the center. The eschar eventually sloughs, leaving an ulcer that may take months to heal. The severity of these lesions depends on the response of the immune system to the toxin.

The viscerocutaneous form involves the development of a Coombs'-negative hemolytic anemia that may last for 7 days, thrombocytopenia, and disseminated intravascular coagulopathy. The extent of the cutaneous lesion and the

severity of the systemic signs do not appear to be correlated. A single bite can be lethal but in most cases results in dermonecrosis and prolonged wound healing (2 to 3 months). The bite itself is painless. Renal failure from the hemolytic anemia is the major cause of death from *Loxosceles* envenomation.

Figure 67-1 **A,** *Crotalus molossus*, blacktail rattlesnake; **B,** Color variant.

Figure 67-2 *Agkistrodon contortrix*, broad banded copper snake.

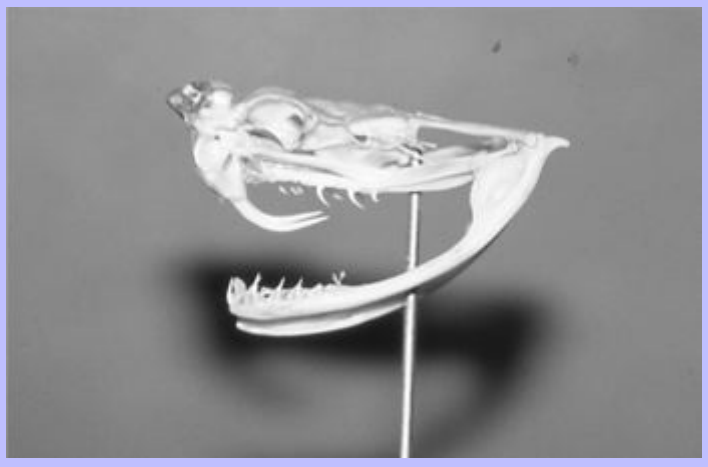
The exact mechanism of loxoscelism is unknown; however it is likely the result both of the toxin and the immune response to the toxin. An immune-mediated vasculitis, hemolysis, and platelet abnormalities all play a part in the mechanism. Sphingomyelinase D is the major toxin. The venom causes rapid coagulation and thrombosis of the capillaries. Depletion of clotting factors VIII, IX, XI, and XII also occurs, with resultant prolongation of the activated partial thromboplastin time.

No definitive test for *Loxosceles* envenomation exists. The diagnosis is based on the history and clinical signs and on laboratory findings of a Coombs'-negative hemolytic anemia, hemoglobinemia, hemoglobinuria, and a prolonged activated partial thromboplastin time. Hemolysis usually is seen only in the early stages and is followed by the cutaneous lesions. Systemic signs may be used to monitor the response to therapy. Other diagnostic possibilities include necrotizing fasciitis, mycobacterial infection, a burn wound, or a decubital ulcer.

Antivenin has had disappointing results when given after the lesions became obvious. Dapsone (1 mg/kg given orally for 14 days) has shown some efficacy in reducing the size of the cutaneous lesions. Dapsone inhibits chemotaxis, thereby minimizing the vasculitis caused by polymorphonuclear cells. Some evidence suggests that the use of hyperbaric oxygen (2 atmospheres twice daily) may be beneficial. Corticosteroids and surgery have not been shown to be efficacious in these cases. Viscerocutaneous symptoms may require intravenous fluids or blood products, and systemic antibiotics and analgesics may be necessary. Any analgesic that interferes with renal function should be avoided.

Figure 67-3 Crotalus horridus, timber rattlesnake.

Figure 67-4 *Crotalus* spp. skull.



67.5 TICK PARALYSIS

Dermacentor andersoni, D. variabilis, and *Haemaphysalis cinnabarina* are found in the western United States and British Columbia, and *D. variabilis* is found in the central and eastern United States and in southern portions of Canada. However, tick paralysis does not occur at all locations, which suggests a variation in the potency of the toxin. This is also true for the transmission of tick-borne diseases. Tick paralysis is more likely to occur in the spring and summer months.

Holocyclotoxin, a presynaptic neurotoxin at the neuromuscular junction, is secreted in the saliva of *Ixodes holocyclus*. It is similar to the toxin isolated from *D. andersoni*. The toxin inhibits the release of acetylcholine. The *Dermacentor* toxin can cause mortality, if left untreated, by means of a progressive, ascending paralysis that results in respiratory failure. Local effects of paralysis may be noted before the generalized form is seen. This is

most evident when the tick bite occurs close to the eye, resulting in ptosis or lack of a palpebral reflex. In such cases exposure keratitis may develop, requiring a temporary tarsorrhaphy. Recent studies on *I. holocyclus* have shown that toxin to have a direct effect on the heart, causing a reduction in the fractional shortening and a prolongation of the QT interval. Aspiration pneumonia secondary to megaesophagus is not uncommon in severely affected animals.

Clinical signs usually first appear 5 to 9 days after tick attachment. The diagnosis is based on the clinical signs and a history of exposure to ticks. Most ticks are found around the head, neck, and forelegs, and clipping of the patient sometimes is necessary to find them. Recovery from the paralysis usually occurs spontaneously 3 days or more after removal of the tick. Treatment is supportive during this time, which in severe cases may mean artificial ventilation for respiratory failure. Fiprinol sprays are a good alternative to organophosphates for eliminating other ticks. The main differential diagnoses for tick paralysis are polyradiculoneuritis and botulism.

249

Figure 67-5 *Heloderma horridum*, beaded lizard.

67.6 HYMENOPTERAN STINGS (INSECT BITES)

The bites and stings of some winged insects and fire ants (*Solenopsis* sp.) have the potential to cause serious toxic or allergic effects. Toxic reactions are dose dependent unless hypersensitivity to the toxin is a factor. The venoms of this group have three broad components: low molecular weight toxins, peptides, and high molecular weight toxins. Low molecular weight toxins consist of histamine, dopamine, noradrenaline, amino acids, epinephrine, and acetylcholine and are involved only in the local reaction. Peptides (melittin, apamin, kinins, hemolysin, mast cell degranulating factors, and chemotactic factors) cause cytolysis and can act as neurotoxins, inducing hyperexcitability. High molecular weight toxins consist of phospholipase A and B, hyaluronidase, and proteases and cause allergic reactions. Dialkydpiperidine is the main cytotoxic alkaloid found in fire ants.

Allergies are mediated by immunoglobulin E (IgE) and usually occur after a period of sensitization. The common bee *(Apis mellifera)* has the greatest propensity to cause an allergic reaction. Reactions to hymenopteran stings can include localized angioedema, urticaria, emesis, diarrhea, hematochezia, respiratory distress, and death. The most significant stings occur around the head and neck.

The diagnosis of hymenopteran stings is based on historical evidence of contact with stinging insects and clinical signs. Certain breeds of dogs (boxers, Staffordshire terriers, and bull terriers less than 18 months of age) have a

higher chance of a severe reaction to the stings. Other diagnostic possibilities include skin testing, specific IgE or IgG antibodies, histamine release assay, and sting challenge. Treatment consists of administration of corticosteroids and antihistamines and supportive care. In severe cases, prednisolone sodium succinate may be administered intravenously; however, most cases respond to dexamethasone sodium phosphate given intravenously or intramuscularly. Severe cases may require supportive care with oxygen therapy, intravenous fluids, gut protectants, positive inotropes, and vasopressors. Patients with airway obstruction or bronchial constriction may require a tracheostomy or the use of bronchodilators.

Figure 67-6 *Heloderma suspectum*, Gila monster.

Figure 67-7 *Sistrurus catenatus*, Eastern massauga.

Figure 67-8 *Crotalus atrox*. **A,** Western diamondback rattlesnake tail; **B,** Western diamondback rattlesnake.

249

250

Table • 67-1 Toxins of the Gila Monster

TOXIN	ACTION
Gilatoxin	Acts as a neurotoxic protein
Helothermine	Reduces body temperature
Hyaluronidase	Damages local tissue, allowing toxins to spread
Phospholipase A_2	Causes release of histamine, serotonin, acetylcholine, kinins, and other slow-release substances
Helodermatine	Causes vasodilatation, increased permeability and edema
Arginine hydrolase	Causes release of bradykinin
Helospectin and helodermin	Have activity similar to that of vasoactive intestinal peptides

67.7 HELODERMATIDAE LIZARD (GILA MONSTER)

The genus *Heloderma* includes two species of lizard that are venomous to humans (*H. suspectum* and *H. horridum*) (see Figures 67-6 and 67-5, respectively). The venom of the helodermatids is a mixture of proteins and peptides. The intravenous LD_{50} of the crude toxin is 0.4 to 2.7 mg/kg in mice; the toxic dose in dogs and cats is unknown.

Bite wounds typically are obvious and commonly are found around the face or forelegs. Clinical signs include salivation, lacrimation, emesis, tachypnea, respiratory distress, tachycardia, hypotension, and shock. Coagulopathies have not been reported, although a coagulation profile and minimum data base are indicated to help rule out snake envenomation. Treatment is symptomatic and may include intravenous fluids, respiratory support, debriding of the wound, and administration of broad-spectrum antibiotics and analgesics. An antivenin has been produced by the Poisonous Animal Research Laboratory at Arizona State University, but it is not yet commercially available.

68 CHAPTER • 68 Plant Toxicities

Lynn R. Hovda

Plant toxicity continues to account for about 10% of all companion animal exposures reported to poison control centers. Pets less than 1 year of age make up about 50% of the cases, with dogs having significantly higher exposure rates than cats.[1] Ingestion usually occurs secondary to playfulness, boredom, or confinement; although the number of pets poisoned by well-meaning owners is increasing.

Veterinarians and pet owners are often faced with determining whether or not a plant ingestion is responsible for poisoning. This is rarely an easy task because most ingestions are not witnessed and many pet owners do not know the names of plants in their house, garden, or yard. Several reliable sources of plant identification aid the veterinarian, as does some baseline knowledge of toxic plants indigenous to the local area.

Very few antidotes are available for plant poisoning. Treatment generally consists of symptomatic and supportive care. Unless contraindicated, emesis or gastric lavage followed by activated charcoal with a cathartic should be performed. Identification of the specific plant, the quantity and parts ingested, the time of ingestion, and the age and breed of animal all are necessary for formulating a treatment plan. Examination of stomach contents (seeds, bulbs, flowers) may confirm ingestion, assist in plant identification, guide therapy, and offer a prognosis.[1]

68.1 NEWER PLANT TOXICITIES

68.1.1 Grapes and Raisins

Ingestion of grapes and raisins has just recently been associated with the onset of acute renal failure in dogs. Literature is sparse, and signs and treatment are based on case reports with no firm scientific research as a backup.[2] No specific breed predilection or geographic location has been noted. Neither the toxin nor the mechanism of action has been identified. Toxicity varies and has been reported with ingestion of just a few raisins or grapes up to several pounds. Homegrown grapes or raisins appear to be just as toxic as those purchased in stores. Vomiting partially digested grapes or raisins occurs 1 to 3 hours after ingestion and is followed by anorexia, severe abdominal pain, and diarrhea with partially digested grapes or raisins in feces. Later signs include central nervous system (CNS) depression and decreased urine output. Results of serum chemical analysis taken 24 to 36 hours after ingestion are consistent with acute renal failure. Treatment is symptomatic and includes early and aggressive intravenous (IV) fluid diuresis or peritoneal diuresis in anuric dogs. Signs may last from a few days to many weeks. Prognosis is good if treated early, although sporadic deaths have occurred in well-treated cases.

68.1.2 Macadamia Nuts

Reports of dogs poisoned by ingesting macadamia nuts have increased over the past 3 to 4 years.[3] Macadamia nuts, produced by *Macadamia integrifolia* and *Macadamia tetraphylla* trees in Hawaii, can be found in most grocery stores throughout the United States. Both the toxin and mechanism of action remain unknown. Generally, signs occur within the first 2 to 12 hours after ingestion, with the most frequently reported signs associated with locomotor disturbances. Almost all dogs have difficulty walking, with the gait best described as drunken or staggering. Tremors, ataxia, and weakness (hind end > front end) have also been reported.[3] Other

reported signs include depression, vomiting, abdominal pain, and hyperthermia.[3] Laboratory analysis shows a mild increase in serum alkaline phosphatase and lipase, as well as a delayed increase in serum triglycerides. No antidote exists, and treatment is mainly supportive. Prognosis is excellent, with signs generally resolving over 24 to 48 hours with appropriate care.

68.2 COMMON PLANT TOXICITIES

68.2.1 Plants Affecting the Blood

Ingestion of raw or cooked onion (*Allium* spp.) is well associated with toxicity in dogs and cats.[1] A hereditary abnormality makes Akitas and Shibas more susceptible to toxicity than other dogs.[4] Most recently, reports have surfaced of cats poisoned by eating baby food with onion powder as an ingredient.[5] The primary toxin is *n*-propyl disulfide, an alkaloid found in onions, wild onions, leeks, garlic, and chives. The toxin oxidizes free sulfhydryl groups on hemoglobin, and the oxidized hemoglobin precipitates Heinz bodies in red blood cells (RBCs).[1] Anemia occurs when the spleen removes affected RBCs. Onset of action varies from a few hours to several days. Signs are consistent with anemia and include increased heart and respiratory rates, pale mucous membranes, fatigue, weakness, exercise intolerance, and collapse.[4] Laboratory findings include hemoglobinuria, decreased hematocrit, decreased hemoglobin, Heinz bodies in RBCs, and mild methemoglobinemia. Treatment depends on the hematocrit; some animals need a transfusion.

68.2.2 Plants Primarily Affecting the Cardiovascular System

Plants with cardiac glycoside activity include the common oleander *(Nerium oleander)*, yellow oleander *(Thevetia peruviana)*, foxglove *(Digitalis purpurea)*, lily of the valley *(Convalleria majalis)*, and kalanchoe *(Bryophyllum* spp.).[1] Five different types of cardiac glycosides have been identified in common oleander. The seeds, stems, and roots are toxic. Yellow oleander contains the cardiac glycosides thevetin A, thevetin B, and peruvoside. All parts of the plant are toxic, with seeds having the highest concentration. Digoxin, digitoxin, and digitonin are the most common toxins in foxglove, with seeds again having the highest concentration. Lily of the valley contains at least 15 toxins, with convallatoxin, convallarin, and convallamarin the most common. Seeds contain the highest concentration, whereas the fruit flesh is minimally toxic. Kalanchoe contains bufadienolides, with most poisonings occurring during the plant's flowering season. The mechanism of action for all cardiac glycosides occurs at the cellular membrane level. Inhibition of the sodium-potassium ATPase pump causes slowed electrical conductivity with decreased active transport of sodium and an efflux of potassium.

Signs associated with cardiac glycoside-containing plants are generally related to either the cardiovascular system or gastrointestinal (GI) tract.[1] Vomiting and abdominal pain begin several hours before deterioration in myocardial function. Marked bradycardia with first-, second-, or third-degree atrioventricular (AV) block, ventricular arrhythmias, asystole, and sudden death can occur. Hyperkalemia is usually prominent, although scattered reports of hypokalemia exist. Sap from oleander plants has caused contact dermatitis and blistering of the nose and footpads. Diagnosis depends on physical identification of the plant. Digoxin assays could aid in identification of oleander and foxglove.[1] Serum digoxin levels might be a screening tool, but the correlation between the level and degree of toxicity is very poor.

Treatment varies from case to case but may include correction of potassium abnormalities, appropriate antiarrhythmic drugs, implantation of a temporary pacemaker, and antidigitalis antibody fragments (Fab).

Prognosis is generally poor unless intervention is early and aggressive. An extremely bitter taste and spontaneous vomiting help limit the number of deaths from oleander.

Azaleas (*Rhododendron* spp.) are associated with severe toxicity and death.[1] The precise mechanism of action is unknown, but it appears that grayanotoxins act by binding to closed sodium channels. Slower opening and increased sodium permeabilities cause a decreased resting membrane potential in Purkinje's fibers. Clinical signs include severe weakness, hypotension, dyspnea, and respiratory failure. GI signs unrelated to grayanotoxins include salivation, vocalization, vomiting, and diarrhea. Sodium channel–blocking drugs like quinidine and procainamide have been used successfully.

The yew (*Taxus* spp.) is a common ornamental shrub found in the United States and Canada.[1] Common species include the Japanese yew *(T. cuspidata)*, English yew *(T. baccata)*, Florida yew *(T. floridana)*, and ground hemlock *(T. canadensis)*. Bark, leaves, and seeds are toxic but not the fleshy part of the bright-red fruit. Taxine, a cardiotoxic alkaloid, causes conduction disturbances by direct effect on cardiac muscle ion channels. In dogs, bradycardia, vomiting, diarrhea, weakness, and seizures have been reported. Sudden death may occur. Caged birds may be poisoned by bark or other shrub pieces placed in their cages. Clinical signs in birds include crop regurgitation, ruffled feathers, dyspnea, weakness, ataxia, and sudden death. Treatment is supportive and symptomatic. Prognosis is poor, and once clinical signs have occurred, further treatment is of limited value.

68.2.3 Plants Primarily Affecting the Gastrointestinal System

Oxalate-containing plants (family Araceae) are the most frequently reported household exposures.[1] Common household plants containing insoluble crystals include dumbcane *(Dieffenbachia* spp.), philodendron (*Philodendron* spp.), peace lily (*Spathiphyllum* spp.), and devil's ivy (*Epiprennum aureum*). Crystals are usually concentrated within a raphite structure in the stalk. Chewing on the stalk releases oxalate crystals and other as yet unidentified enzymes. Clinically, stomatitis and glossitis, ocular, or systemic scenarios can occur.

68.2.3.1 Stomatitis and Glossitis

Irritation to the mucous membranes of the mouth and throat causes immediate and intense pain, local swelling, and profuse salivation. These may be accompanied by head shaking, loss of vocalization, and rarely airway compromise. Treatment is symptomatic. The mouth should be thoroughly examined and any remaining plant pieces removed. Cool fluids, ice chips, and analgesics increase comfort until signs resolve. Most typically, it takes 30 to 90 minutes for this to occur, but signs can be prolonged for hours in animals with airway compromise.

68.2.3.2 Ocular

Eye exposures, although rare in animals, cause severe burning pain and swelling. Left untreated, conjunctivitis, abrasions, and corneal ulcers develop. Treatment includes a 10-to 15-minute eye irrigation followed by a thorough eye examination with fluorescein dye staining or slit lamp examination. Ophthalmic protectant medications are used as indicated.

68.2.3.3 Systemic

Systemic effects occur primarily in cats exposed to *Philodendron* spp. Signs are referable to the renal system and CNS and include hyperexcitability, tetany, and seizures. Treatment is symptomatic and supportive.

Rhubarb (*Rheum* spp.) contains soluble oxalate crystals concentrated in the leaf. The stalk is edible and generally causes no systemic effects. When leaves are ingested, soluble oxalates can be absorbed and bind to circulating calcium ions. Symptoms include diffuse GI tract irritation and infrequently systemic hypocalcemia. Oral calcium hydroxide is used to bind oxalates in the GI tract. If systemic signs are noted, IV calcium gluconate or chloride should be administered.

The chinaberry tree *(Melia azedarach)* can be found throughout temperate regions of North America. All parts of the tree are toxic, although dogs are generally poisoned by eating fruit fallen from trees.[6] Toxicity has been reported in rabbits, guinea pigs, rats, and other species. Many potential toxins have been isolated, with meliatoxins found in highest concentration in the fruit. Clinical signs usually occur within 1 to 2 hours after ingestion. Vomiting and diarrhea (with or without blood) are the most common signs along with anorexia, severe abdominal pain, hypersalivation, and straining to defecate.[6] Neurologic effects are similar to nicotine, and signs include depression, ataxia, seizures, and coma. Other reported signs include hyper-or hypothermia, tachycardia or bradycardia, mydriasis or miosis, and muscle rigidity.[6] Death generally occurs from respiratory depression and arrest. Treatment is symptomatic and supportive. Prognosis for recovery decreases significantly with the onset of neurologic signs.

Cycad palms or sago palms (*Cycas and Macrozamia* spp.) are subtropical to tropical houseplants known to cause toxicity in dogs.[7] All plant parts are toxic, with the seeds containing the greatest concentration. The plants contain three toxins: (1) cycasin, which causes GI effects and liver necrosis; (2) β-methylamino-L-alanine, which causes neurologic effects; and (3) an unknown toxin associated with neurologic effects. The onset of action is variable, with signs occurring from a few hours to a day or so. The most commonly reported signs are vomiting and diarrhea (with or without blood) followed by lethargy, depression, liver failure, and death.[7] Laboratory work shows an increase in liver enzymes (alanine transferase and alkaline phosphatase) and bilirubin. Treatment includes multiple-dose activated charcoal and supportive care with special emphasis on the liver.

English ivy *(Hedera helix)*, a common houseplant and ground cover, contains hederagenin, a saponin associated with GI irritation.[1] Other *Hedera* spp. of ivy with suspected toxicity include Persian ivy, Irish ivy, Atlantic ivy, and Nepal ivy. Ingestion of leaves and berries causes profuse salivation, abdominal pain, vomiting, and diarrhea. Treatment is symptomatic and supportive.

Abrus precatorius, the jequirity bean, has been used for centuries in Latin American necklaces and jewelry. It has long been illegal to import this jewelry into the United States, yet it frequently shows up at flea markets and garage sales. Abrin, the toxin, is a toxalbumin similar to botulinum, cholera, and diphtheria.[1] The castor bean plant *(Ricinus communis)* has similar toxic principals. Castor bean plants are widely used as an ornamental shrub throughout North America. Ricin, the toxin, is present in all parts of the plant but is most concentrated in seeds. Abrin and ricin are among the most deadly poisons in the world but must be released from their shell to be absorbed. Dogs are most often poisoned by chewing on the hard outer shell and ingesting the contents. Once absorbed, abrin and ricin enter cells and inhibit protein synthesis resulting in cell death. Signs of toxicity occur within 6 hours of ingestion and include severe abdominal pain, vomiting, diarrhea, seizures, and cerebral edema.[1] Treatment is supportive. Prognosis for recovery is poor once clinical signs develop.

Ornamental holiday plants include holly (*Ilex* spp.), poinsettia *(Euphorbia pulcherrima),* and mistletoe *(Phoradendron flavescens)*. Well over 300 species of holly are found in the United States alone, making

actual plant identification difficult. The toxin remains unidentified but may be ilicin (ilexanthin and ilex acids), a saponin causing GI effects. Poinsettias produce only mild toxicity. The unidentified toxin in the latex sap, thought to be a diterpenoid ester, rarely causes more than mucous membrane irritation or contact dermatitis. Clinical signs include salivation, mild GI irritation, and occasional diarrhea. Mistletoe has the potential for more serious effects, although few animal case reports exist.[8] The toxin is a phytotoxin or toxalbumin that can cause severe gastroenteritis with prolonged emesis. Signs occur up to 18 to 24 hours after ingestion of leaves, berries, or tea made from berries. Treatment associated with any of these plants is symptomatic and supportive. Demulcents and antacids are often of great benefit.

Several varieties of poisonous plants grow from bulbs, tubers, or corms. Included are amaryllis, jonquil, and daffodil (family *Amaryllidaceae*); tulip (family *Liliaceae*); and iris (family *Iridaceae*).[1] The toxic principal is unknown, but ingestion of the bulb has been associated with only mild-to-moderate gastroenteritis. Treatment is symptomatic and supportive.

Autumn crocus *(Colchicum autumnale)* and glory lily (*Gloriosa* spp.) contain colchicine, a toxic alkaloid that concentrates in the tuber and seeds. Colchicine causes cell death by inhibiting normal cell division.[9] Clinical signs include vomiting and diarrhea (with or without blood), hypersalivation, abdominal pain progressing to depression, weakness, ataxia, and collapse. Signs progress further to include several organ systems and finally, multiple organ system collapse. Treatment is supportive. Prognosis is poor if multiple organ systems are affected.

Solanine-containing plants are members of the Solanaceae family. Included are the tomato *(Solanum lycopersicon)*, potato *(S. tuberosum)*, eggplant *(S. melongena)*, bittersweet *(S. dulcamara)*, deadly or black nightshade *(S. nigrum)*, and Jerusalem cherry *(S. pseudocapsicum)*.[1] The primary toxin is solanin. Some plants also produce tropane belladonna (deadly nightshade) or solanocapsine (Jerusalem cherry). Solanine is poorly absorbed orally, and most members of this family act only as GI irritants. Systemic absorption only occurs when substantial GI mucosa damage exists. Systemically, solanine causes CNS depression and cardiac arrhythmias. Deadly nightshade may cause a mixed picture, depending on which toxin is prevalent. Solanine usually predominates, but anticholinergic signs occasionally occur and physostigmine may be indicated. Solancapsine affects cardiac muscle, causing decreased heart rate and conductive changes. Treatment is symptomatic and supportive.

Life-threatening mushroom ingestions include amanitin poisoning *(Amanita virosa, Amanita phalloides, Conocybe filaris)*, orellanine poisoning *(Cortinarius orellanus*, *Cortinarius rainierensis)*, and monomethylhydrazine *(Gyromitra esculenta)*. Of these, amanitin toxicity is the most widely reported in dogs. *A. phalloides* are found in wooded areas throughout the United States and Canada. Signs usually do not develop for 6 to 24 hours after ingestion. Typically, signs include a 24-to 36-hour GI phase, followed by 24 hours of remission, then a late hepatic phase characterized by jaundice, coma, and death. Survivors of the hepatic phase may ultimately die from renal tubular necrosis. Diagnosis is difficult. Liver enzymes are marked early in the process and blood urea nitrogen (BUN) and creatinine increase later. Occasionally, spores are found in GI contents or feces. A few commercial laboratories are able to perform amatoxin tests on urine. If a sample mushroom is available, the Meixner blue test is a useful qualitative test for amatoxins. Early treatment includes gastric lavage and activated charcoal with a cathartic. Charcoal hemoperfusion is perhaps the most helpful therapeutic agent but rarely performed on animals. Further treatment is supportive and symptomatic. Experimentally, high-dose penicillin, silymarin, *S* Adenosylmethionine, thioctic acid, N-acetylcysteine, cimetidine, and cytochrome-*c* have all been used with mixed success. Liver transplant remains the proven therapy.

252

253

68.2.4 Plants Primarily Affecting the Neurologic System

Animals ingest tobacco *(Nicotiana tobacum)* from cigarettes, chewing tobacco, cigars, or pipe tobacco.[1] Nicotine is a rapidly acting toxin that stimulates and then depresses the autonomic ganglia. Centrally mediated emesis often occurs before significant absorption, and no further signs develop. Animals with severe poisoning show signs of CNS involvement and cardiac abnormalities. Death is from paralysis of the muscles of respiration. Treatment is first aimed toward assisting respiration and then removing residual tobacco from the GI tract.

Many plants are associated with hallucinogenic effects. Poisoning may be accidental or intentional. Diagnosis is often difficult because many owners are reluctant to cooperate. Sporadically reported in dogs are poisonings from psilocybins or "magic mushrooms."[1] Muscle weakness, ataxia, abnormal mutation, vocalization, and temperature changes occur 20 to 30 minutes after ingestion. Marijuana *(Cannabis sativa)* poisoning is infrequently reported in dogs. Dogs become glassy eyed, ataxic and hyperactive, or comatose. Other less common hallucinogenic plants are jimsonweed *(Datura stramonium)*, thorn apple *(Datura metaloidyl)*, blue morning glory *(Ipomoea violacea)*, nutmeg *(Myristica fragrans)*, and peyote (family Cactaceae). Signs vary from plant to plant; however, in general all of these plants cause changes in the CNS. Treatment is supportive and signs generally resolve in 24 to 48 hours.

Nettle toxicity (family Urticaceae) is seen primarily in hunting or field dogs.[1] Some species of nettles contain hairs that break off when an animal rubs against them, allowing injection of the contents into the animal. The toxic agents are histamine, acetylcholine, serotonin, and formic acid. Clinical signs are variable and depend on which toxin predominates. Muscle weakness is the most common sign but may be accompanied by salivation, vomiting, pawing at the mouth, tremors, dyspnea, and a slow, irregular heartbeat. Atropine in large doses, antihistamines, and sedation are useful. Generally, animals respond to treatment in less than 24 hours.

68.2.5 Plants Primarily Affecting the Renal System

All parts of the Easter lily *(Lilium longiflorum)* and day lily (*Hemerocallis* spp.) are toxic to cats.[10] Tiger lilies *(L. tigrinum)*, Japanese showy lily *(L. speciosum)*, and Asiatic lilies have also been implicated.[10] The toxic agent and mechanism of action are unknown. Clinical signs generally occur within 2 hours and include vomiting, depression, and anorexia, followed in 1 to 3 days by acute renal failure.[1,10] Laboratory work shows an increase in BUN, creatinine, potassium, and phosphorous. Epithelial casts have been found in the urine as early as 18 hours after ingestion. Early intervention is necessary for survival. Treatment includes aggressive GI decontamination with multiple doses of activated charcoal and fluid diuresis until BUN and creatinine have returned to normal. Peritoneal dialysis may be helpful in anuric cats. Prognosis is poor if treatment is delayed past 18 to 24 hours or anuria is present. Renal tubular epithelial cell necrosis precedes death.

68.2.6 Plants Primarily Resulting in Respiratory Signs

All above-ground parts of the avocado tree *(Persea americana)* are toxic to caged birds, rabbits, and mice.[11,12] The toxin is unknown but is suspected to be persin.[12] The mechanism of action is unknown. Onset and duration of signs vary from species to species. In caged birds, signs occur 12 to 29 hours after ingestion and consist of acute respiratory distress, ruffled feathers, abnormal wing posture, and sitting in the bottom of the cage. Death

is from respiratory arrest. Rabbits develop acute cardiac arrhythmias, mammary gland enlargement, and sudden death.[12] Treatment is symptomatic and supportive. Prognosis is poor once respiratory or cardiac signs occur.

68.2.7 Plants Resulting in Sudden Death

Seeds and leaves from many fruit trees (apple, apricot, cherry, peach, plum) contain cyanogenic glycosides.[13] The glycosides concentrate in the seed and, depending on the tree, as few as 5 to 25 fruit seeds can cause toxicosis. Cyanide binds to cytochrome oxidase and inhibits cellular respiration. Onset of signs occurs within 30 to 90 minutes after ingestion; once signs occur, death follows in just a few minutes.[13,14] The most common clinical sign is sudden death although this may be preceded by ataxia, dyspnea, and tremors. Many treatment modalities have been tried, but the use of IV sodium nitrite followed by IV sodium thiosulfate is still the most successful and widely used.[14] Repeated doses of IV sodium thiosulfate and administration of 100% humidified oxygen[14] may be helpful.

69 CHAPTER • 69 Topical Toxins

Patrick M. Burns

According to poison information centers throughout the United States, topical toxins are a major cause of death in companion animals. Synthetic pyrethrins, organophosphates, and carbamates are discussed in chemical toxicities. This chapter focuses on some of the more commonly encountered topical toxins.

When dealing with these types of intoxications, practitioners must protect themselves from exposure by wearing gloves. Washing the patient with a mild soap is adequate for most poisons, although a degreaser may sometimes be necessary. Long-haired patients may require clipping of the coat. Care must be taken in handling any skin that has been burnt. Analgesia and or a general anesthesia may be required to handle these animals humanely. A thorough endoscopic examination may also be required in some cases.

69.1 TOAD POISONING

The two main species of toads found in the United States are *Bufo marinus* (the marine or cane toad) and *Bufo alvarius* (the Colorado River toad). These Hawaiian natives are introduced species that are found mainly in Arizona, Colorado, Florida, and Texas. Intoxications tend to occur more often in spring and summer, especially after a period of rain. The peak time of exposure ranges from late afternoon to around midnight. In a common scenario, the pet is allowed out at night briefly and then is found acutely drooling and having seizures.

The most common signalment is a young male terrier weighing approximately 5 kg. The smaller the pet, the more toxin that is absorbed on a body weight basis. In the toad, the toxin is secreted by two large parotid glands just caudal to the eyes and then is spread over the rest of the body. The toxins are absorbed via mucosal membranes. Swallowing of toads is very rare because the toxins have a bitter taste. However, they are still active even if the toad has died and the body has dried up.

Toad toxins contain a variety of catecholamines, along with digitalis-like substances (bufagenins and bufotoxins) and a hallucinogen (bufotenin) that is similar to the hallucinogen lysergic acid diethylamine (LSD). A synergism exists between these groups of toxins. The bufagenins and bufotoxins also have potent local anesthetic properties.

Major clinical signs of intoxication are disorientation, ataxia, stupor, seizures, nystagmus, profuse drooling, brick-red mucous membranes, mydriasis, cardiac arrhythmias, and death. The onset of clinical signs occurs within minutes of exposure. Laboratory changes may consist of the following: a stress leukogram, mild fluid loss, mild elevation in serum alkaline phosphatase activity and mild increase in serum potassium concentration, whereas serum sodium, phosphorous, and total protein concentration tend to decrease. It is also possible to confirm exposure with a digoxin serum immunoassay, although practically not required. Geographic differences exist in the severity of clinical signs; the worst are seen in Florida.

Clients should be advised to flush the animal's mouth with water for at least 10 to 15 minutes prior to transportation to the veterinarian's office. Charcoal is thought to be of some benefit because some of the toxins enter the enterohepatic circulation. Seizures may be controlled with diazepam given nasally, rectally or intravenously. Propofol and pentobarbital also can be used to treat the seizures. Control of the seizures allows further flushing of the mouth and eyes. In severe cases, cerebral edema may occur secondary to the seizure activity and may need to be treated with short-acting corticosteroids, mannitol, and furosemide.

Table • 69-1 Toad Poisoning: Treatment of Electrical Disturbances

TYPE OF ARRHYTHMIA	TREATMENT OPTIONS
Bradycardia and heart blocks	Atropine, 0.02 mg/kg intravenously (IV)
Sinus tachycardia	Esmolol, 0.5 mg/kg IV, then a constant-rate infusion (CRI) of 50 to 200 µg/kg/min. Propranolol, 0.5 to 2.0 mg/kg IV +/−CRI 60 µg/kg/min.
Ventricular tachycardia	Lidocaine, 1 to 2 mg/kg IV bolus, followed by CRI 40 to 80 µg/kg/min. Procainamide, 6 to 8 mg/kg IV, then CRI 25 to 40 µg/kg/min. Correction of hypomagnesemia if present.

As soon as possible, an electrocardiogram should be analyzed to determine the type of electrical disturbance present. Bufagenins and bufotoxins can cause any type of digoxin-like arrhythmia. Also, any type of bradydysrhythmia or tachydysrhythmia may be seen, and these should be treated with the appropriate drug (Table 69-1). Most of the arrhythmias improve with flushing of the mouth and control of the seizures.

A novel therapy that may prove very useful in counteracting the deleterious effects of the digoxin-like toxins is administration of digoxin immune Fab. These anti-digoxin antibodies have been shown to cross-react with bufagenins and bufotoxins. This therapy would be useful for plant-derived cardiac glycoside intoxications.

Administration of intravenous fluids may be indicated in severe cases. Most animals respond favorably to this therapy within 1 to 2 hours. Of patients that reach veterinary care, the vast majority survive. The differential diagnoses for toad poisoning include heat stroke; metaldehyde, organophosphate, carbamate, oleander, or theobromine poisoning; and contact irritants. A good history helps in the differentiation of the diagnosis.

69.2 NEW GENERATION INSECTICIDES

Topical agents such as fipronil, imidacloprid, lufenuron, and selamectin all have wide margins of safety; the only reported side effect has been one unverified case of localized dermatitis. However, all these drugs have the potential to cause hypersensitivity reactions. The clinical signs seen with overdoses are caused by the carrier vehicle rather than the active ingredient. Mild gastrointestinal upset is usually seen, and symptomatic therapy may be required. Ocular exposure is best treated with saline lavage and fluorescein staining to assess the extent of any damage. Hypersensitivity reactions require shampooing with a mild soap and the use of glucocorticoids if indicated. Lufenuron appears to reduce fertility in the dog in high doses (Table 69-2).

69.3 ANTIBIOTICS

The antibiotics found in dermatologic preparations are well tolerated orally; extremely high dose rates over a prolonged period (on the order of months) are required to produce any serious effects. In general, antibiotics cause signs of gastrointestinal upset, such as nausea, anorexia, vomiting, and diarrhea. Neomycin, polymyxin B, bacitracin, and ampicillin, to name a few, are antibiotics used in topical preparations that have low bioavailability, hence the high oral tolerance. It should also be remembered that with any antibiotic preparation, an anaphylactic reaction is possible. Anaphylaxis to bacitracin-neomycin-polymyxin ointments in cats has been reported when the ointments were used prophylactically with routine surgeries.

69.4 TOPICAL GLUCOCORTICOSTEROIDS

Ophthalmic and dermatologic preparations of glucocorticoids usually contain hydrocortisone, betamethasone, or triamcinolone. Oral intoxication from ingestion of these preparations may result in mild gastrointestinal signs caused by the carrier vehicle. Overdoses usually are self-limiting and require only supportive care. Clinical signs are caused by the local and systemic effects of glucocorticoids. Long-term use of these preparations may result in a cushingoid patient.

254

255

Table • 69-2 Topical Pesticides and Their Mode of Action

DRUG	VETERINARY PRODUCT LD_{50}	MODE OF ACTION
Fipronil (Frontline; Merial Laboratories)	>2000 mg/kg (rabbit dermal)	Noncompetitive blocker of gamma aminobutyric acid-gated chloride channels +/−glutamate-gated channels
Imidacloprid (Advantage; Bayer Animal Health)	2000 mg/kg (rat dermal)	Competitive inhibitor of nicotinic receptors in postsynaptic nerves
Lufenuron (Program; Novartis Animal Health)	Tested in dogs using 20 times the recommended dose and in cats using 10 times the recommended dose; no ill effects seen	Inhibitor of chitin synthetase
Selamectin (Revolution; Pfizer Animal Health)	Safe in doses up to 10 times the recommended dose	Inhibitor of glutamate-gated channels

69.5 ANTIFUNGALS — ZINC UNDECYLENATE

Sunscreens, diaper rash ointments, and antifungals can all contain zinc. Acute ingestion of zinc oxides usually results in a self-limiting emesis that rarely requires treatment. These episodes do not usually result in zinc toxicosis. Prolonged use of sunscreens and antifungals may cause zinc toxicosis, manifesting as gastrointestinal disturbances, hypotension, hemolytic anemia, jaundice, and pulmonary edema. Milk or water given orally helps reduce intestinal absorption of zinc, and calcium ethylenediamine tetra-acetic acid (EDTA) chelates the zinc that has been absorbed systemically. In severe cases of zinc toxicosis, the use of blood products may be indicated.

69.6 CLEANING PRODUCTS

In the United States, the number of animals that die of poisoning from cleaning products is more than three times the number that die of bites and stings from poisonous insects. This discussion focuses on chemicals that are directly irritating to the skin or that are absorbed through the skin and cause systemic signs of intoxication. Acids and alkalis are commonly found throughout the household (Box 69-1.)

Acids induce intense pain, which limits the duration of contact with these chemicals. Acids cause rapid protein coagulation, resulting in a localized necrotic lesion. Full-thickness mucosal lesions are rare. Alkaline substances tend to be more damaging to the skin and alimentary tract. Chemicals with a high pH have a greater propensity to cause full mucosal thickness injuries, with a resultant liquefactive necrosis.

69.6.1 Box • 69-1 Examples of Household Acids and Alkalis

69.6.1.1 Acids

Antirust compounds

Toilet bowl cleaner

Gun barrel cleaning fluid

Automobile batteries

Swimming pool cleaning agents

69.6.1.2 Alkalis

Drain and toilet bowl cleaners

Liquid cleansers

Washing detergents and powders

The formulation of the preparation also affects the extent and location of the lesions. Solids tend to cause more buccal cavity and upper esophageal injuries, whereas liquids cause more lower esophageal and stomach lesions. However, this is a generalization, and it should be remembered that up to 30% of esophageal burns show no oral lesions. A full inspection of the entire upper alimentary tract is always indicated for complete evaluation of the extent of injury. A thoracic radiograph may reveal signs of esophageal perforation, as indicated by a pneumomediastinum.

Neutralization of any acid or alkali is contraindicated, because the resultant exothermic reaction may cause a thermal burn. Charcoal is ineffective, and gastric lavage is contraindicated with corrosive substances. Washing the affected area with copious amounts of water or administering milk helps dilute the effects of these corrosive substances on the alimentary tract. Ocular lavage may also be necessary. These measures must be taken as quickly as possible to have any effect. If any evidence suggests esophageal perforation (e.g., signs of bleeding), a full endoscopic examination may be prudent; however, it must be done with caution. Stricture formation may not be evident until some time after the injury. Glucocorticoids may help reduce the amount of fibroblastic activity early in the healing process; however, their efficacy is unproven. Caution should be used if gastric ulceration has occurred. Prophylactic antibiotics may be necessary with severe mucosal damage or extensive dermal burns, but their use is controversial, especially if no signs of infection are present at the time this therapy is instituted. In severe cases of buccal cavity or esophageal injury, an esophagostomy or a gastrostomy tube feeding regimen may be indicated.

69.6.2 Phenols

Phenols can be found in disinfectants, soaps, shampoos and detergents. These compounds are rapidly absorbed via the oral, respiratory and dermal routes. The phenol LD_{50} in the dog is approximately 0.5 g/kg body weight. Limitations in glucuronide transferase activity in the cat make this species more susceptible to intoxication. Dermal burns have resulted from concentrations greater than 1%; however, the severity of dermal absorption

depends more on the area of contact than on the concentration. Phenols cause intense pain followed by local anesthesia to the affected skin. The coagulative necrosis discolors the skin white, and a dry eschar eventually forms over several days. Corrosive burns to the mouth and esophagus occur with oral ingestion. Severe burns are seen with ocular exposure.

255
256

Initially, with phenol intoxication, vomiting, hypersalivation, apprehension, panting, and ataxia may be seen, with progression to muscle fasciculations, shock, cardiac arrhythmias, and death. Phenols cause methemoglobinemia. Histopathologically, both hepatic fatty degeneration and necrosis and renal tubular degeneration and necrosis are seen.

Demulcents such as milk or eggs, rather than water, should be given as soon as possible, because some evidence suggests that water may enhance phenol absorption. For dermal exposure, the area should be washed first with polyethylene glycol or glycerol and then with a mild, soapy solution, followed by a final rinse with water. Gloves must be worn during this procedure. Any wounds should be bandaged with dressings soaked with sodium bicarbonate 0.5%. Oily dressings enhance dermal absorption. Ocular lesions must be flushed with saline for 20 to 30 minutes and treated appropriately. Aggressive fluid therapy is needed to correct any acid-base disturbance, to support hepatic and renal function and to reverse any signs of shock. Hepatic and renal function may also be supported by use of N-acetylcysteine for the first 3 days after intoxication. Methylene blue and ascorbic acid may be indicated for methemoglobinemia. Tube feeding is necessary for severe injuries to the oral cavity and upper alimentary tract.

69.6.3 Essential Oils

Essential oil extracts, which are incorporated into products such as insecticide sprays, collars, shampoos, soaps, fragrances, and cleaning solutions, are generally thought by the general public to be nontoxic. Two commonly used essential oils are citrus oil (*Citrus* spp.) and tea tree oil *(Melaleuca alternifolia)*.

The main active ingredients are *d*-limonene and linalool oils (citrus oil) and terpenes (tea tree oil). Cats appear to be more susceptible to essential oils than dogs, partly because they metabolize these oils poorly and because their grooming habits increase oral exposure. The lipid nature of essential oils allows them to be absorbed rapidly via the dermal and oral routes, especially when mixed with organic solvents or surfactants. Urinary excretion is the main route of excretion.

The exact mechanism of intoxication by essential oils is unknown, and the LD_{50} varies. Clinical signs can develop within 6 to 8 hours of exposure. Central and peripheral vasodilatation tends to occur with exposure. Transient hypersalivation is seen in the cat. Muscle tremors may occur in response to the mild-to-severe hypothermia that can develop. Mydriasis, weakness, collapse, and paralysis are seen in advanced cases. In the dog, lesions similar to toxic epidermal necrolysis have been documented and were followed by disseminated intravascular coagulopathy and death. Tea tree oil has caused transient paresis in small dogs when applied as a flea treatment to the backline. With severe exposure, hepatic failure may result, especially in the cat because of the need for glucuronide conjugation. Induction of the cytochrome P-450 system may also occur.

Decontamination of the skin with a mild soap and symptomatic treatment of other clinical signs are necessary. Gut decontamination, through the use of emesis, gastric lavage, charcoal, or enemas, may be performed, especially in cases of recent exposure. Emesis should not be performed if the level of consciousness is altered or if aspiration pneumonia is a concern. No specific antidote exists for essential oil intoxication. In humans, N-acetylcysteine has been used for pennyroyal toxicosis. The prognosis is guarded, depending on the severity of clinical signs, which may last several days; however, with supportive care most animals recover.

70 CHAPTER • 70 Chemical Toxicities

David C. Dorman

Janice A. Dye

Hazardous chemicals are found throughout the home, and a significant potential exists for poisoning after exposure to these agents. Most veterinary toxicology cases are the result of accidental dermal or oral exposure arising from improper storage or handling of these chemicals within the home. Timely decontamination through bathing, gastric lavage, or use of emetics, activated charcoal, and cathartics serve to reduce systemic absorption acutely after exposure. However, risks associated with these procedures (e.g., handling, aspiration, sedation) must be weighed against potential therapeutic benefits. This chapter provides brief synopses of commonly involved chemicals, both active and vehicle ingredients. Its purpose is to provide a framework for appropriate case management of the poisoned small animal patient. For success, management must always be tailored to the animal's initial, and ever changing, clinical signs.

70.1 PETROLEUM DISTILLATES AND OTHER ALIPHATIC HYDROCARBONS

70.1.1 Sources

Kerosene, gasoline, and mineral seal oil are prototypical hydrocarbons.[1] Turpentine, a similar hydrocarbon product, is derived from pine oil. Hydrocarbons are found in lubricants, degreasers, waxes, varnishes, cleaning fluids, lamp oil, and starting fluids.

70.1.2 Signs

Most commonly the pulmonary system, central nervous system (CNS), and gastrointestinal (GI) system are involved.[1] Some animals emit a characteristic hydrocarbon odor, and many develop vomiting or diarrhea. Hepatotoxicity, renal toxicity, and cardiac arrhythmias may also occur. Of note, aspiration and chemical-induced pneumonitis are especially common after exposure to low-viscosity or highly volatile hydrocarbons. Aspiration is less common with higher viscosity hydrocarbons such as tar, oil, and grease. Nevertheless, owing to the risk of aspiration during drug-induced emesis or gastric lavage, these procedures are generally not recommended. Because volatile hydrocarbons may displace oxygen when aspirated, transient hypoxia and respiratory dysfunction may occur within minutes of exposure. Other signs related to aspiration pneumonitis include cough, hyperthermia, dyspnea, and cyanosis.

70.1.3 Management

Thoracic radiographs may reveal changes consistent with aspiration pneumonia. Oxygen and positive end-expiratory pressure therapy may prove necessary in cases where alveolar collapse and cyanosis are evident. Animals that remain asymptomatic for 6 to 12 hours after exposure are unlikely to develop pneumonitis. For dermal contamination with thick tarry or asphalt materials, mild detergents and fur clipping is most useful. Vegetable oil may be used to soften the material prior to removal. Of note, solvents or other hydrocarbons should never be used in an attempt to “dissolve” these compounds. Prophylactic antibiotics and steroids are generally not recommended.

70.2 NAPHTHALENE

70.2.1 Source

The primary source of naphthalene is moth balls.

70.2.2 Signs

Ingestion of large quantities of naphthalene may be associated with vomiting, lethargy, seizures, acute hemolytic anemia (reportedly at “doses of” 411 mg/kg), Heinz body formation, methemoglobinemia, hemoglobinuria, and renal failure.

70.2.3 Management

Treatment is largely based on GI decontamination and supportive care (i.e., fluid therapy, warming, control of methemoglobinemia with ascorbic acid or methylene blue) until recovery.

70.3 ETHANOL

70.3.1 Sources

Sources of ethanol[2] are ethanol-containing beverages, consumer products, and fermenting materials (e.g., raw sourdough, uncooked pizza dough, rotting apples[3]). The oral lethal dose is 5 to 8 g/kg.

70.3.2 Pathogenesis

Ethanol is metabolized by alcohol dehydrogenase to acetaldehyde, which is subsequently metabolized to acetate by aldehyde dehydrogenases. Metabolic acidosis resulting from acetate accumulation has been reported.

70.3.3 Signs

Intoxication generally develops within 1 hour of ingestion and may result in CNS depression, behavioral changes (e.g., vocalization, excitability), ataxia, hypothermia, and respiratory or cardiac arrest.

70.3.4 Management

Blood alcohol levels can confirm a diagnosis. Treatment is largely based on GI decontamination and supportive care (i.e., fluid therapy, warming, assisted ventilation) until recovery.

70.4 METHANOL (WOOD ALCOHOL)

70.4.1 Sources

Sources of methanol (wood alcohol[2]) are methanol-based automotive windshield fluid, antifreezes, and related consumer products. The oral lethal dose of methanol in the dog is 4 to 8 g/kg.

70.4.2 Pathogenesis

Methanol is metabolized to formaldehyde and formate. Unlike people, formate accumulation and subsequent blindness does not occur in dogs or cats exposed to methanol.

70.4.3 Signs

Clinically, methanol toxicosis resembles that of ethanol poisoning; it is therefore treated similarly.

70.5 ETHYLENE GLYCOL

70.5.1 Sources

Sources of ethylene glycol are automobile radiator antifreeze, heat exchange fluids, and some photographic solutions. A lethal dose of 95% ethylene glycol is 1.4 mL/kg in cats and 4.4 mL/kg in dogs. It remains one of the most common causes of poisoning in small animals.[4]

70.5.2 Pathogenesis

The initial metabolism of ethylene glycol to glycoaldehyde by alcohol dehydrogenase is rate limiting. Other major metabolites include glycolic acid, glyoxylic acid, and oxalic acid. An anion gap metabolic acidosis typically develops due to formation of these organic acids, in particular glyoxylic acid. Most of the oxalic acid is excreted in the urine; however, some may be retained as calcium oxalate. Calcium oxalate and hippuric acid crystals often precipitate in the renal tubules and in other organ vasculature systems.

70.5.3 Signs

Ethylene glycol toxicosis is best described as a triphasic syndrome.[4] Initially (within 1 hour of exposure), the animal appears ataxic or “drunk,” followed by a relatively asymptomatic period. Secondly (12 to 24 hours after ingestion), cardiopulmonary involvement inconsistently develops (e.g., cardiac failure). Thirdly (1 to 3 days later), animals commonly develop oliguric renal failure with renomegaly. These animals are depressed, anorexic, and often develop vomiting, renal pain, hypothermia, coma, and ultimately death. Unfortunately, many companion animals are not presented until this third phase.

70.5.4 Management

Urinalysis with polarized light microscopy may reveal the presence of calcium oxalate crystalluria. In addition, blood and tissue ethylene glycol levels can confirm a diagnosis. For recent exposure (≤2 hours), treatment consists of administering an emetic followed by activated charcoal and a cathartic. If the animal is presented within 8 to 12 hours after ingestion, treatment with ethanol or fomepizole (4-methyl-pyrazole [4-MP]) is indicated to inhibit further ethylene glycol metabolism.[5] Ethanol is given intravenously (IV) as a 20% solution in saline at a dose of 5 to 5.5 mL/kg every 6 hours for 5 to 6 treatments. The dose should be titrated to produce CNS depression but not semicoma. Alternatively, in dogs, 4-MP may be administered as a 5% solution, given as a slow IV bolus using a decreasing dose regimen. Initially, 4-MP is given at 20 mg/kg; followed by 15 mg/kg at 12 hours and again at 24 hours; and then 5 mg/kg at 36 hours.

Additional 4-mp doses of 3 mg/kg every 12 hours may be required if the animal has yet to fully recover or if ethylene glycol blood levels are still detectable. The advantage to using 4-MP is that it has minimal depressive side effects; however, it is not effective in cats.[5,6] Sodium bicarbonate may be given intraperitoneally to dogs and cats to control acidosis. In addition, diuresis with furosemide, mannitol, or dopamine may be necessary to correct unresponsive anuria or pulmonary edema. Peritoneal dialysis may also be used to manage acute oliguric renal failure. In general, with aggressive and appropriate therapy, exposed animals that have been examined before developing overt renal insufficiency would be expected to recover. Symptomatic animals have a poorer prognosis as a result of associated renal damage; however, renal tubular regeneration is still possible because the tubular basement membrane remains relatively unaffected.

70.6 PROPYLENE GLYCOL

70.6.1 Source

The source of propylene glycol is automotive radiator antifreeze. The acute oral lethal dose is approximately 9 mL/kg (dogs).

70.6.2 Signs

This toxic syndrome is similar to that observed during the acute phase of ethylene glycol toxicosis (i.e., ataxia, CNS depression).

70.6.3 Management

Treatment largely consists of supportive care and early GI decontamination. Alcohol dehydrogenase inhibitors are not required because propylene glycol is metabolized to lactic and pyruvic acid, both of which have low renal toxicity.

70.7 PHENOL PRODUCTS

70.7.1 Sources

The sources of phenol products[7,8] are household cleaners, disinfectants, and some antiseptic and germicidal agents. They are also used, in lesser concentrations, as preservatives. The oral LD_{50} of phenol in dogs is estimated to be only 0.5 g/kg. Cats are even more sensitive because of their limited glucuronyl transferase activity. Toxicosis induced by phenolic compounds is considered a medical emergency.

70.7.2 Pathogenesis and Signs

Phenols are very cytotoxic. Dermal exposure may result in coagulative dermal necrosis accompanied by intense pain. Ocular exposure may lead to significant corneal damage. Ingestion is associated with severe corrosion of the upper GI tract. Systemic effects include ataxia, weakness, tremors, coma, seizures, methemoglobinemia, and respiratory alkalosis. Liver and kidney damage may develop within 12 to 24 hours after exposure.

70.7.3 Management

N-acetylcysteine administration (140 mg/kg orally [PO] or IV initially; then 50 mg/kg every 4 hours for 3 days) may be partially effective to reduce hepatic and renal injury. Resultant methemoglobinemia should be treated with ascorbic acid or methylene blue.

70.8 ANTICOAGULANT RODENTICIDES

70.8.1 Sources

Anticoagulant rodenticides[9] include short-acting (e.g., warfarin) and long-acting (e.g., bromadiolone, brodifacoum, chlorophacinone, diphacenone, valone, pindone) agents.

70.8.2 Pathogenesis

These compounds principally interfere with vitamin K_1 hydroquinone recycling and thus inhibit clotting factor synthesis. A coagulopathy affecting the intrinsic, extrinsic, and common pathways ensues. Lethal doses vary considerably depending primarily on the anticoagulant involved but also on patient predisposing factors such as age, concurrent disease, and exposure history (single dose versus repeated ingestions). The acute oral toxic dose of warfarin in the dog or cat is 5 to 50 mg/kg; whereas repeated daily ingestion of as little as 1 mg/kg may result in severe toxicosis. The toxic dose of brodifacoum in dogs and cats is 0.2 to 4 and 25 mg/kg, respectively. Secondary or relay toxicity arising from the ingestion of poisoned rodents is uncommon.

70.8.3 Signs

Typically, signs develop within 2 to 5 days after exposure and may vary considerably depending upon the site and volume of blood loss. Signs may include petechiae and ecchymosis of the skin and mucous membranes,

hematomas, weakness, pallor, respiratory distress, and CNS depression. Hematemesis, epistaxis, melena, ataxia, paresis, seizures, and sudden death have also been reported.

70.8.4 Diagnosis

Significant prolongation of the activated clotting time (ACT), prothrombin time (PT), and activated partial thromboplastin time (aPTT) occurs. Elevated levels of the carboxylated forms of the vitamin K dependent coagulation factors also occur in exposed animals, and the proteins inhibited by vitamin K antagonists (PIVKA) test can help identify a vitamin K_1–responsive coagulopathy. Poisoned animals exhibiting respiratory distress should be radiographed to establish the presence of pleural, mediastinal, or pericardial fluid. Necropsy findings often include hemoperitoneum, hemothorax, and pulmonary hemorrhage. Postmortem samples for chemical analysis should include unclotted blood, liver, and GI contents.

70.8.5 Treatment

Vitamin K_1 is antidotal, with a recommended oral dose of 2.5 to 5.0 mg/kg given every 8 to 12 hours for either 2 or 4 weeks depending upon whether the ingested anticoagulant was a short-or long-acting agent. Synthesis of new clotting factors takes at least 12 hours. In the interim, clinically ill patients may need life-support measures (e.g., whole blood, fresh-frozen plasma transfusions) to prevent further blood loss. Coagulation screening tests should be reassessed 48 to 72 hours after cessation of vitamin K_1 therapy to determine whether additional K_1 supplementation is warranted. Restricting movement and exercise and providing a warm, safe environment is essential in preventing trauma-induced hemorrhage.

70.9 ZINC PHOSPHIDE

70.9.1 Source

Zinc phosphide[9,10] is a rodenticide. The lethal dose in dogs and cats is 20 to 50 mg/kg. Secondary toxicity is rare.

70.9.2 Pathogenesis

Within the acidic environment of the stomach, ingested zinc phosphide is converted to phosphine gas that in turn damages capillary endothelium and erythrocyte membranes within the lung, liver, and kidney.

70.9.3 Signs

Anorexia, lethargy, weakness, abdominal pain, and vomiting commonly occur within 1 to 4 hours of ingestion. 258
Signs may progress to recumbency, whole-body tremors, seizures, cardiopulmonary collapse, and death. Gross 259
and microscopic findings may include pulmonary edema and hemorrhage, as well as mild hepatic and renal necrosis.

70.9.4 Management

No specific antidote exists; however, supportive therapy including antacids (containing magnesium or aluminum hydroxide) is considered beneficial.

70.10 CHOLECALCIFEROL (VITAMIN D)

70.10.1 Sources

The sources of cholecalciferol (vitamin D[9,11]) are certain rodenticides and vitamin D–based creams and medications. The toxic dose of cholecalciferol in dogs is 1.5 to 8 mg/kg. Cats are likely equally sensitive.

70.10.2 Pathogenesis

Cholecalciferol and other vitamin D metabolites abnormally increase intestinal absorption of calcium, stimulate bone resorption, and increase the renal tubular reabsorption of calcium, thereby resulting in persistent hypercalcemia (serum calcium >12 mg/dl). Soft tissue mineralization may occur and when severe can be apparent radiographically. Death is usually due to cardiac failure, renal failure, or both. Serum phosphorus, ionized calcium, parathyroid hormone, and 25-hydroxycholecalciferol levels may serve to rule out other causes of hypercalcemia.

70.10.3 Signs

Signs of cholecalciferol toxicity typically appear within 3 to 5 days after ingestion and include anorexia, CNS depression, vomiting occasionally with hematemesis, muscle weakness, constipation, bloody diarrhea, polyuria, and polydipsia.

70.10.4 Treatment

Prompt GI decontamination is indicated as soon after ingestion as possible. Ancillary therapy is directed at increasing renal calcium excretion via furosemide administration (5.0 mg/kg IV followed by 2.5 mg/kg PO three times a day (tid) or four times a day (qid) in combination with aggressive fluid therapy (physiologic saline at rates up to two times maintenance). In addition, prednisone (2 to 3 mg/kg PO once a day [qd] to twice a day [bid]) aids in decreasing both osteoclastic activity and GI calcium absorption. Calcitonin (4 to 6 IU/kg subcutaneously [SQ] every 2 to 3 hours) may serve to further reduce serum calcium concentrations; however, some animals become refractory. Vomiting and anorexia are common adverse side effects. Pamidronate disodium IV (1.3 to 2.0 mg/kg in 0.9% saline) has been shown to reverse cholecalciferol-induced hypercalcemia.[6] Prolonged treatment (up to 4 weeks in some cases) may be required. Periodic reassessment of serum calcium, phosphorus, potassium, blood urea nitrogen (BUN), and creatinine levels is prudent. Once serum calcium and phosphorus levels have been normalized and the patient appears stable, most animals can be treated on an outpatient basis.

70.11 BROMETHALIN RODENTICIDES

Cats are especially sensitive to bromethalin rodenticides,[8,12,13] with toxic doses of 0.3 and 2.5 mg/kg in cats and dogs, respectively.

70.11.1 Pathogenesis

Bromethalin uncouples oxidative phosphorylation, resulting in myelin edema in the brain and spinal cord.

70.11.2 Signs

Relatively high-dose acute exposure results in severe muscle tremors, hyperexcitability, vocalization, running fits, seizures, hyperesthesia, vomiting, and dyspnea. More commonly, however, this toxic syndrome has a delayed and insidious onset (>12 to 24 hours); with clinical signs characterized by progressive ataxia, paresis, hind limb paralysis, and progressive CNS depression that may culminate in semicoma or coma.

70.11.3 Management

Treatment consists of (1) GI decontamination using repeated administration of oral activated charcoal; (2) control of cerebral edema with mannitol, dexamethasone, and furosemide; and (3) supportive care including effective control of seizures. Animals ingesting mild-to-moderate doses may improve over a 2-to 3-week period with aggressive supportive care. Prognosis is poor for severely affected animals.

70.12 PYRETHRINS AND PYRETHROID INSECTICIDES

Pyrethrins and pyrethroid insecticides[14,15] are lipophilic insecticides used for the control of ectoparasites. They are rapidly metabolized and excreted and rarely cause adverse effects in dogs and cats when used according to label instruction. Excessive or inappropriate administration, however, may result in clinical toxicity.

70.12.1 Signs

Most commonly, affected animals develop an acute onset of CNS depression, hypersalivation, muscle tremors, vomiting, ataxia, dyspnea, and anorexia. Less commonly, hyperthermia, hypothermia, weakness, and seizures may occur. Death is rarely observed. Of note, neither pyrethrins nor pyrethroid insecticides are inhibitors of acetylcholinesterase. Gross and microscopic changes are nonspecific.

70.12.2 Management

Treatment is aimed at reducing dermal or GI absorption and providing supportive care. Diazepam may be used to control muscle tremors and seizure activity. Atropine, although not a true antidote, can be used at low doses to control hypersalivation. The overall prognosis is very favorable, and the majority of animals recover within 1 to 3 days.

70.13 ORGANOPHOSPHOROUS AND CARBAMATE INSECTICIDES

Organophosphorous (OP) and carbamate insecticides[15] are lipophilic insecticides that are well absorbed from the skin and GI tract. Toxicity due to these agents is highly variable (Box 70-1).

70.13.1 Box • 70-1 National Pesticide Telecommunications Network

The National Pesticide Telecommunications Network is a useful source of toxicity data for pesticides (phone: 800-858-7378; website: http://ace.orst.edu/info/nptn). ASPCA-Animal Poison Control Center is another valuable resource that is provided on a fee-for-service basis. (phone: 888-426-4435).

259

70.13.2 Pathogenesis

Carbamate insecticides are reversible acetylcholinesterase inhibitors. Most OP insecticides irreversibly inhibit this enzyme. In fact, most OP insecticides covalently bind this enzyme (i.e., aging) within 24 hours of exposure.

70.13.3 Signs

Toxicity results in a "cholinergic crisis" that is marked by muscarinic (i.e., salivation, lacrimation, bronchial secretion, vomiting, diarrhea), nicotinic (i.e., muscle tremors, respiratory paralysis), and mixed (i.e., CNS depression, seizures, miosis, hyperactivity) signs.

70.13.4 Diagnosis

Determination of reduced cholinesterase activity (<50% normal activity) in blood, brain, and retinal tissues is highly supportive of a diagnosis.[16] The prognostic value of this test is difficult to assess, especially in cats, where the very sensitive pseudocholinesterase enzyme comprises a large percentage of total blood esterase activity.

70.13.5 Treatment

Life-saving symptomatic therapy should be instituted immediately. Atropine sulfate (0.1 to 0.2 mg/kg, repeated as needed) is useful to alleviate severe bradycardia and excessive bronchiolar constriction and mucus hypersecretion. The reader should note, however, atropine will not abolish muscle tremors and other signs related to excessive nicotinic stimulation. Atropine doses should be adjusted to provide the minimum amount that alleviates dyspnea, bradycardia, and other signs of cholinergic stress. However, if tachycardia, GI stasis, hyperthermia, or severe behavioral changes (e.g., aggressiveness, delirium) occur, atropine should be decreased or discontinued. Enzyme reactivators may be used for treatment of OP insecticide toxicosis. Reactivators act on the OP insecticide-acetylcholinesterase complex to free the enzyme and restore normal function. Reactivators are most effective if "aging" has not yet occurred. Of the enzyme reactivators, pralidoxime chloride has received the widest clinical use. Pralidoxime chloride is given (20 mg/kg intramuscularly, repeated every 12 hours) to relieve tremors and other nicotinic signs and should be continued until these signs are alleviated or until additional benefit is no longer observed. Pralidoxime chloride generally has low toxicity; however, overdoses can cause tachycardia and cardiac arrhythmias. It is critical that further exposures to OP and carbamate insecticides be avoided until the animal is fully recovered. Complete recovery is ultimately dependent on the resynthesis of sufficient quantities of acetylcholinesterase enzyme—which may require up to 4 to 6 weeks.

70.14 2,4-DICHLOROPHENOXYACETIC ACID

70.14.1 Source

Animals are occasionally poisoned with the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D).[17,18] The approximate lethal dose of 2,4-D in dogs is 100 mg/kg. Poisoning is not expected to occur after exposure of pets to treated lawns.

70.14.2 Pathogenesis

The mechanism of action of 2,4-D is poorly understood.

70.14.3 Signs

Moderate exposure can result in an acute onset of anorexia, vomiting, and diarrhea with signs of toxicity typically abating within 48 hours. Greater exposures may result in CNS depression, ataxia, and hind limb myotonia.

70.14.4 Management

The diagnosis often relies on a known history of exposure, development of compatible clinical signs, typical electromyogram changes (e.g., fibrillation potentials), and residue analysis of urine samples. Treatment is nonspecific and includes the general principles of decontamination and maintaining normal fluid and electrolyte status. Fortunately, affected animals typically recover within a 24-to 72-hour period.

70.15 LEAD

Lead poisoning continues to be a significant toxicologic problem in companion animals.

70.15.1 Sources

A common cause of lead poisoning is ingestion of paints found in the interior of older buildings.[19] Veterinarians should warn owners of lead-poisoned animals that exposure of children may occur in the same environment. Other lead sources include batteries, linoleum, solder, plumbing supplies, and fishing line weights.

70.15.2 Signs

Chronic low-level lead poisoning is most commonly associated with GI signs, as evidenced by vomiting, abdominal pain, anorexia, diarrhea, and megaesophagus.[20] Constipation occurs less frequently. Acute, high-level lead exposure results most commonly in CNS signs, including behavioral changes, hysteria, ataxia, tremors, opisthotonos, blindness, and seizures.[21,22] In cats, GI signs appear to be more common than CNS signs.

70.15.3 Diagnosis

Nucleated erythrocytes may be found in peripheral blood smears of affected dogs without evidence of severe anemia.[22] Basophilic stippling is sometimes observed in red blood cells (RBCs). In cats, nucleated erythrocytes and basophilic stippling is found only occasionally. Toxicosis may be confirmed definitively by chemical analysis with blood lead concentrations ≥0.20 ppm being considered diagnostic.

70.15.4 Treatment

The cornerstone of treatment is the use of chelators to enhance metal elimination.[23] In general, chelator therapy should be initiated as soon after metal exposure as possible. However, prior to chelator use one should attempt to eliminate the source of lead within the GI tract. Surgery is indicated for removal of large lead-containing objects. For dispersed lead-laden material (e.g., paint dust, paint chips), oral administration of magnesium sulfate or sodium sulfate may serve to precipitate lead within the intestinal tract, thereby limiting further absorption. Of note, chelator administration may initially aggravate the clinical signs, and one should be prepared to control aggressiveness or seizures. Furthermore, to safely mobilize lead in patients with relatively high-dose exposures, several "courses" of chelator therapy may be warranted (i.e., 5 days of chelator therapy followed by 5 days of no therapy and so forth). Of the available agents, succimer (meso-2, 3-dimercaptosuccinic acid) is an orally active agent that appears quite effective in dogs and cats.[6,24] It has recently been approved for use in children and will likely emerge as the primary drug of choice in veterinary medicine. It is administered at 10 mg/kg, three times a day for 10 to 17 days. To date, it has been associated with few side effects. Alternatively, calcium disodium EDTA is an effective metal chelator. It should be diluted to 10 mg/ml with 5% dextrose, then administered subcutaneously at 25 mg/kg, qid, for 2 to 5 days. Another agent, D-penicillamine has also been used, most commonly as a follow-up agent after treatment with calcium disodium EDTA. D-penicillamine is administered orally at 110 mg/kg/day (divided every 6 to 8 hours) for 1 to 2 weeks. If toxicity to D-penicillamine develops, as evidenced by vomiting, CNS depression, and anorexia, the dose should be reduced.

260
261

70.16 ZINC

70.16.1 Sources

Sources of zinc include zinc nuts, pennies minted after 1981, and zinc oxide-containing products (e.g., diaper rash ointments, cosmetics).[25,26]

70.16.2 Signs

Acute zinc oxide poisoning results in severe vomiting, CNS depression, and lethargy, with diarrhea occurring less commonly. Subacute or chronic elemental zinc poisoning may result in anorexia, vomiting, diarrhea, CNS depression, pica, hemolysis, regenerative anemia, spherocytosis, an inflammatory leukogram, icterus, and renal failure.

70.16.3 Diagnosis

Diagnosis is based on the history of exposure, development of compatible clinical signs, and the presence of radiodense material within the GI tract. Hypocupremia may be present, presumably from zinc antagonism of the GI absorption of copper. Blood and tissue levels may confirm a clinical diagnosis, but care should be taken to collect samples in containers appropriate for trace mineral analysis.

70.16.3.1 Treatment

As with lead ingestion, removing the source of zinc, either through emesis or surgery, is important. Supportive care and chelation therapy with calcium disodium EDTA are also indicated.[26] Of note, animals with zinc poisoning appear to have high postoperative complication rates. One should also anticipate that serum zinc concentrations would decrease rapidly after removal of the source.

70.17 IRON

70.17.1 Sources

Sources of iron are multivitamins and other iron-containing medications. Animals should be monitored for possible clinical signs of iron toxicosis if elemental iron has been ingested in excess of 60 mg/kg. Potentially lethal doses of iron are in the range of 200 to 250 mg/kg.

70.17.2 Signs

Clinical signs observed shortly after ingestion are characterized by certain acute GI effects: vomiting, abdominal pain, diarrhea, hematemesis, and melena. These signs may resolve within 6 to 24 hours after ingestion. Many poisoned animals do not progress beyond this stage; however, life-threatening signs associated with multisystem failure may occur 1 to 3 days after ingestion.

70.17.3 Management

Treatment of animals that have ingested large amounts of iron includes the use of an emetic if ingestion was less than 2 hours. This is followed by administration of activated charcoal plus a saline or osmotic cathartic. If potentially toxic amounts (>60 mg/kg) of iron were ingested, gastric lavage with magnesium hydroxide at 5 to 10 times the dose of elemental iron has been shown to be effective. Whole-bowel irrigation with a polyethylene glycol electrolyte solution may also be effective for decontaminating the GI tract after iron ingestion. Finally, deferoxamine, a chelating agent, should be considered after large ingestions of iron. It is administered 15 mg/kg/hour IV.[27]

71 CHAPTER • 71 Clinical Genetics

Urs Giger

Recent developments in molecular and human genetics have increased the interest in using this tool in the diagnosis, management, and control of hereditary disorders. Genetics has emerged as an important discipline in small animal practice for several reasons. Effective preventative measures have reduced the frequency of infections, nutritional disturbances, and intoxications. Furthermore, life-saving advances in medicine and surgery have increased the chance of survival of companion animals and thus tend to raise the recognition of genetic defects. Inbreeding practices to preserve desirable traits in certain breeds favor the occurrence of recessively inherited diseases. Technologic advances have allowed the recognition and characterization of the clinicopathologic, biochemical, and molecular basis of many hereditary diseases. In the past, genetics played a large role in a few patients; however, today hereditary disorders and genetic predispositions to diseases are critical in small animal practice for most patients. Specific hereditary disorders are covered under chapters of individual organ systems. This chapter on clinical genetics reviews the general characteristic clinical features of hereditary diseases in small animals, the various modes of inheritance, the screening of specific tests used to reach a diagnosis, as well as the management of these diseases and control in future generations. The importance of genetic counseling is addressed (i.e., providing information for pet owners and breeders of animals afflicted with hereditary disorders, concerning the consequence of such disorders and the ways in which they can be prevented by informed breedings). Furthermore, the recent completion of the human and canine genome sequence and initiative for a feline genome sequence have greatly facilitated the research of single-gene and complex inherited diseases. The field of *genomics* is the study not only of single genes but also of the organization, function, and interaction of all genes in the genome, including their interaction with environmental factors.

71.1 FREQUENCY

Because of the increased awareness (on the part of breeders, pet owners, and veterinarians) of genetic defects and improved diagnostic abilities in clinical practice, the number of reported hereditary diseases in small animals is rapidly growing. Originally, diseases with apparent clinical manifestations affecting the appearance and gait of an animal were recognized. Thus it is not surprising that skeletal malformations, skin and eye abnormalities, and neuromuscular defects were more frequently reported than disorders involving internal organs. Furthermore, clinicians now recognize that animals with recurrent or chronic infections or immune-mediated diseases may have a genetic defect that dysregulates one of their immune functions. Other genetic predispositions of certain animals, families, or breeds to develop disorders such as hip dysplasia, gastric torsion, adverse drug reactions, and cancer have been clearly established.

At present, approximately 430 hereditary diseases in dogs and 180 disorders in cats have been adequately documented. By comparison, several thousand hereditary disorders have been accumulated in the compendium known as *Online Mendelian Inheritance in Man* (OMIM) by Victor McKusicks. Practically all hereditary diseases described in small animals have also been seen in humans and generally represent close homologues.

Although any genetic defect may occur in any animal, many have been documented only in one family or breed. In some breeds, the frequency of a particular disorder and the mutant allele may reach high proportions. This may be due to a “founder” effect in which one or more of the founders of a small ancestral group was a carrier or even affected, or it may be as observed in several smaller breeds in which a “popular sire” was later determined to be a carrier of a mutant gene. Unfortunately, genetic disease frequencies are generally not available or are severely biased because of data collection. For instance, the prevalence of hip dysplasia may differ greatly depending on

methods used to reach a diagnosis and whether a registry requires or only encourages recording of every examined animal. Large-scale randomized screening programs and open registries with data on genetic diseases in certain breeds have rarely been established. In people, a disease occurrence of 1 in less than 500 individuals is considered a high-frequency disorder. In companion animals, many hereditary diseases appear to occur in 1% to 10% of certain breed populations. Recently, resources have become available to obtain genetic information. In addition to the list of hereditary diseases and associated breeds in the appendices of this book, other published lists organized by breed or disease are available. A list of genetic diseases in all species with references assembled by Frank W. Nicholas, known as *Mendelian Inheritance in Animals* (MIA), can be obtained online on Cambridge University's website. The most comprehensive and updated searchable information on canine hereditary traits, however, is Donald F. Patterson's *Canine Genetic Disease Information System*, available in book format.

71.2 INHERITANCE

Genetic diseases are caused by chromosomal alterations or gene mutations. Disease-causing mutations are heritable changes in the sequence of genomic deoxyribonucleic acid (DNA) that alter the expression, structure, and function of the coded protein. The *genotype* refers to the animal's genetic makeup (reflected by its DNA sequence), whereas the *phenotype* relates to the entire makeup of an animal (determined both genetically and environmentally). The molecular genetic defect is now known for more than 40 hereditary disorders in small animals (Table 71-1). Among the disorders caused entirely or partly by genetic factors, three main types are recognized: (1) chromosomal, (2) single gene, and (3) complexor multifactorial disorders. For approximately half of the disorders suspected to be of a genetic nature, however, the mode of inheritance remains unknown. These molecular genetic changes include point mutations, deletions, and insertions in the DNA sequence that result in a missense or nonsense sequence with an altered codon sequence. A codon is a three base sequence of DNA or RNA that specifies a single amino acid.

Table • 71-1 Examples of Hereditary Disorders Characterized at the Molecular Genetic Level

DISORDER	BREED
Hematologic Disorders	
Elliptocytosis (band 4.1) deficiency	Mixed breed dog
Pyruvate kinase (PK) deficiency	Basenji, West Highland white terrier, Cairn terrier, Beagle, Eskimo toy, Dachshund, Abyssinian, Somali, DSH cat
Phosphofructokinase (PFK) deficiency	English springer and American cocker spaniel, mixed breed dog
Hemophilia A (Factor VIII)	Mixed breed, Irish setter
Hemophilia B (Factor IX)	Airedale terrier, Labrador retriever, mixed breed
von Willebrand disease	Doberman, Manchester terrier, Pembroke Welsh Corgi, Bernese mountain dog, Kerry Blue, Poodle, Papillon
vWD type 1	
vWD type 2	German shorthair, wirehair pointer
vWD type 3	Dutch Kooiker, Scottish terrier, Shetland sheepdog
Severe combined immunodeficiency (SCID)	Basset, Pembroke Welsh corgi
Leukocyte adhesion deficiency (LAD)	Irish setter, red and white setter
Complement component 3 deficiency	Brittany spaniel
Hereditary Eye Diseases	
Progressive retinal atrophy	Irish setter, red and white setter
PRA dominant	Bull mastiff, English mastiff
PRA type A	Miniature schnauzer
PRA X-linked	Samoyed, Siberian husky
PRA red 1	B phosphodiesterase
PRA red 1a	Sloughi
PRA red 3 (pred)	Cardigan Welsh Corgi
Progressive cone dysplasia	Chesapeake Bay and Labrador retriever, English cocker spaniel, Portuguese water dog, Australian cattle dog, Miniature and toy poodle, Entlebuchers,
PRA pred (linkage)	American Eskimo, Nova Scotia Duck Tolling Retrievers
Stationary night blindness	Briard
Con (retinal) degenerative	German short haired pointers
Neuromuscular Diseases	
Shaking puppy syndrome	English springer spaniel
Dystrophin muscular dystrophy	Golden retriever, Rottweiler, DSH cat, mixed breed
Mucopolysaccharidosis type I	Plott hound
type IIIA	Wirehaired dachshund, New Zealand Huntaway dog
type IIIB	Schipperke
type VI	Siamese cat (two mutations), Miniature pinscher, miniature Schnauzer
type VII	German shepherd, mixed breed, DSH cat
Alpha mannosidosis	Persian, DSH cat
Gangliosidosis GM1	Siamese, Korat cat, Portugese water dog
GM2	Korat cat
Globoid cell leukodystrophy (Krabbe)	West Highland white and Cairn terrier
Glycogenosis type IV	Norwegian forest cat
Alpha fucosidosis	English springer spaniel
Neuronal ceroid lipofuscinosis	English setter
Myotonia congenital	Miniature schnauzer
Narcolepsy	Doberman, Labrador retriever, dachshund
Ivermectin toxicity (MDR-1 gene)	Collie, Sheltie, Australian cattle dog
Deafness	German short haired pointers
Hepatic Diseases	
Congenital hypothyroidism with goiter	Toy fox terrier
Hyperchylomicronemia	DSH cat

Glycogenosis type Ia	Maltese
Copper toxicosis	Bedlington terrier
Cobalamin malabsorption	Giant Schnauzers
Renal Diseases	
Cystinuria type I	Newfoundland, Labrador retriever
Renal adenocarcinoma and nodular dermatitis	German shepherd (linkage)
X-linked nephropathy	Samoyed
Polycystic kidney disease	Persian and other cats
A list of test laboratories is available at www.vet.upenn.edu/penngen.	

The dog has 76 autosomes (38 pairs) and 2 sex chromosomes (78XX or 78XY), whereas the cat has 38XX or 38XY. The human genome project has facilitated progress in canine and feline gene mapping. Furthermore, the canine genome sequence is nearing completion. Through physical and genetic mapping strategies, genes have been assigned to and localized along a chromosome, and new genes can be identified.

71.2.1 Chromosomal Disorders

Chromosomal disorders are caused by an excess or deficiency of genes contained in a chromosome or chromosomal segment. Understandably, such defects may result in severe, often lethal clinical syndromes. Although alterations of autosomes have only rarely been reported in small animals—some had syndromes with multiple defects—they are commonly reported in infants and are often responsible for fetal losses. In contrast, abnormalities involving the X and Y chromosomes leading to sex development disorders are well recognized. The best example is the tricolored (calico, tortoiseshell) male cat with testicular hypoplasia and an XXY chromosome set. However, not every sex developmental disorder is due to a defect in the sex chromosomes (e.g., XX sex reversal reported in various canine breeds).

71.2.2 Single-Gene Traits

The inheritance of a single-gene defect is often called *Mendelian trait* and involves one mutant gene (allele) at a single locus. When an animal has a pair of identically mutant genes (alleles), it is said to be *homozygous* (a homozygote), whereas when only one of the alleles is mutated, it is said to be *heterozygous* (a heterozygote) at that gene locus. The pattern of inheritance depends mainly on two factors: (1) whether the mutation is located on an autosome (autosomal) or on the X chromosome (X linked) and (2) whether the phenotype, the observable expression of a genotype as a disease trait, is dominant (i.e., expressed when only one chromosome of a pair carries the mutation) or recessive (i.e., expressed when both chromosomes of a pair carry the mutation). Therefore it is the phenotype rather than the mutant gene or protein that is dominant or recessive. In humans most diseases are dominantly inherited, whereas recessive traits resulting from inbreeding practices are more commonly been in small animals.

71.2.3 Autosomal Recessive Inheritance

Autosomal recessive inherited traits are common in small animals. The parents of affected animals must carry the mutant allele. Because they are generally asymptomatic carriers (heterozygotes), they are called *obligate carriers*. Typically one fourth of males and females in a litter are likely to be affected. Phenotypically normal offspring may be in a ratio of 2:1, either carriers (heterozygotes) or free of the mutant allele (“clear,” homozygous normal). Although the parents could also be affected, diseased animals generally are not used for breeding, unless they remain unrecognized because signs do not develop until later in life (late-onset diseases).

71.2.4 X Chromosomal Recessive Inheritance

In X chromosomal recessively inherited disorders, males who are hemizygous for the X chromosome are either affected or normal, whereas females are typically carriers (one normal and mutant allele on X chromosome). When heterozygous females (carriers) are mated to a normal male, half of their male offspring will be affected and half of their female offspring will be phenotypically normal carriers (whereas the other males and females will be "clear"). The mutant X chromosomal gene is never passed on from the sire to a male offspring but is transmitted by an affected male to all of its female offspring (obligate carriers). Affected females would occur only if a carrier female is mated with an affected male. Heterozygous females are usually unaffected, although some manifestations may occur because of X chromosomal inactivation. In addition, an X-linked dominant trait may need to be considered but has been reported only in Samoyeds with a specific glomerulonephropathy. X-linked disorders should not be confused with sex-limited disorders, such as diseases related to the primary and secondary sex organs. Y chromosomal diseases have not been reported in animals.

71.2.5 Autosomal Dominant Inheritance

In autosomal dominant conditions, the disease appears in every generation. An affected animal generally has one affected parent unless this animal has a new mutation in the gamete of a phenotypically normal parent or when the disease is variably expressed (nonpenetrant in parent). *Penetrance* refers to the likelihood that an animal carrying a particular mutation will exhibit an altered phenotype. Males and females are equally likely to transmit the disease to an offspring of either sex. Because affected animals are generally heterozygous, half of all offspring will be affected. Affected animals generally are not used in breeding programs, hence rapidly eliminated. Furthermore, homozygous states of dominant traits are often lethal and thus result in fetal loss or stillborns.

71.2.6 Mitochondrial Inheritance and Imprinting

Mitochondrial inheritance is a rare and atypical hereditary disorder involving mitochondrial DNA. Because all mitochondrial DNA is transmitted from the ova (mother), all offspring from an affected female (but none from an affected male) will be diseased. In humans, several neuromuscular diseases are known to be associated with mutations in mitochondrial DNA. In dogs, some myopathies may be caused by a mitochondrial defect.

Imprinting is another non-Mendelian mechanism for single-gene disorders. Here the effects of certain genes depend on whether they are inherited through the maternal or paternal parent. In companion animals this phenomenon has not yet been documented.

71.2.7 Complex or Multifactorial Inheritance

A number of developmental disorders resulting in congenital malformations are caused by complex or multifactorial inheritance, as well as other disorders in adult animals. Rather than having one single-gene error, several major and minor gene defects (polygenic) in the genetic information, together with certain environmental factors, can produce or predispose to a serious illness. Hip and other dysplasias and certain congenital heart defects (conotruncal defect) are examples, and the degree to which a trait (e.g., hip dysplasia) is genetically determined may greatly vary between breeds (heritability). Thus the hereditary nature of a particular disease may be suggested or established by a certain familial occurrence, breed predilection, breeding studies, established mode of inheritance, identified gene defect, or a combination of these factors.

71.3 CLINICAL SIGNS

Hereditary defects can involve any gene and hence, any organ. Therefore the clinical signs of hereditary diseases are extremely variable and may mimic acquired disorders. Some typical features, however, may raise our suspicion of a genetic disorder. In contrast to infectious diseases, intoxications, and nutritional imbalances that generally affect an entire litter, hereditary diseases often involve only a few in a litter. Furthermore, the age of onset of clinical signs for a particular gene defect is rather specific and independent of environmental factors.

266

267

Most genetic defects cause clinical signs early in life. Fetal resorptions, late abortions, and stillborns may be caused by genetic traits but are rarely determined. Most puppy and kitten losses occur during the first week of life, shortly after the maternal homeostatic system can no longer compensate for an endogenous defect and are generally not shown to the veterinarian as they are considered of the usual losses by breeders. Some neonatal kitten losses have recently been attributed to blood type incompatibility: Type A and AB kittens born to Type B queens develop life-threatening neonatal isoerythrolysis when nursing and absorbing anti-A–containing colostrum during the first day of life. Certain congenital malformations may also not be compatible with life, such as severe cleft palates and hernias. The term *congenital* only implies that the disease is present at birth, however, and does not necessarily mean it is hereditary.

A common problem in puppies or kittens that have problems due to hereditary conditions is *failure to thrive*. These animals lag behind their healthy littermates in their development; they do not gain weight at a normal rate and are generally lethargic. They often fade (hence the term *fading puppy or kitten syndrome)* and finally die. Failure to thrive should not be confused with *growth retardation*, which refers to a proportionally stunted growth that may or may not be associated with other clinical signs. In addition to these relatively unspecific clinical signs, some hereditary defects may cause specific clinical manifestations. Easy to recognize are malformations that involve any part of the skeleton and can lead to disproportionate dwarfism, gait abnormalities, facial dysmorphia and other malformitives. A large number of hereditary eye diseases have been described in dogs, some of which are not recognized until adulthood. Neuromuscular signs may vary from exercise intolerance to ataxia and seizures. Defects of many other internal organs are associated with unspecific clinical signs. Many disorders cause an isolated typical sign, whereas others produce a characteristic overall pattern of anomalies known as specific *syndromes*.

Clinical manifestations of hereditary diseases are extremely variable, ranging from benign to debilitating and lethal. They are usually chronic, progressive (i.e., once an animal shows signs, it probably will not recover), and often cause death at an early age. A few hereditary defects, however, result in intermittent or recurrent problems, such as hereditary bleeding disorders and primary immunodeficiencies.

71.3.1 Diagnostic Tests

Diagnostic tests generally are required to support or confirm the diagnosis of a genetic disorder. Radiology and other imaging techniques may reveal skeletal malformations or cardiac anomalies. Ophthalmologic examination may further define an inherited eye disease; although some are not recognized before several years of age. Routine tests such as complete blood count (CBC), chemistry screen, and urinalysis may suggest some specific hematologic or metabolic disorders or rule out many acquired disorders. Furthermore, clinical function studies may better define a GI, liver, kidney, or endocrine problem. Histopathology or electron microscopy of a tissue biopsy (or both) from an affected animal or from the necropsy of an affected littermate or relative may give the first clue as to a genetic defect.

A few laboratories provide special diagnostic tests that allow a specific diagnosis of an inborn error of metabolism. *Inborn errors of metabolism* include all biochemical disorders due to a genetically determined, specific defect in the structure, function, or both of a protein molecule. Aside from the classical enzyme deficiencies, genetic defects in structural protein receptors, plasma and membrane transporters, and other proteins covered by this definition will result in biochemical disturbances. The laboratory approach is to detect the failing system or to determine the specific protein or gene defect. Disorders of intermediary metabolism typically produce a metabolic block in a biochemical pathway leading to product deficiency, accumulation of substrates, and production of unusual substances via alternative pathways. The most useful specimen to screen for biochemical derangements is urine because abnormal metabolites in the blood will be filtered through the glomeruli but fail to be reabsorbed (because no specific renal transport system exist for most abnormal metabolites).

Once the failing system has been identified, the defect can be determined at the protein level. These protein assays include the classic enzyme function tests and immunologic assays. Because most enzymes are present in abundant amounts, no major functional abnormalities are generally observed unless the enzyme activity is severely reduced, usually to less than 20% of normal value. Thus homozygously affected animals have very low-protein activity, quantity, or both, often in the range of 0% to 10%. These tests may also be used to detect carriers (heterozygotes) that typically have intermediate quantities at the protein level (30% to 70%) but no clinical signs. Unfortunately, protein assays are labor intensive and require submission of appropriate fresh tissue or fluid (and a control sample) under special conditions to specialized laboratories. The section of Medical Genetics at the School of Veterinary Medicine of the University of Pennsylvania performs tests to diagnose known conditions and to study potential new disorders (www.vet.upenn.edu/penngen).

The molecular defect has been identified for over three-dozen hereditary diseases in companion animals; thus DNA screening tests have been developed. These tests are mutation specific and can therefore only be used in animals suspected of having the exact same gene defect. Small animals within the same or a closely related breed will likely have the same disease-causing mutation for a particular disease (e.g., phosphofructokinase deficiency in English springer and American Cocker spaniels), as will mixed breed dogs due to mother-son or father-daughter matings with one parent. However, dogs, cats, and unrelated breeds of species with the same disorder will likely have different mutations, as shown with X-linked muscular dystrophy and erythrocyte pyruvate kinase deficiency in various breeds of dogs and cats.

DNA tests have several advantages over other biochemical tests. The test results are independent of the age of the animals; thus tests can be performed long before an animal is placed in a new home and before clinical signs become apparent. DNA is stable, and only the smallest quantities are needed. Therefore no special shipping arrangements are necessary as long as one follows the specific instructions for biologic products. DNA can be extracted from any nucleated cell (e.g., blood, buccal mucosa [cheek swabs], hair follicle, semen, formalinized tissue). For instance, blood can be sent in an EDTA tube, or a drop of blood can be applied to a special filter paper for DNA extraction. Buccal swabs can be obtained with special cytobrushes. This method should not be used in nursing animals, or only hours after nursing and rinsing the oral cavity with water. The DNA segment of interest is amplified with appropriate forward and reverse primers and polymerase chain reaction (PCR). The mutant or normal allele (or both) is identified by DNA size difference directly on a gel (in case of deletions or insertions) or after restriction enzyme digestion for point mutations or other suitable test systems to differentiate normal and mutant allele. These tests are generally simple and accurate as long as appropriate techniques and controls are used, but human errors in identifying samples can still occur. Furthermore, they can be used not only for the detection of affected animals but also for carriers. Such testing is extremely valuable to select breeding animals that will not cause disease or further spread the disease-causing allele. For instance, phosphofructokinase deficiency was recognized to cause intermittent anemia and myopathy

267

268

in English springer spaniels, and a DNA-based test became available in the early 1990s. There were still 4% and 1% carriers in the field trial and conformation lines, respectively, in the first randomized survey performed in 1998. If an animal with all the desirable qualities is found to be a carrier, it could be bred to a clear animal (homozygous normal) because this would not result in any affected offspring. However, offspring would need to be tested, and only clear animals would be used in subsequent breedings.

For many inherited disorders the defective gene remains unknown; however, for a few, a polymorphic DNA marker that is linked to the disease-causing mutant allele has been discovered (see chapter on genome). Such linkage tests were first developed for copper toxicosis in Bedlington terriers and are now available for some forms of retinopathy, in various breeds and renal carcinoma with nodular dermatitis in German shepherds. They are accurate for a particular animal as long as an affected animal is in its family (informative family). At present, mutation-specific and linkage tests are available only for single-gene defects in small animals. However, complex genetic traits may also soon be approached by these methods.

71.3.2 Prognosis and Therapy

Because the clinical consequences of the many hereditary disorders vary greatly, it is not surprising that the prognosis for survival and quality of life ranges from excellent to grave. The clinical course and outcome for a particular defect is rather similar among affected animals. Some defects are recognized as a breed characteristic (e.g., fold ear in Scottish folds and lack of tail in Manx [both dominant traits]) or an incidental finding (e.g., microcytosis in Akitas), whereas others are progressive and lead to severe organ dysfunction and death (e.g., many lysosomal storage diseases).

At present the therapeutic options in the treatment of hereditary diseases are limited, and ethical principles need to be carefully considered. Although several structural malformations can be surgically corrected (e.g., cryptorchism, hernias, hepatic shunts, patent ductus arteriosus [PDA]), these animals should not be shown or bred. In a few cases a deficient protein, cofactor, substrate, or metabolite can be supplemented to correct the defect. For instance, vitamin B_{12} deficiency in cachectic and lethargic giant schnauzers and Border collies with an ileal receptor defect can be helped by monthly cobalamin injections. Pancreatic enzyme supplementation and daily insulin injections are used to manage animals with exocrine or endocrine pancreatic insufficiency, respectively. Fresh frozen plasma is administered in the treatment of hereditary coagulopathies and von Willebrand's disease whenever animals excessively bleed. Other enzyme and protein replacements are also experimentally attempted.

Although kidney transplants have been established in clinical practice for chronic renal failure in cats, they have not been applied in animals with hereditary (juvenile) renal disorders. Several hereditary disorders of hematopoietic cells have been experimentally corrected by bone marrow transplantation (e.g., pyruvate and phosphofructokinase deficiency, cyclic hematopoiesis, and interleukin-2 [IL-2] receptor defects). Furthermore, bone marrow transplantation is being attempted to deliver functional cells or active proteins to other tissues including liver, bone, and brain (e.g., in lysosomal storage disease). Finally, gene therapy, the integration of a functional gene into the patient's own defective cells, will likely be clinically feasible in the twenty-first century. Experiments in rodent models have provided encouraging results. However, effective gene therapy has proven more difficult in larger mammals, and the technology needs to be further improved to achieve persistent and regulated gene expression in larger mammals including humans, dogs, and cats. One of the first and most promising canine gene therapy experiments has been the correction of mucopolysaccharidosis type VII in neonatal puppies with a retroviral vector carrying the beta-glucuronidase gene; these treated animals remain ambulatory, whereas affected animals become tetraparetic by a few months.

71.3.3 Control

Much more important than the treatment of hereditary disorders is the control of these traits in breeding programs. Thus to reduce the frequency or altogether eliminate a genetic defect, the further spread of the mutant gene has to be prevented in a family or entire breed. It is obvious that affected animals of any genetic disease should not be used for breeding. This approach is simple and effectively eliminates disorders with a dominant trait. For recessively inherited disorders, however, the elimination of affected animals is not sufficient to markedly reduce the prevalence of a defect within a breed, kennel, or cattery. It may be safest not to breed any related animals of affected animals, as requested by some kennel clubs; however, this practice may (because of inbreeding and narrow gene pools in some breeds) eliminate all breeders in an entire kennel or cattery and severely reduce the genetic diversity of a breed. Thus it will be pivotal to detect carriers (heterozygotes) and truly “clear” animals (homozygous normal). Obligate carriers can be readily identified for autosomal (both parents of affected) and X chromosomal recessive (mother of affected) disorders. As mentioned previously, for some diseases, reliable carrier detection tests are available, and many breeders know about them and inform the veterinarian. For instance, carriers have half-normal (~ 50%) enzyme activity by functional assays or have a normal *and* mutant DNA sequence for the diseased gene on a DNA test. Breeders should therefore be encouraged to screen their animals before breeding for known genetic diseases whenever carrier tests are available. Their availability is also listed on several websites including www.vet.upenn.edu/penngen. Unfortunately, many breeders mistrust these newer tests; either they were disappointed by inaccuracy of early tests, such as the radiographic examination for hip dysplasia, or they fear that the results may become public and could hurt their business. Thus breeders need to be educated by well-informed veterinarians. If a particular carrier needs to be used because of a narrow gene pool and many desirable traits, it should only be bred with a homozygously normal (clear) animal; all its offspring need to be tested, and only clear animals should be used in future breedings. If no carrier tests are available, a test mating between the dog in question and a known affected or carrier could be performed, and as long as no affected offspring and at least 5 healthy puppies or 11 healthy kittens, are born to “clear” an animal of a carrier state. For many breeders this approach is ethically unacceptable because it may produce affected animals.

In conclusion, it is exciting to learn about recent advances in the understanding of hereditary disorders and genetic predispositions in small animal practice, be it the advances in diagnostic approach to a hereditary disease, understanding of its pathophysiology, or its control. In addition to the clinician's responsibility to suspect a genetic disease and to appropriately diagnose it with modern, specific techniques, clinicians must become involved in the control of these disorders in the breeders' kennels or catteries. Practitioners thus can make an important contribution toward controlling the further spread of mutant genes and reducing future suffering of animals.

72 CHAPTER • 72 Abdominocentesis and Diagnostic Peritoneal Lavage

Elke Rudloff

Sterile procedure: There should be no gross evidence of intra-abdominal mass lesions, and the urinary bladder must be empty before the procedure. If the animal is unable to void voluntarily, careful manual expression or urinary catheterization is performed.

Surgical scrub required: The ventral abdominal skin from the xyphoid to pubis region is clipped free of hair and surgically prepared.

Conscious sedation: The clinician uses intravenous butorphanol 0.4 mg/kg or hydromorphone 0.2 mg/kg and diazepam 0.2 mg/kg; this is more important for diagnostic peritoneal lavage (DPL) than for centesis.

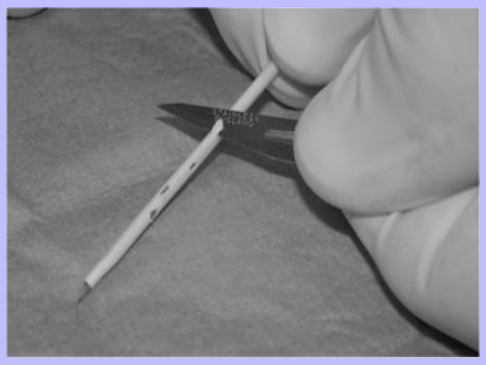
Local anesthesia required: Up to 4 mg/kg of lidocaine is used in the region where the needle or catheter is placed.

If an *abdominocentesis* is to be performed, the animal can be standing or in lateral recumbency. Ultrasound-guided centesis of any fluid pocket is the preferred method for fluid collection. If ultrasound is unavailable, a four-quadrant tap should be performed. In each of the four abdominal quadrants, an 18 to 22 gauge 1-inch needle or over-the-needle catheter is percutaneously inserted. Sample yield is maximized if fluid is allowed to flow out of the needle under the influence of gravity and not aspirated. A negative tap *does not* rule out the presence of intra-abdominal pathology.

If a DPL is to be performed, the animal should be placed in left-lateral recumbency or in a ventrodorsal position to avoid traumatizing the spleen.

Catheter placement for DPL: When using an over-the-needle catheter (Figure 72-1), the clinician should make a small skin incision at the site of the skin block and insert the catheter just through the body wall. There will be a slight pop as the peritoneum is penetrated. The catheter should then be rotated and advanced over the needle until it is fully inserted. If the catheter does not advance easily, it may still be in the subcutaneous tissue or against an organ and should be repositioned.

Figure 72-1 Over-the-needle abdominal catheter. Small side holes (two to four) are carefully cut into a 14-to 18-gauge 2-inch catheter 2 mm apart with a scalpel blade. The edges of the holes are kept smooth to prevent the catheter from barbing and possibly breaking.



Peritoneal lavage catheters (Figures 72-2 and 72-3) are usually placed using a Seldinger technique, with instructions contained in the kit. The kits contain all the materials necessary (except for the fluid to be infused), including local anesthetic, drapes, and disinfectants.

When placing a catheter, the following points should be kept in mind:

- If fluid freely drains from the catheter, samples should be collected (Figure 72-4).
- If no fluid drains, the clinician should infuse 20 mL/kg of warmed isotonic replacement crystalloid (e.g., 0.9% sodium chloride, Ringer's lactate solution) and clamp the infusion set. Then the animal should be gently rolled back and forth and turned on its side. The infusion set should then be opened, and the first few milliliters should be allowed to drain out of the catheter before collecting samples.
- If an abdominal bleed is suspected, the catheter can be sutured in place to permit evaluation of follow-up samples. If septic peritonitis is suspected, the catheter can be left in place until surgical intervention to permit periodic lavage to dilute and drain septic material. If an aseptic peritonitis or pancreatitis is suspected, the catheter can be left in place to permit periodic abdominal lavages to dilute and drain inflammatory mediators.

269

271

- Complete removal of the fluid is not always possible or necessary; it may be used to partially replace calculated fluid deficits when peritonitis is not present.
- If the catheter is to be removed, the skin is pinched around the catheter while it is removed and a temporary dressing is placed on the area.
- Cytology: The presence of vegetable or meat fibers, intracellular bacteria, or toxic neutrophils is an indication for surgical exploration and culture submission.
- Special laboratory tests required: The packed cell volume (PCV) of the abdominal fluid can be compared with the peripheral PCV and serially monitored if abdominal hemorrhage is suspected. A white blood cell (WBC) count greater than $1000/mm^3$ is diagnostic for peritonitis. If chemical analysis reveals that the creatinine or potassium level (or both) in the abdominal fluid is higher than the peripheral blood, a urinary tract rupture is suspected. If the total bilirubin of the fluid is greater than that of peripheral blood, a leaking biliary system is suspected.

73 CHAPTER • 73 Abdominal Ultrasound: Aspirations and Biopsies

Wendy D. Fife

73.1 INTRODUCTION

Ultrasonography has many advantages, including its ability to detect parenchymal changes within organs and define the origin and extent of lesions. Abnormalities detected with ultrasonography are often nonspecific, with a great deal of overlap in the appearance of various disease processes. Ultrasound-guided fine needle aspirates or tissue-core biopsies are therefore often required for cytology or histopathology to reach a definitive diagnosis. The use of ultrasound guidance when obtaining diagnostic samples allows for real-time monitoring of needle placement so that a selected portion of an organ or a focal mass lesion may be sampled. Ultrasonography allows for the assessment of nearby vessels or other structures to be avoided and can be used to reassess the patient after the biopsy procedure for evidence of complications, such as hemorrhage. Ultrasonography and ultrasound-guided biopsies are noninvasive and rarely require general anesthesia when compared with surgery.

73.2 INDICATIONS

Percutaneous ultrasound-guidance may be used to obtain diagnostic samples or to provide therapeutic intervention. Fine needle, large-gauge needle, or tissue-core biopsies are chosen based on the size and type of lesion to be sampled. Biopsy samples of a specific organ may be warranted in cases of diffuse parenchymal abnormalities, (focal loss of parenchymal homogeneity) or mass lesions, or in the case of a normal ultrasonographic appearance of an organ when the results of other diagnostics indicate organ dysfunction. Therapeutic uses of ultrasonography include the drainage of intra-abdominal or intrathoracic cysts, abscesses, or fluid, or to instill local chemotherapeutics or other chemical therapy.

73.3 MATERIALS

Sector or linear-array transducers may be used, depending on the depth of the structure to be biopsied. Linear-array transducers provide superior resolution for more superficial structures, whereas sector transducers are used to biopsy deeper tissues. The lesion to be biopsied should be placed within the focal zone of the transducer to allow for the best resolution. Some transducers are equipped with biopsy guides, and separate guides are available for attachment to conventional transducers. The guides function to keep the needle in the plane of the ultrasound beam (Figure 73-1).

Dedicated biopsy transducers and those equipped with biopsy guides often display electronic markers on the display screen. The lesion or tissue to be biopsied is placed between the markers and the needle is inserted with its position continuously monitored. Dedicated biopsy transducers are more expensive and specialized than conventional transducers or transducer biopsy guides and are rarely used in veterinary medicine.

The size and type of needle to be used depends on the size of the lesion being sampled and the type of sample desired. The smallest needle that will provide a diagnostic sample should be used because larger needles may be associated with higher complication rates, such as hemorrhage. Fine needle samples most commonly yield samples for cytology, whereas histologic evaluation requires a tissue-core biopsy. Fine needle samples are commonly obtained when the organ being sampled has a diffusely abnormal appearance or when a small lesion (<1 cm) is being sampled. Tissue-core biopsies may be preferred in the case of a large mass or when

histopathology is necessary. In many cases, a fine needle aspiration may be obtained first and a tissue-core biopsy pursued if the sample is inconclusive or nondiagnostic.

For fine needle aspiration, 20-to 25-gauge needles are typically used. In the case of the freehand technique, standard injection needles are used. A longer needle (e.g., 3½ inch) is required if a transducer guide is used. This length is necessary to pass through the biopsy guide and into the tissue. In the case of a tissue-core biopsy, a 14-to 18-gauge needle is used. Manual and automated biopsy devices are available. A manually operated Tru-Cut® needle requires two hands to operate, so two people are required for the procedure: one to place the transducer and another to operate the biopsy device. The operator is able to control the depth of the needle and the length of tissue to be sampled. Several types of semiautomatic and automatic biopsy devices have been developed. The inner cutting needle is manually advanced to the desired depth with a semiautomatic device. The outer cutting shaft, which is spring loaded, is then triggered. The exact depth of tissue biopsied is manually controlled. The inner cutting needle and outer shaft of an automatic device are initially advanced manually, 1.5 to 2.0 cm superficial to the tissue to be biopsied. Automatic biopsy guns automatically advance the cutting needle and external shaft when triggered. Caution is advised when using an automatic biopsy gun; the inner cutting shaft advances a specific distance (15 to 20 mm) beyond the external shaft to acquire the tissue sample when it is triggered. Most automatic biopsy guns accept disposable needles of varying sizes, and the distance the cutting shaft will advance can be adjusted to control the length of tissue sampled. This is particularly useful in cats and in the case of small lesions. This gun is reusable and can be sterilized. Individual disposable spring-loaded automatic and semiautomatic biopsy needles are available in various sizes.

73.4 TECHNIQUE

The needle should not enter more than one organ or pass through an organ, and a separate needle should be used for each organ sampled. Multiple samples of an organ or lesion are usually obtained.

The freehand technique can be used, in which case the transducer is operated with one hand and the needle with the other (Figures 73-2 and 73-3). This allows for greater flexibility in the approach to the structure of interest but requires hand-eye coordination and practice. The entire length of the needle must be kept within the ultrasound beam, and the tip must be localized. Moving the needle gently up and down while fanning the region with the ultrasound probe may aid in locating the needle tip. Under no circumstances should the location of a needle be determined by moving the needle side to side within an organ. This causes unnecessary tissue trauma. Roughening the outer needle shaft prior to introduction will create an irregular interface to increase sound reflection and sonographic visualization. Commercially available Teflon or other highly reflective-coated needles are available to enhance visualization. Use of a larger-gauge needle will facilitate visualization but may increase the risk of complication. The needle tip should be placed at the focal zone of the transducer to enhance resolution. Injection of a small amount of air or sterile saline may help localize the needle tip. After needle placement, and stylet removal in the case of a spinal needle, a syringe or extension tubing and syringe are attached to the needle. If the lesion is fluid filled, fluid is then aspirated. If large amounts of fluid are to be aspirated, a three-way stopcock is attached. For cytologic samples, aspiration is performed as the needle is moved slightly up and down within the tissue or lesion. Some individuals prefer to simply move the needle up and down within the tissue, without aspiration, to obtain a cytologic sample. This technique may provide less blood contamination within the sample and has been shown to yield diagnostic results. Fine needle samples may be obtained with the stylet in place as the needle is advanced (Figures 73-4 and 73-5). Once the needle is placed at the desired depth, the stylet is removed and the sample is acquired. This may be particularly useful in the case of traversing fat within the falciform ligament to obtain a liver aspirate in the cat. Without a stylet, the sample may consist of fat only, which may be improperly interpreted as hepatic lipidosis.

Use of a needle guide requires less dexterity, but once the needle enters the skin, the probe cannot be moved. Transducer guides also cause the angle of the needle relative to the ultrasound beam to be fixed, thereby limiting the angle at which the surface of the patient can be approached and prohibiting biopsy of superficial structures.

73.4.1 Patient Preparation

The patient is usually placed in dorsal recumbency on a padded trough. An intravenous catheter is placed in the case of a tissue-core biopsy so that intravenous sedatives can be administered. In the case of a very small lesion or a lesion in close proximity to large vascular structures, general anesthesia may be required. The use of some drugs should be avoided, including those that cause splenic enlargement or panting.

Depending on the tissue being sampled, the patient's clinical status, and the type of biopsy being performed, screening of the patient's coagulation status is recommended. For fine needle aspirations, coagulation-screening profiles are not routinely performed unless the lesion to be sampled is extremely vascular or the patient is at an increased risk of bleeding.

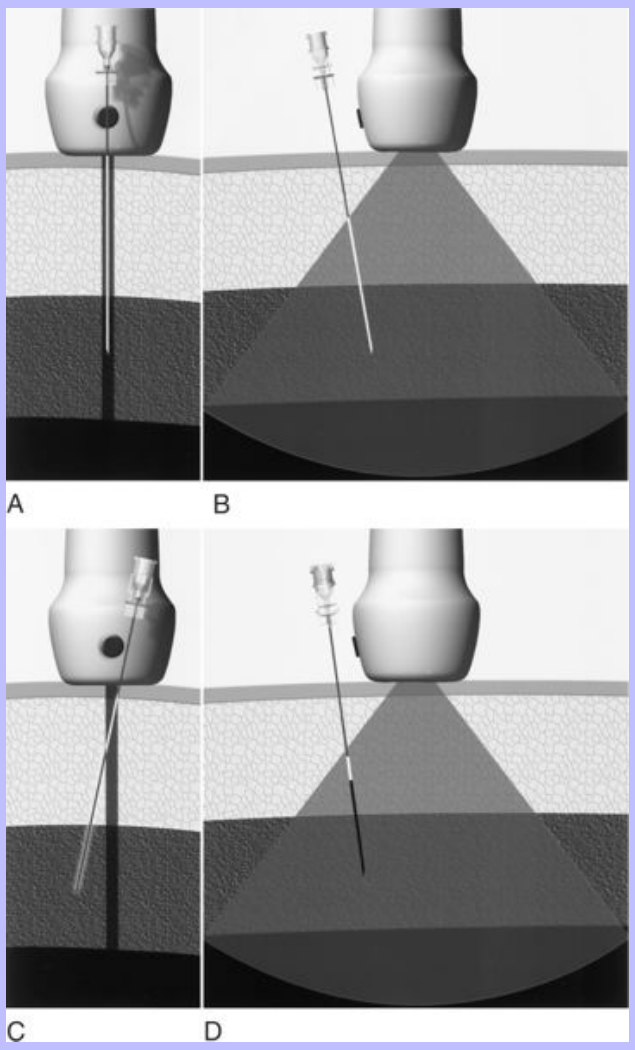
73.4.2 Specific Biopsy Sites

Fine needle aspiration and tissue-core biopsies of the liver are commonly done. Fine needle aspiration is performed when sampling focal masses that are complex or highly vascular, whereas a tissue-core biopsy is preferred in the case of a focal solid–appearing mass. In cases of diffuse hepatic disease, a fine needle aspirate may be done first and often yields a diagnosis in cases of specific diseases, such as lymphoma or hepatic lipidosis. Other diffuse hepatic diseases may require a tissue-core biopsy for a definitive diagnosis. The left-lateral aspect of the liver is generally the safest area to sample because it is the largest and the gallbladder and hilar vessels can be avoided. If a focal lesion is in a different location, or if the liver is small, sampling of another portion of the liver may be warranted. If the liver is small or located cranially, an intercostal approach is sometimes used, being cautious to avoid lung tissue. General anesthesia and positive pressure ventilation may also be used to displace the liver caudally for easier access. Multiple biopsies are routinely obtained.

The gallbladder may be sampled in cases of acalculous cholecystitis for culture and cytology. A transhepatic approach and a 22-gauge needle are used. The transhepatic approach is reported to decrease the risk of bile leakage.

Diffuse infiltrative splenic diseases, such as lymphoma and mast cell disease, and focal splenic masses are common indications for aspiration. Needle biopsy without aspiration may decrease the potential for blood contamination in splenic samples. If the aspiration technique is used, aspiration should be discontinued if blood appears in the hub of the needle. Complications due to splenic aspirates are extremely rare, but caution should be used when sampling complex, cavitary masses, such as those seen in splenic hemangiosarcoma. If fine needle samples of the spleen are nondiagnostic, a tissue-core biopsy of a solid mass lesion or the solid portion of a complex lesion may be indicated.

Figure 73-1 The angle of the biopsy instrument relative to the plane of the ultrasound beam is essential to visualize the tissue being sampled with the freehand method. **A** and **B,** Proper alignment of the biopsy instrument and ultrasound beam, with the two remaining parallel the entire length of the needle. **C** and **D,** Improper alignment of the needle relative to the ultrasound beam. Only a small segment of the length of the needle can be seen as it intersects the plane of the beam. The tip of the needle and therefore the tissue being sampled cannot be seen. The white portion of the needle represents that which transects the path of the scanning plane and is therefore visualized.



Renal biopsy may be performed in cases of diffuse renal disease or focal renal masses. Fine needle aspirates are usually performed if diffuse disease such as lymphosarcoma is suspected, whereas tissue-core biopsies are required to diagnose glomerular and tubular diseases and renal mass lesions. Sampling of the left kidney is preferred in cases of diffuse bilateral renal disease due to its relatively caudal location and easier access. The caudal cortex of the kidney should be sampled (including glomeruli but avoiding the medulla and hilar vessels). The biopsy plane should be directed laterally to avoid puncturing the renal hilus, caudal vena cava, or aorta. Feline renal biopsies are commonly done by manually stabilizing the kidney close to the ventral or lateral skin surface while performing a core biopsy of the lateral cortex with or without direct ultrasound guidance. Complications are rare and in most cases self-limiting but may include intra-abdominal hemorrhage or hemorrhage manifested as hematuria. Small dogs and cats may have an increased risk of hemorrhage and cats with hypertension are at particular risk. The animal's packed cell volume (PCV) should be monitored for several hours after the procedure. Renal biopsies should not be performed indiscriminately because fatal hemorrhage can occur.

Urinary bladder masses are commonly identified ultrasonographically. They are usually readily accessible for aspiration with a 21-or 22-gauge needle. In cases of transitional cell carcinoma, percutaneous biopsy often yields a diagnostic sample, but seeding of the tumor into the abdomen and subcutaneous tissues can occur. Ultrasound-guided urinary catheter placement and vigorous suction is a viable diagnostic alternative and avoids the potential for seeding of tumor cells.

Percutaneous biopsy of the prostate may be indicated when parenchymal abnormalities or prostatomegaly are identified. Fine needle aspiration of fluid-filled cysts or cavities within the prostate may be obtained for culture and cytology. These lesions may occur in association with prostatitis or neoplasia. If neoplasia is suspected, a tissue-core biopsy should be performed. The biopsy is obtained from the caudal abdomen, lateral to the prepuce. Adjacent vascular structures, such as the aorta and caudal vena cava, should be avoided. If the prostate is small or caudally located, the pubic bone may interfere.

The pancreas may be aspirated to differentiate between pancreatitis and pancreatic neoplasia. Secondary pancreatitis is an uncommon complication. Infection may develop in conjunction with pancreatic neoplasia, so false-negative diagnoses may occur.

Other abdominal structures that may be aspirated or biopsied include enlarged intra-abdominal lymph nodes and gastrointestinal (GI) masses. Aspiration of adrenal masses has been reported in veterinary medicine but is uncommonly performed; blood pressure alterations and severe hemorrhage may occur in the case of pheochromocytoma. Close proximity to the caudal vena cava and aorta are additional risks.

Ultrasound-guided percutaneous drainage of intra-abdominal abscesses is performed in people as an alternative to surgical treatment. This technique may be useful in veterinary patients. With the patient under sedation, the abscess cavity is drained using a 20-gauge or larger needle. Samples are submitted for culture and cytology. Follow-up ultrasound examinations, possibly in conjunction with repeated abscess drainage, are done. The procedure may reduce morbidity and mortality associated with abdominal abscesses treated surgically.

73.4.3 Contraindications and Complications

Complications related to ultrasound-guided biopsy procedures are uncommon. The risk of complication varies based upon the size of the needle being used and the location of the lesion. A 22-to 25-gauge needle should be used when possible, and larger gauge and tissue-core biopsies pursued if samples are nondiagnostic. 273
Hemorrhage is minor and self-limiting in most instances. The results of physical examination and laboratory 274

testing when necessary will identify patients at increased risk for hemorrhage. Color Doppler imaging is recommended when available to assess the vascularity of tissues and adjacent structures before the biopsy is performed and to monitor for hemorrhage in the postbiopsy period. The risk of peritonitis associated with penetration of the bowel is small in cases of fine needle aspiration, but bowel should be avoided with larger-gauge needles and tissue-core biopsies. Seeding of a tumor along a needle tract is also rare but has been reported in cases of transitional cell carcinoma in the canine urinary bladder. As with any procedure, adequate restraint and sedation are necessary to minimize risk to the patient.

Figure 73-2 Freehand biopsy technique. The ultrasound probe is held in one hand and the biopsy instrument in the other hand. The biopsy instrument must be maintained within the plane of the ultrasound beam. **A,** Proper alignment of biopsy instrument relative to ultrasound beam. **B,** Improper alignment, with the biopsy instrument angled relative to the ultrasound beam. This will not allow proper visualization of the biopsy instrument within the scan plane.

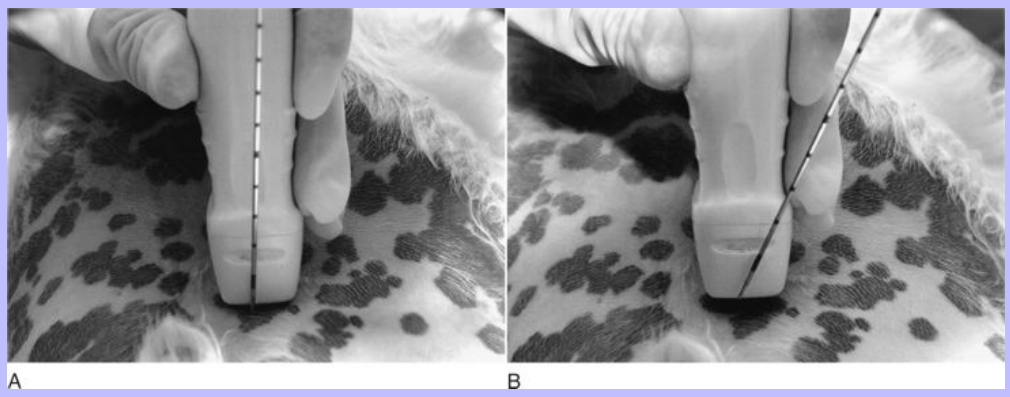


Figure 73-3 **A,** Freehand biopsy technique. The instrument is held with one hand and the biopsy instrument, in this case a Biopty® gun, is held with the other. The angle of the biopsy needle relative to the transducer is not fixed. **B,** Biopsy with guide attached to transducer. In this case, an external metal guide is attached to this sector transducer. The angle of the biopsy needle relative to the probe is fixed.

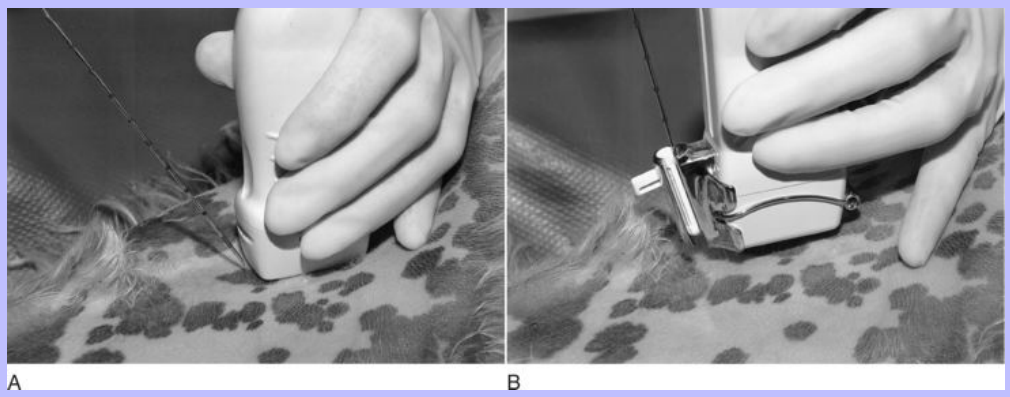

73.5 FUTURE TRENDS

Ultrasonographic-guided percutaneous antegrade pelography has been used to confirm obstructive uropathy and the site of obstruction in the dog and cat. This procedure does not require the intravenous administration of iodinated contrast medium as it does with excretory urography (EU). A 22-gauge spinal needle is introduced into the renal pelvis via the lateral cortex, to avoid hilar vessels, and nephropyelocentesis is performed by withdrawing 4 to 6 ml of urine. The clinician then injects 2 to 4 ml of iodinated contrast medium into the renal pelvis and radiographs are performed. This procedure is useful in animals with poor renal function and resultant inadequate pyelogram phase during EU to diagnose a ureteral obstruction. The possible nephrotoxic effects associated with intravenous contrast administration are decreased. Transcutaneous pyelocentesis can also be used to collect urine for culture when pyelonephritis is suspected and cystocentesis samples yield a negative culture.

Figure 73-4 Fine needle aspirate of the liver using a sector transducer. **A,** Color Doppler identifies blood flow in hepatic vessels, which are to be avoided by the path of the biopsy needle. **B,** The entire length of the needle can be seen coursing through the hepatic parenchyma as a linear hyperechoic structure *(arrows)*.

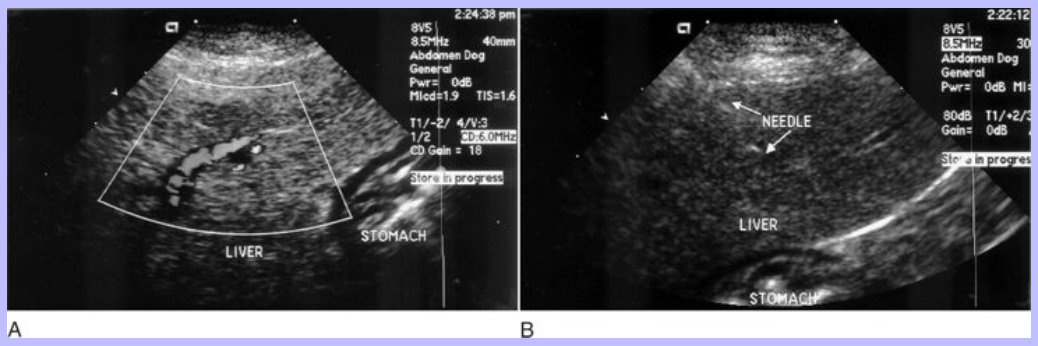

Figure 73-5 Fine needle aspirate of the spleen using a linear transducer in a cat with splenomegaly. A linear transducer is useful for biopsy of superficial structures. The entire length of the needle can be seen. The needle tip is causing distal acoustic shadowing due to its high degree of echogenicity. *SI,* Small intestinal segment.

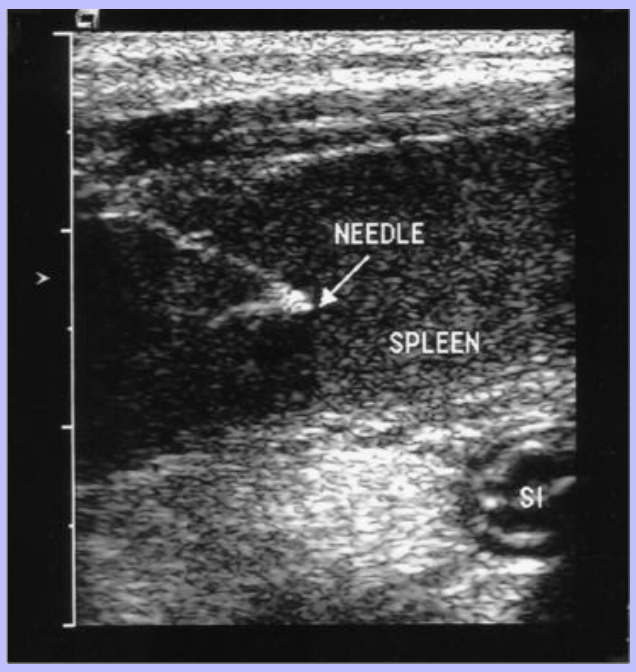


Local administration of pharmaceuticals can be performed with ultrasound guidance. Percutaneous injection of ethanol has been used to treat thyroid and parathyroid disease in veterinary patients. Local chemotherapeutics have been placed with ultrasound guidance in cases of abdominal neoplasia.

Endoscopic and laparoscopic ultrasonography are being used in people to evaluate structures more directly and to obtain aspirates and biopsies. These procedures are less invasive and quicker than open surgical biopsies. The necessary equipment is expensive and not yet widely available in veterinary medicine.

74 CHAPTER • 74 Arthrocentesis and Arthroscopy

Mark C. Rochat

74.1 ARTHROCENTESIS

Synovial fluid is a dialysate of plasma combined with hyaluronic acid produced by type 2 (B) synoviocytes. The viscosity of normal synovial fluid provides lubrication, shock absorption, and joint stability. Arthropathy results in loss of integrity of the synovial membrane and introduction of inflammatory mediators into the joint. Inflammatory cells and infectious agents release hyaluronidase and other matrix metalloproteinases, resulting in breakdown of hyaluronic acid. Loss of normal hyaluronic acid leads to loss of synovial fluid viscosity, improper cartilage nutrition, and decreased shock absorption.

Arthrocentesis is the process of withdrawing synovial fluid from a joint by use of a hypodermic needle and syringe. Arthrocentesis is a secondary diagnostic tool that should be preceded by a thorough history, physical and orthopedic examination, and diagnostic imaging studies. Diagnostic imaging studies should be performed prior to arthrocentesis because artifacts such as hematomas may be created, leading to difficulty in interpreting the diagnostic images.

Arthrocentesis is indicated for characterizing the nature of arthropathies. The source of lameness can usually be isolated to a specific joint by history, as well as physical and orthopedic examination. Rarely, joint effusion, pain, or other signs of arthropathy cannot be readily identified, and the animal has vague and often diffuse lameness. This is common in immune-mediated polyarthropathies. In these situations, arthrocentesis is indicated as a screening tool when historical information supports a diagnosis of polyarthropathy. Multiple joints should be aspirated to enhance the likelihood of identifying the arthropathy. The carpus and hock are commonly involved in immune-mediated disease but can be difficult to aspirate due to their small size. On occasion, arthrocentesis yields a definitive diagnosis. For example, the presence of *Ehrlichia* morulae in intra-articular monocytes is diagnostic for joint sepsis due to ehrlichiosis. More often, arthrocentesis reveals the general cellular pattern and characteristics of the synovial fluid and joint environment, allowing broad classification of the arthropathy. Arthrocentesis is also the primary method of monitoring response to therapy for immune-mediated polyarthropathies.

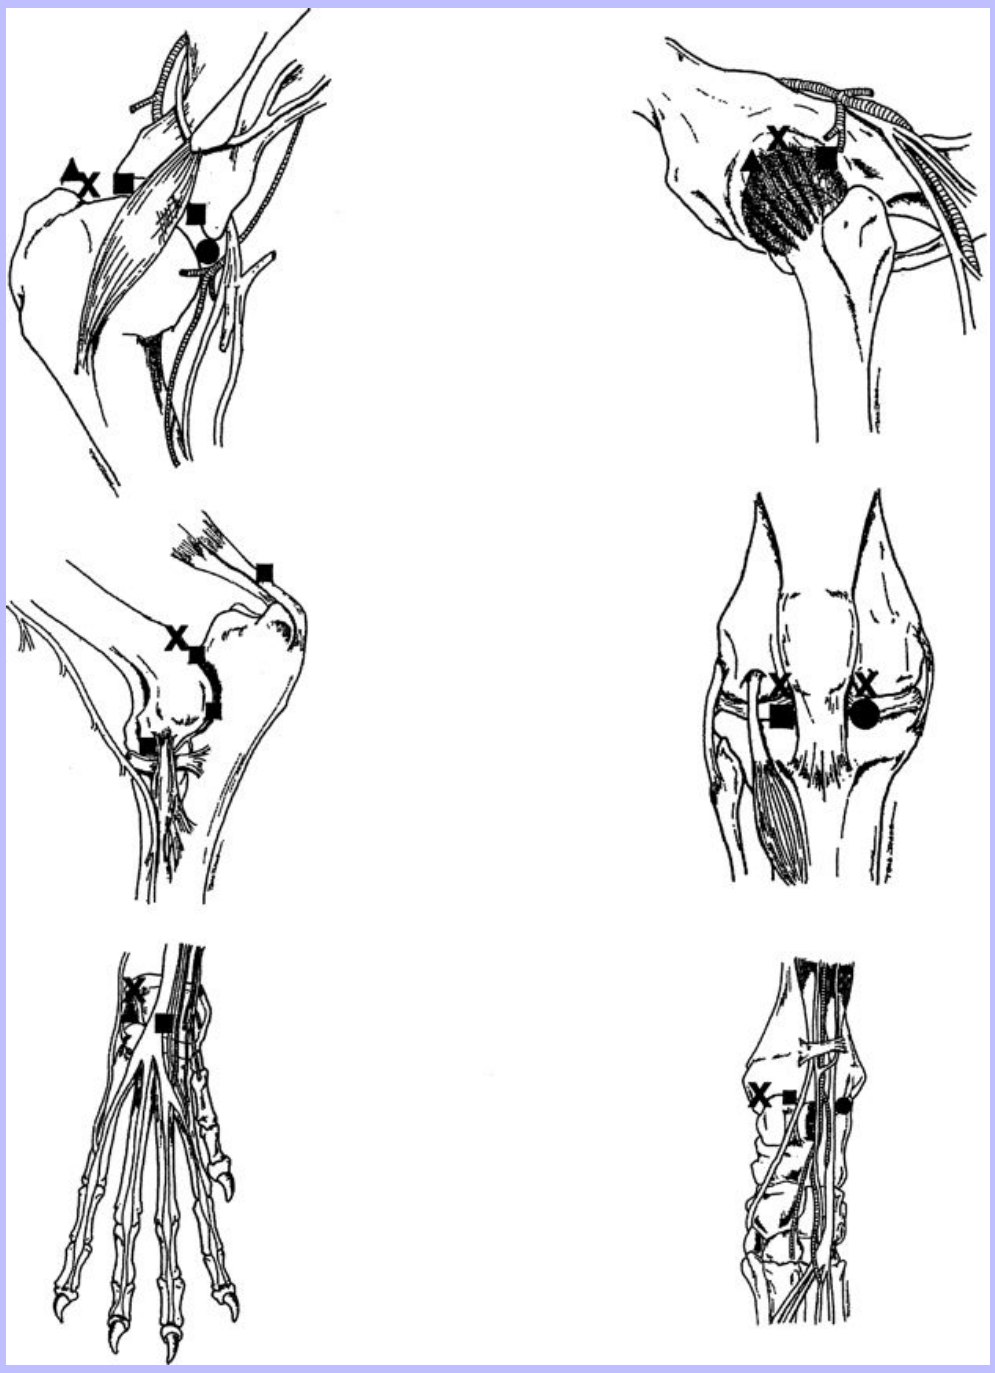
Arthrocentesis may require brief heavy sedation or anesthesia to allow safe aspiration of synovial fluid while minimizing the risk of injury to intra-articular structures or articular cartilage if the animal is fractious, painful, or energetic. Aseptic technique is required. To perform arthrocentesis, the animal is positioned in lateral recumbency with the affected limb uppermost. A 20-to 25-gauge needle attached to a 3-to 5-cc syringe is inserted with the clinician's dominant hand, while the opposite hand stabilizes the limb and joint. Proper orientation of the needle to safely enter the joint is facilitated by palpation of the joint during flexion and extension, reviewing diagrams illustrating proper needle placement (Figure 74-1), or by viewing skeletal specimens. The needle is inserted and gentle vacuum applied with the hand that inserts the needle and syringe. The needle is advanced until synovial fluid enters the syringe. Use of a 3-to 5-cc syringe allows the operator to achieve an adequate degree of suction while using one hand to insert the syringe and needle. The needle should be withdrawn if blood is encountered, and a new needle and syringe should be used for a second aspiration attempt. Hemarthrosis secondary to trauma does occur in small animals but is uncommon. Aspirated blood is usually a contaminant and should clot. Generally as much as 1 to 2 ml of fluid should be aspirated if possible, but the application of excessive negative pressure or aspiration of large volumes of fluid may increase the risk of aspirating blood, thereby ruining the sample. After the fluid is collected, negative pressure is released and the needle withdrawn. If no synovial fluid is obtained, the

needle is redirected after reviewing the angle of placement. If the needle is properly aligned but little or no synovial fluid is obtained, the needle may be plugged with soft tissue or hematomas or there may be insufficient fluid for aspiration as is true with normal joints.

Aspirated fluid should be immediately transferred to an EDTA tube, if a sufficient amount of fluid was aspirated (0.5-cc fluid for a 3-cc EDTA tube). Smears of the synovial fluid should also be made and air-dried prior to submission. If sufficient synovial fluid remains for bacterial culture and susceptibility, it can be inoculated at room temperature for 24 hours in a sterile red tube top with blood culture media at a 9:1 ratio. If only a small amount of fluid (1 drop) remains in the needle hub, 0.5 cc of blood culture media can be aseptically aspirated in a separate syringe, the needle with residual synovial fluid placed on the syringe, and the media flushed through the needle into a sterile red top tube and incubated as previously described.

Prepared slides and the EDTA tube should be submitted to a clinical pathology laboratory for evaluation. Synovial fluid characteristics that should be evaluated include volume, color, turbidity, total protein, total cell count, cell differential, viscosity, mucin clot test, and cytologic exam for cellular characteristics, infectious organisms, neoplastic cells, crystals, and other abnormalities (see Figure 74-2). Synovial fluid characteristics for cats are extrapolated from dogs. If immediate results are needed, some aspects of synovial fluid analysis can be determined in the clinical setting. Some appreciation of color, turbidity, and viscosity can be made when the fluid is expelled onto the glass slide. Cytologic examination of the fluid will provide a rough estimate of the cellularity of the sample, the types of cells present, and specific cellular characteristics such as inclusions or organisms, cytoplasmic granules, nuclear changes, phagocytosed cellular debris, and vacuolation. Other findings such as crystals may be identified. Cytologic examination is the single best test for determining the nature of the arthropathy if the amount of fluid obtained limits the extent of the fluid analysis. Complications are rare and generally limited to articular cartilage injury, hemorrhage, and iatrogenic infection.

Figure 74-1 Sites for arthrocentesis (X), egress portal (▲), arthroscope portal (■), and instrument portal (•) for the large joints of the appendicular skeleton.



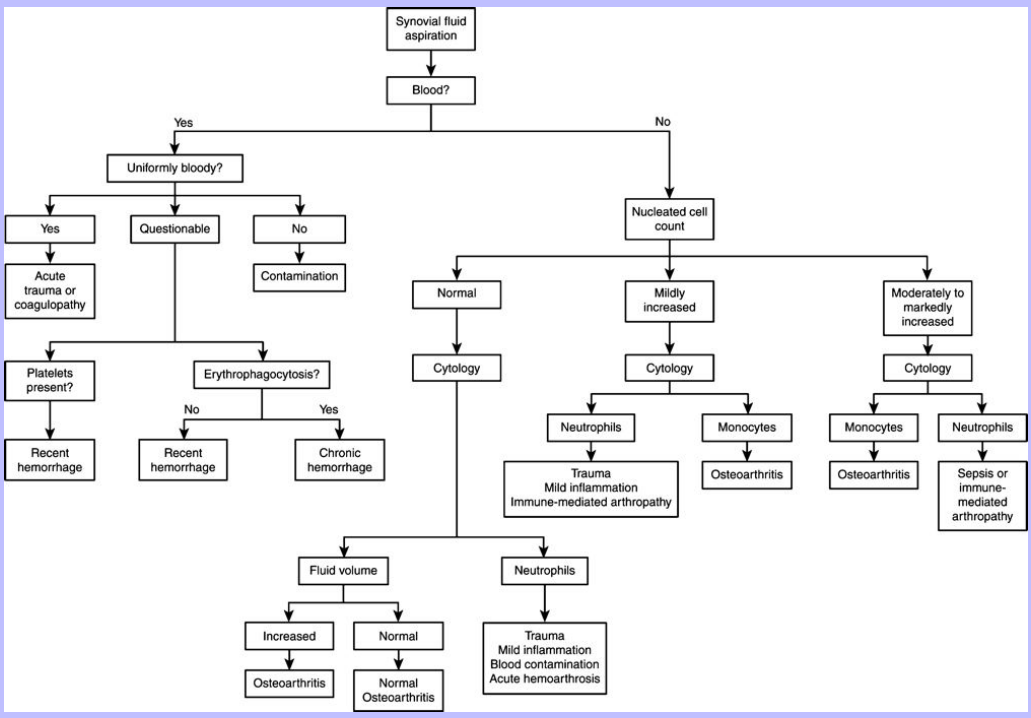
74.2 ARTHROSCOPY

Arthroscopy is the process of examining and treating joint disorders by use of a small fiber-optic telescope. The advantages of arthroscopy are a minimal degree of invasiveness, decreased recovery times from surgery, visualization of a greater percentage of the joint surfaces than what is possible by arthrotomy, and improved visualization of joint pathology. The disadvantages of arthroscopy are the expense of the associated equipment, steep learning curve to master the technique, and limitation of the technique to the shoulder, elbow, carpus, hip, stifle, and hock joints of medium to large breed dogs.

277

278

Figure 74-2 Algorithm for synovial fluid aspiration.



278

279

Arthroscopy is indicated for characterizing ill-defined arthropathies of the previously mentioned joints by synovial biopsy and visualization of the pathology. Arthroscopy is also indicated for treating a limited number of joint diseases including osteochondritis dissecans, bicipital tenosynovitis, fragmented medial coronoid process disease, cranial cruciate ligament disease, and stifle meniscal injury. As the science and instrumentation of arthroscopy improves, other techniques for addressing various arthropathies may also be treated by arthroscopic methods.

The basic principles of surgery are observed whenever arthroscopy is performed. Canine arthroscopy must be performed with the patient under general anesthesia. The patient is clipped and prepared in the same fashion as for an arthrotomy. Strict adherence to principles of aseptic technique should be observed throughout the procedure. Perioperative antibiotics are unnecessary due to the minimally invasive nature of the procedure and the continuous irrigation of the joint surfaces. The instrumentation required for arthroscopic surgery in dogs is not extensive but

somewhat delicate and very expensive. A complete discussion of arthroscopic instrumentation and technique is presented elsewhere.

Complications observed with arthroscopy include failure to properly create an arthroscopic or instrument portal, damage to intra-articular structures, premature dislodgement of the arthroscope, collapse of the joint capsule secondary to excessive fluid extravasation, hemorrhage from inadvertent puncture or injury of periarticular vessels or the stifle intra-articular fat pad, damage to the arthroscope from excessive bending forces applied to the arthroscope, neurologic injury, infection, and inability to adequately explore or treat the joint disease. The incidence of complications is, for the most part, directly related to the experience of the participating arthroscopist.

75 CHAPTER • 75 Artificial Insemination in the Dog

Catharina Linde-Forsberg

Success rates in having dogs conceive after artificial insemination (AI) are dependent on a number of factors. These include the timing of the AI relative to the time of ovulation, how many times during estrus the AI is performed, the quality of the freshly ejaculated semen, how that semen was handled, and the AI technique used. This chapter will only deal with AI techniques.

75.1 AI TECHNIQUES IN THE DOG

Methods for AI in bitches include vaginal deposition of semen and transcervical intrauterine deposition, surgical intrauterine deposition, and intrauterine insemination by laparoscopy. The canine vaginal tract consists of the vulva, the vestibule, the vagina, the narrow paracervical region, the cervix, and the fornix (Figure 75-1).

Significantly higher whelping rates (range, 30% to 50%) are obtained with both fresh, chilled, and frozen-thawed dog semen when inseminated into the uterus, as opposed to when it is deposited in the vaginal tract. For frozen-thawed semen, litter size is also significantly increased by intrauterine AI. It has been estimated that 10 times as many spermatozoa are required to obtain similar results by vaginal AI as by intrauterine AI. For these reasons intrauterine AI should always be attempted in the dog. The problems faced in attempting to catheterize the canine cervix relate to its relative inaccessibility.

75.1.1 Palpation of the Cervix

To obtain good results using AI in the bitch, it is absolutely essential to learn location of the cervix by abdominal palpation so that semen can be deposited correctly and so that the bitch is not injured during the insemination procedure. The bitch should have an empty stomach and bladder to facilitate palpation. While training to palpate the cervix, the rigid single-use plastic canine AI catheter is introduced into the vagina of the patient. The introduction of the catheter is facilitated if the vulva is elevated to just below the anus (such as when the bitch stands for the male dog). By inserting the catheter along the left or right side of the vestibulum, the centrally located urethral opening can be avoided. Because the urethral opening of the bitch is located at the pelvic brim, it is surprisingly easy for the plastic AI catheter, or a thin rigid endoscope, to be unintentionally introduced into the urinary bladder. Apart from the hazards of perforating the bladder with the catheter, it is obvious that no pregnancy would follow AI of the bladder. Thus the correct position of the catheter should always be checked by palpation before depositing a semen dose. If the catheter is in the urinary bladder, the cranial part of the vagina and the cervix can be palpated above the catheter. The walls of the urinary bladder usually are thinner than the walls of the vagina and the tip of the catheter stands out more distinctly, therefore, than if it were in the vagina. When the tip of the catheter is introduced just cranial to the pelvic brim, its position should be checked by palpation. Cranially the vagina in most bitches slopes slightly downward. However, in some breeds, especially the sight hounds that have a very arched loin, the vagina may have a more dorsal direction (see Figure 75-1). The cranial end of the catheter should now be lowered closer to the abdominal wall to make it more accessible to palpation. In large or obese bitches and in bitches with large and pendulous mammary glands, it may be easier to grasp the cervix by palpation via the flank, which is usually thinner than the ventral abdominal wall. The tip of the catheter should then be lowered and also deflected toward the left flank (if the left hand is used for palpation). When the catheter tip can be palpated and its correct position in the vagina thus checked, it is carefully introduced further, under continued palpatory control, until it reaches the paracervical area. This is the narrow, cranial portion of the vagina created by the dorsal, median

postcervical fold that can be palpated as a 1-to 2-cm long, usually somewhat firm structure. It ends at the cervix, which in a bitch in estrus is a 0.5-to 1.5-cm hard, rounded-to-ovoid, freely movable structure (see Figure 75-1). The rigid plastic AI catheter, which has a diameter of 5 mm, may be too wide to be introduced into the paracervical area in some bitches, especially those of the smaller breeds or those that have not given birth to a litter of pups. Consequently, it is usually not possible to pass the outer protecting sheath of the Scandinavian catheter, which has a diameter of 10 mm, into the paracervical area (Figure 75-2). Once the cervix has been identified, the corpus uteri and the uterine horns can be palpated in front of this structure. This can be achieved by lowering the tip of the catheter and closing the tip of the thumb against that of the index finger above the catheter, then lifting the cranial end of the catheter in such a way that the cervix and the uterine horns are pulled upward between the fingers. Their size and consistency then become evident. (This method of palpating the uterus is also useful for early pregnancy detection and to examine bitches with suspected pyometra.)

Figure 75-1 Schematic drawing of the canine caudal reproductive tract. **1,** Plicate area of vagina; **2,** rugose area of vagina; **3,** dorsal median fold of paracervix (number is placed on caudal tubercle of dorsal median fold); **4,** vaginal cervix; **5,** paracervix and paracervical area (*v,* single permanent ventral median fold in vestibule; *c,* cingulum at vaginovestibule junction). (From Lindsay FEF: The normal endoscopic appearance of the caudal reproductive tract of the cyclic and non-cyclic bitch: post-uterine endoscopy, *J Small Anim Pract* 24:1, 1983, with permission.)

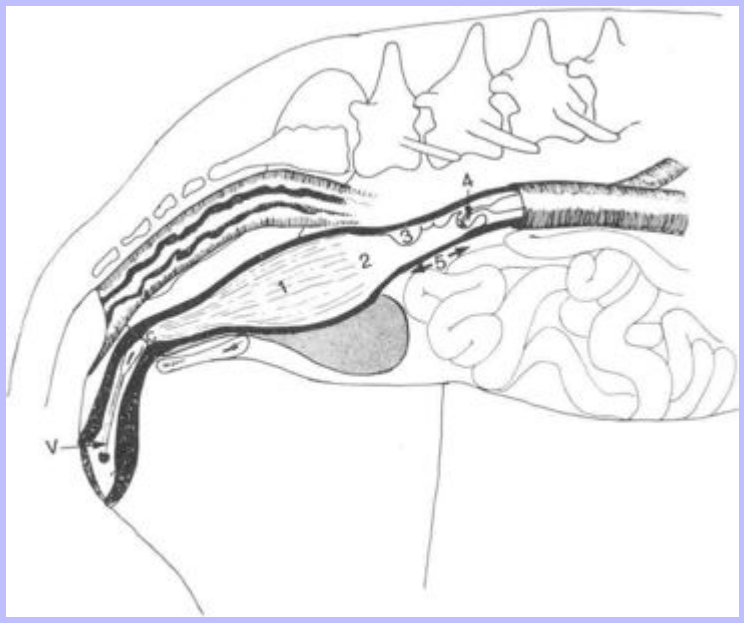


Figure 75-2 The three sizes of the Scandinavian AI catheter for dogs. (The Scandinavian catheters can be obtained from the Norwegian Fur Breeders' Association, PO Box 136, Økern, N-0509 Oslo 5, Norway. Phone: +47-23-25 81 00; Fax: +47-22-64 35 91.)

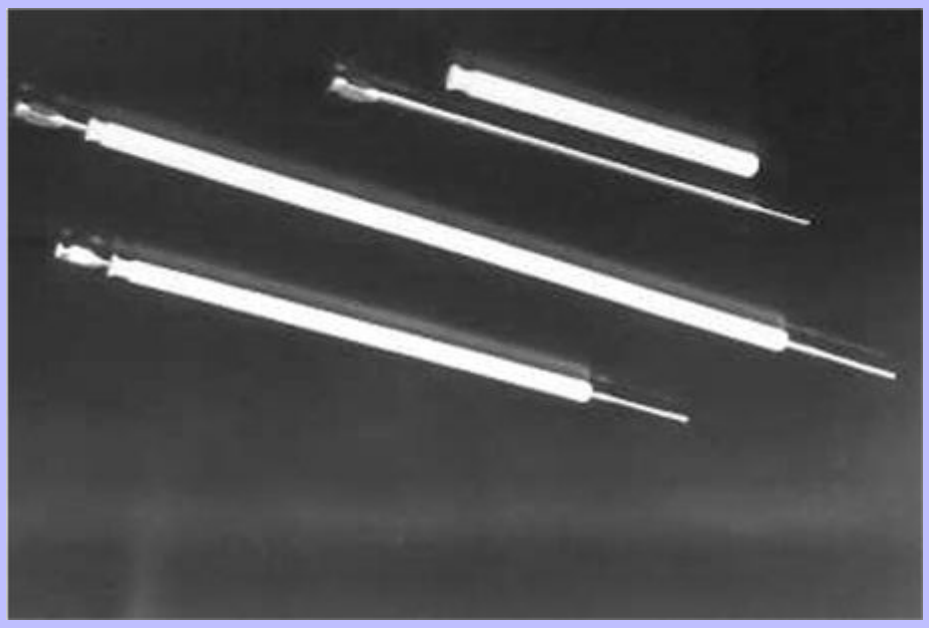


75.2 VAGINAL INSEMINATION

Vaginal AI involves using a rigid plastic single-use catheter (20-to 45-cm long and 5 mm in diameter) that is introduced into the cranial vagina and as close to the cervix as possible. With the catheter in place in the cranial vagina, the syringe containing semen is attached and the hindquarters of the bitch then elevated before infusing the semen. After deposition of the semen dose, the catheter is withdrawn and the bitch is held with elevated hindquarters for 5 to 10 minutes to facilitate the transport of spermatozoa toward the oviducts. The bitch should also be feathered around the vulva and perineal region to stimulate uterine contractions. Spermatozoa may reach the tip of the uterine horn within 30 seconds to 1 minute during a natural mating and within about 30 seconds to 2 minutes after a vaginal AI if the bitch is held with elevated hindquarters. Vaginal AI with the bitch standing horizontally may prevent the transport of spermatozoa into the uterus and oviducts.

280

281

75.3 INTRAUTERINE INSEMINATION USING THE SCANDINAVIAN CATHETER

The Scandinavian catheter consists of a 3-mm wide steel catheter with a 1-to 2-mm diameter tip. It comes in three different lengths (20, 30, and 40 cm) and is used together with an outer protecting nylon sheath that is 10 mm in diameter (see Figure 75-2). The medium sized catheter fits most small-and medium-sized bitches.

Intrauterine AI with the Scandinavian catheter is performed with the bitch standing on the floor or on a table. Sedation is rarely needed. On the contrary, most bitches in estrus freely accept this type of handling. If light

sedation is necessary (in a large, obese, or nervous bitch), 1-to 3-mg/kg xylazine intramuscularly or intravenously can be used. The nylon sheath is first introduced into the vagina as far as possible. If lubrication should prove necessary, a small amount of liquid paraffin or Vaseline, which are not spermicidal, can be used. If the nylon sheath is introduced together with the inner steel catheter, the tip of the steel catheter must be placed so that it is completely protected by the nylon sheath. The cranial end of the nylon sheath is palpated in front of the pelvic brim as previously described. If the tip of the sheath is lowered closer to the abdominal wall, the cervix usually can be palpated a few centimeters in front of and above the catheter. In large or obese bitches it may be easier to palpate and grasp the cervix via the flank. The steel catheter is then introduced through the sheath until its tip reaches the ventral fornix. The cervix is fixed between the thumb and the index finger and, by applying a slightly downward traction at the corpus uteri, it is tilted so that the angle of the cervical canal becomes more horizontal. The tip of the steel catheter is then carefully withdrawn while pushing it repeatedly against the surface of the cervix in search of the opening of the cervical canal. In most cases the sensation when this opening is found can be described as the sensation of touching cartilage (i.e., “crispy”). Once the opening has been found, the catheter should be fixed and the cervix worked against the catheter. The cervical canal is 5-to 10-mm long and not always completely straight (see Figure 75-1). Thus slight pressure may have to be applied, while rotating the catheter to ease it through. In most bitches the tip of the catheter can easily be felt in front of the cervix in the corpus uteri. In some bitches, however, the sensation is not as distinct. In a few bitches the catheter can only be introduced halfway through the cervix, which is usually sufficient. The syringe containing semen is firmly connected to the catheter, and the semen is slowly infused into the uterus while pressure is applied with thumb and index finger around the cervix to prevent backflow. Sometimes a resistance to infusion occurs because the opening of the catheter may be pressed too hard against the endometrial mucosa. Slight downward traction at the corpus uterior of the cervix usually alleviates resistance and allows semen to be infused. (To check that the catheter really is in the uterus, 1 to 2 ml of physiologic saline can be infused. If the catheter is in the right position in the uterine body, the fluid can easily be infused. If, on the other hand, the catheter is in the paracervical region, there will be an almost immediate backflow of saline between the catheter and the nylon sheath). After intrauterine deposition of the semen, the catheter is withdrawn; to minimize backflow of semen and to facilitate uterine transport of spermatozoa toward the oviducts, the bitch should be held with elevated hindquarters for 5 to 10 minutes after the AI while being feathered around the vulva and perineal region to stimulate uterine contractions and sperm transport.

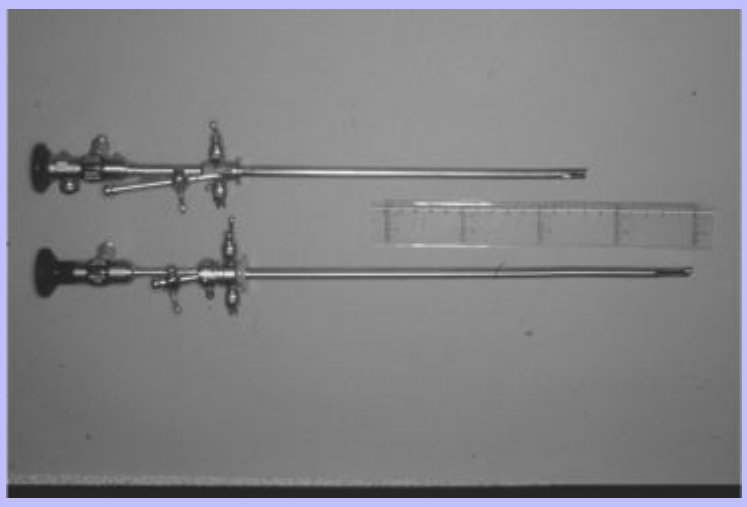
To learn this technique requires some practice, but once learned it is a quick procedure, usually being accomplished within minutes. Once learned, less than 5% of attempts are unsuccessful. It is recommended that, initially, organ specimens be obtained for training purposes and anatomic study. It is also advised that first attempts be made in medium-sized, calm, lean bitches that have given birth to one or more litters. They are usually considerably easier to catheterize. Perforations may occur if the catheter is introduced blindly or with force. Provided that the catheterization is performed under careful palpatory control, however, the technique is completely safe. (This technique can also be used for procedures such as intrauterine infusion of contrast medium for hysterographic examinations of the bitch with suspected pyometra.) Some bitches are more difficult to catheterize, particularly those belonging to some of the giant breeds, as well as obese or nervous animals. Should transcervical catheterization fail and the decision be made to deposit the semen in the vagina, a change should be made to the single-use vaginal catheter to avoid a backflow of semen between the nylon sheath and the steel catheter.

75.4 INTRAUTERINE INSEMINATION USING ENDOSCOPIC VISUALIZATION OF THE CERVIX

Transcervical intrauterine insemination on the standing, nonsedated bitch can also be accomplished with the aid of a rigid fiber-optic endoscope (i.e., a cystourethroscope) that is 23 to 29 cm in length and 4 mm in diameter with an oblique viewing angle of 25 to 30 degrees, together with a stainless steel sheath (23 French gauge) (Figure 75-3).

A dog urinary catheter, 6 to 8 French gauge, is passed through the operating channel of the sheath. The endoscope is introduced into the vagina and advanced past the vaginal folds and into the narrow paracervical area until the external os of the cervical canal can be visualized. To guide the endoscope through the sometimes tortuous vaginal vault, it can be quite helpful to let the urinary catheter lead the way by a few centimeters, thus indicating the right direction. Similar to use of the Scandinavian catheter, it can also be established (by abdominal palpation) whether the tip of the endoscope is correctly positioned in relation to the cervix. If the lumen in the paracervix is very narrow, the catheter may have to be introduced along one side of the dorsal median fold. The urinary catheter is then manipulated into the cervical opening and further into the uterus by a pushing and twisting movement. If the 281
opening of the cervical canal is directed away from the endoscope and thus out of sight, the cervix can be 282
manipulated by pushing it with the tip of the rigid endoscope or with the catheter while moving the instrument from side to side below the cervix. After semen has been deposited into the uterus, the catheter and the endoscope should be removed and the bitch kept with elevated hindquarters for 5 to 10 minutes.

Figure 75-3 Transcervical intrauterine insemination can also be accomplished with the aid of a rigid fiber-optic endoscope connected to a cold light source and a canine urinary catheter (6 to 8 French gauge). The endoscope comes in different lengths.



A significant advantage of this technique is that it allows direct visualization of the cervical opening. However, it involves manipulation of the scope and catheter and requires some practice. Although the equipment is expensive, it should be a good investment for practitioners specializing in canine reproduction and AI to obtain at least one endoscope of medium size, which will fit most breeds. The endoscope is also a great help when training to perform transcervical catheterization with the Scandinavian catheter.

75.5 INTRAUTERINE INSEMINATION USING SURGERY

Surgery to effect intrauterine insemination is still widely used. The bitch should be under general anesthesia and in dorsal recumbency. The ventral abdomen is clipped, and after routine surgical preparation a 4-to 6-cm incision is made midway between the pubis and the umbilicus through the linea alba. The uterus is elevated through the incision, and the needle of the syringe containing the semen is inserted into the lumen of the uterine body at a

45-degree angle with the bevel of the needle up. The semen is slowly injected into the uterus. It should flow easily with obvious distention of the uterine horns. If it does not, the needle should be repositioned. A piece of saline-moistened gauze is held over the injection site after the needle is withdrawn. After 1 minute the gauze is removed, the uterus replaced into the abdomen, and the wound closed using routine methodology. To avoid backflow of semen the bitch should be positioned with its rear elevated as she recovers from anesthesia. Whether it is ethically acceptable to resort to surgery to achieve pregnancies is debatable. The method, although advocated by some, is considered by many to be unethical and unacceptably stressful for the bitch. Two obvious disadvantages are (1) the general risks for infection and other complications associated with surgery and (2) the limited number of surgical AIs that can be performed in a given bitch. The method is also costly and time consuming.

75.6 INTRAUTERINE INSEMINATION USING LAPAROSCOPY

Abdominal laparoscopy should offer a somewhat more acceptable alternative to full surgery for AI in the dog; however, this method has not met with acceptance from practitioners, most likely because they are more used to the surgical technique.

76 CHAPTER • 76 Diagnostic Blood Pressure Measurement

Rebecca L. Stepien

Acute blood pressure (BP) measurement is required to diagnose hypertension or hypotension or to exclude these diagnoses as a cause for clinical signs in a patient. Multiple BP measurement techniques are available; each is associated with advantages and disadvantages.

76.1 PATIENT SELECTION

Blood pressure measurements are assessed as one part of a clinical evaluation that includes the patient history, physical examination findings, results of other diagnostic testing, and evaluation of concomitant medications, including anesthetics and sedatives. Many BP measurement techniques have test characteristics that require low diagnostic cutoff values for maximum sensitivity to hypertension (maximum opportunity to correctly identify an abnormally high value). Unfortunately, low diagnostic cutoff values also are associated with increased numbers of false-positive diagnoses. As a result, many BP measurement techniques are best able to correctly identify truly hypertensive patients as abnormal when the test is applied to patient populations with clinical signs or diseases likely to be associated with systemic hypertension. Routine "screening" BP measurements in clinically normal patients may assist the clinician in establishing a typical baseline BP value for an individual patient, but abnormally high BP values obtained from clinically normal patients must be viewed with caution due to the high incidence of false-positive readings in this patient population.

76.2 INDICATIONS FOR BLOOD PRESSURE ASSESSMENT

Blood pressure assessment is indicated in cats suspected of having or already diagnosed with diseases commonly associated with systemic hypertension (i.e., renal insufficiency or thyrotoxicosis); in cats presenting with clinical signs consistent with systemic hypertension; and in cats that have unexplained left ventricular hypertrophy. The most common reason for clinical presentation of hypertensive cats is ophthalmologic abnormalities. Although other causes of intraocular hemorrhage (e.g., coagulopathy) and retinal detachment (e.g., inflammatory disease) should be ruled out, immediate measurement of systemic BP guides the course of the diagnostic evaluation in these patients. For cats with neurologic signs in addition to ophthalmologic signs, diagnosis of critical levels of hypertension and immediate therapy can lead to rapid improvement in BP and relief of clinical signs.

Systemic BP should be assessed in cats whenever auscultatory cardiac abnormalities (e.g., gallop rhythms, left-sided systolic murmurs) and radiographic, electrocardiographic, or echocardiographic findings are consistent with hypertrophic myocardial disease involving the left side of the heart. Systemic hypertension (and hyperthyroidism in cats over 8 years of age) should be excluded by appropriate testing before a diagnosis of idiopathic hypertrophic cardiomyopathy is made. Early recognition of abnormal BP typically leads to evaluation for other systemic diseases, especially renal insufficiency.

Ophthalmologic abnormalities may also be seen in cases of canine hypertension, but systemic hypertension in dogs is most often diagnosed when BP is evaluated as part of the clinical workup of dogs with systemic diseases known to be associated with hypertension. In dogs, the diseases most frequently associated with elevations in BP are protein-losing renal diseases or chronic renal failure of any etiology, hyperadrenocorticism, diabetes mellitus, and pheochromocytoma. As with cats, systemic hypertension should be ruled out as a cause of left ventricular thickening of unknown etiology. Lastly, BP should be evaluated in cats or dogs with intracranial neurologic signs.

Dogs and cats that present with clinical signs of low cardiac output (e.g., weak peripheral pulses, cold extremities), shock, blood loss, or obtundation should be evaluated for hypotension. In some cases, hypotension is diagnosed clinically based on the constellation of history, presenting signs, and suspected clinical diagnosis (see Shock, Chapter 124). Accurate measurement of BP is important in any hypotensive patient to confirm the diagnosis and to provide baseline data for monitoring the response to therapy. BP evaluation methods differ in their sensitivity to low BP. Automated noninvasive techniques (i.e., oscillometric techniques) may fail to detect a pulse when hypotension is present, and operator-reliant techniques for pulse detection (e.g., Doppler sphygmomanometry) can be unreliable if the pulse signal is difficult to discern. Of the methods typically used in acute BP measurement, arterial cannulation is the most accurate method of documenting hypotension.

76.3 CHOOSING A BLOOD PRESSURE MEASUREMENT TECHNIQUE

76.3.1 Acute Diagnostic Blood Pressure Measurement

Detection of systemic hypertension may lead to additional testing for an underlying disease condition. In such cases, it is advantageous to perform BP measurement acutely (i.e., during a clinical examination or diagnostic evaluation), rather than hospitalizing patients and placing indwelling arterial catheters. When a technique to measure BP in a particular animal is chosen, specific issues to be considered include the availability of equipment, the availability of "normal" values to use for comparison, the skill and experience of the person making the measurement, and specific issues related to the animal (e.g., size, obesity, temperament).

The accuracy and usefulness of the measurement technique chosen ultimately depends more on attention to detail and use of applicable normal values (i.e., generated with the same technique as the one in use) than on which technique is used. Although multiple studies have addressed correlation or lack of correlation between invasive and noninvasive techniques in both dogs and cats, few studies are available that address the ability of these techniques to discern "normal" from "abnormal" in a conscious clinical population. Therefore assessment of BP values obtained may involve comparisons with normal values or comparison with values known to be associated with clinical signs.

76.3.2 Continuous Blood Pressure Monitoring: Conscious Patients

The monitoring of BP over time requires either continuous measurement (arterial catheterization) or repeated measurements, recorded automatically (oscillometric or photoplethysmographic techniques) or manually (Doppler sphygmomanometric methods). Arterial catheterization has the greatest number of advantages in conscious patients. Blood pressure obtained via arterial cannulation is accurate when the technique is used correctly and the values obtained are objective and repeatable (no manual pulse detection is required). A particularly important advantage is that the system can be secured to continue BP measurement when the animal moves. The major disadvantages are the technical skills and equipment required to maintain an arterial catheter and transducer system. Noninvasive methods are commonly used to take serial BP measurements in conscious animals. Although noninvasive BP measurements appear to be technically simple to obtain, they are subject to marked inaccuracy with animal movement, poor pulse pressure, arrhythmia, or inconsistent technique. When repeated BP measurements are obtained using these methods, cuff size and positioning, as well as limb position, should be identical for the repeated recordings.

76.3.3 Continuous Blood Pressure Monitoring: Anesthetized Patients

Blood pressure monitoring by most clinical methods is accurate and repeatable in anesthetized animals. The primary confounding problem of patient movement is absent in these patients, which renders them ideal subjects for BP measurement. Nonetheless, differences between values obtained by invasive methods (arterial catheterization) and noninvasive methods have been documented in numerous studies of dogs and cats. These studies indicate that numeric values obtained by means of noninvasive methods often underestimate true BP. In the case of anesthetized animals, this may result in an erroneous diagnosis of hypotension, but it seldom leads to the more dangerous error of overestimating BP in these patients.

76.4 BLOOD PRESSURE MEASUREMENT TECHNIQUES

76.4.1 Arterial Puncture or Arterial Cannulation ("Invasive" or "Direct" Technique)

Direct BP measurement involves advancing a needle attached to a pressure transducer directly into an artery to measure BP. This procedure may be performed acutely to obtain instantaneous BP readings, or BP can be measured over time through the use of an indwelling arterial catheter instead of a needle. Invasive BP measurements are typically used during anesthetic procedures, in critical care patients when ongoing BP information is desired, or to document or exclude hypertension acutely as a clinical diagnosis in dogs. Acute arterial puncture is seldom used for clinical diagnosis of hypertension in cats.

Direct BP measurement is usually performed by means of puncture of the femoral artery in dogs. Use of local anesthesia is strongly recommended for this procedure and is well tolerated by most dogs. The patient is gently restrained in lateral recumbency. Approximately 5 minutes prior to arterial puncture, 1 to 2 mL of 2% lidocaine hydrochloride is injected subcutaneously over the area in which the femoral pulse is palpated. A 22-gauge, 1-inch needle is attached to a transducer and flushed with heparinized saline, ensuring that no bubbles remain in the transducer. The transducer is zeroed at the level of the sternum in the laterally recumbent dog. The femoral 283
pulse is palpated in the femoral triangle, and the needle is carefully advanced into the femoral artery (Figure 284
76-1) until a satisfactory pressure waveform is recorded on the monitor screen. A sample of the tracing is recorded, and the needle is withdrawn. Firm pressure is applied to the area of arterial puncture for a minimum of 5 minutes after measurement. The patient should be monitored for at least 1 hour after the procedure for any complications related to hematoma formation. Systolic, diastolic, and mean BP values from five consecutive cardiac cycles during normal sinus rhythm are averaged to obtain a representative value for the patient. When use of an arterial catheter is preferred, the catheter is usually inserted into the dorsal pedal artery. A local anesthetic may be used as described previously.

76.4.2 Oscillometric Technique

Oscillometric BP measurement involves the use of an automated detection system and a cuff that is wrapped around a limb or tail over an artery. The cuff is inflated automatically to a pressure that causes occlusion of the artery and then slowly deflated. The machine detects oscillations in the vessel wall as the occlusion is eased, and the pressure at which oscillations are maximal is recorded as the mean arterial pressure. Systolic and diastolic pressures are then calculated by the monitor using algorithms specific to the technique. This technique uses data from many cardiac cycles to render a single reading and is therefore unsuitable for use in animals with rapidly changing BP.

Oscillometric BP measurement methods are more accurate in dogs than in cats. This measurement method may return inaccurate results if the patient is not motionless (e.g., trembling), has a weak or irregular pulse, or has a small artery (i.e., most cats). Use of a cuff of appropriate size is extremely important to ensure accurate measurements. Cuff width should be approximately 40% of the circumference of the limb or tail in dogs and approximately 30% of the appendage circumference in cats. When used on the tail, the cuff is wrapped snugly high on the tail head with the dog in sternal or lateral recumbency. Although tail cuffs can be used in standing animals, animal movement often interferes with accurate measurement. Limb cuffs are wrapped around the forelimb distal to the elbow or around the mid-metatarsus at the level of the superficial plantar arterial arch (Figure 76-2).

Figure 76-1 Invasive BP measurement via direct arterial puncture in a dog. A 22-gauge needle (with an attached pressure transducer, previously flushed with heparinized saline and zeroed) is advanced into the femoral artery at the level of the palpable pulse in the femoral triangle.

To maximize accuracy, the cuff should be at the level of the heart during readings; therefore lateral or sternal recumbency is preferred, and use in standing patients is not recommended. In cats, tail cuffs return more repeatable measurements than limb cuffs, but the accuracy of oscillometric BP measurements obtained by this method is questionable. Typically, the cat rests in sternal recumbency during readings (Figure 76-3).

In all cases, best results are obtained when the patient is minimally restrained and soothed during the procedure. A short acclimation period prior to measurement is recommended. A series of at least five readings are obtained at approximately 1-minute intervals. Any readings that are clearly erroneous are discarded. The multiple readings are then averaged to obtain a representative result.

Oscillometric techniques are valuable in anesthetized dogs and cats to monitor trends in BP. Because the animal is immobilized and BP shows less variability over time, repeatable and accurate readings can be obtained over time in both dogs and cats.

76.4.3 Doppler-Ultrasonic Technique (Doppler Sphygmomanometry)

Doppler ultrasonic flow detection through the use of a piezoelectric crystal allows detection of flow in a peripheral artery. Hair is clipped just proximal to the palmar metacarpal pad at the level of the superficial palmar arterial arch for forelimb measurement; over the dorsal pedal artery for hindlimb measurement; or on the ventral aspect of the tail for tail measurement. An occluding cuff (sized as outlined for oscillometric techniques) is placed proximal to the point of flow detection (mid-radius in the forelimb, proximal to the hock in the hindlimb, or proximal to transducer placement on the tail), and measurements are obtained with the cuff at the level of the heart. Ultrasonic coupling gel is placed on the concave surface of the Doppler transducer, and the transducer is held in position during measurements (Figure 76-4) or fixed in position using adhesive tape. An audible pulse signal is obtained, and the cuff is inflated with a bulb attached to a pressure gauge. The cuff is inflated to a pressure no less than 40 mm Hg above the audible cutoff point of the signal. The cuff is then slowly deflated, and the pressure at which the Doppler signal is again audible is recorded as the systolic pressure. The cuff is deflated further, and the pressure at which the audible signal abruptly changes in pitch or becomes muffled is recorded as the diastolic pressure.

284

285

Figure 76-2 Correct cuff placement for oscillometric measurement of BP via the dorsal pedal artery in a dog. The cuff tubing is attached to the oscillometric BP monitor for readings.

Figure 76-3 Correct placement of a tail cuff for oscillometric readings in a cat. The cat is relaxed and minimally restrained in sternal recumbency.

The Doppler flow detection system of BP measurement is considered the most accurate and repeatable of studied noninvasive BP measurement techniques in conscious cats. It is frequently used in dogs but may provide spurious high readings in some individuals. When abnormal readings are obtained by this method from dogs, care should be taken to make sure the abnormal readings are repeatable over multiple measurement periods. The advantages of this technique include flexibility with regard to motion, low pressure, small vessels, or the presence of arrhythmias, as well as speed of measurement. The rapidity of the measurement techniques allows for prompt assessment of changing BP, but meticulous attention must be paid to obtaining strong, audible signals in order to obtain the most accurate BP readings. This technique is also the most operator dependent of the techniques discussed. Accurate identification of diastolic pressures improves with operator practice, and BP measurement using Doppler ultrasonic flow detection techniques is most accurate if a few well-trained individuals in a practice are responsible for this diagnostic test and perform the test frequently.

Figure 76-4 Measurement of BP via Doppler sphygmomanometry from the forelimb of a cat. Note that the inflatable cuff is at the same level as the heart in the sternally recumbent animal.

76.4.4 Photoplethysmography

Photoplethysmographic techniques measure blood volume by attenuation of infrared radiation. The blood volume is held constant by a microcomputer-based servosystem so that cuff pressure equals intra-arterial pressure. The cuff is positioned distal to the hock or at the tail head, and a visible waveform is used to assess the strength of the signal. Because the equipment is designed for use on the human finger, it is most suitable for cats or small dogs. Skin pigment may interfere with readings. This technique has not been studied extensively in conscious dogs and cats but appears to be as accurate as other noninvasive techniques in anesthetized animals.

77 CHAPTER • 77 Techniques for Bone Marrow Aspiration and Biopsy

Leo J. “Ty” McSherry

Peripheral blood abnormalities are the most common indications for the evaluation of bone marrow. These include poorly or nonregenerative anemia, persistent or unexplained neutropenia, unexplained thrombocytopenia, or any combination of peripheral cytopenias. A persistent leukocytosis or thrombocytosis, dysplastic changes, or the inappropriate presence of immature hematopoietic cells in the peripheral circulation are additional indications for bone marrow evaluation. Bone marrow can be used to stage neoplasia, evaluate lytic bone lesions, or determine the cause of unexplained hypercalcemia or hyperproteinemia, especially hyperglobulinemia, as may relate to lymphoma, multiple myeloma, or some systemic infections. Less commonly, bone marrow can be evaluated to help determine the cause of fever of unknown origin or evaluate total body iron stores.

Contraindications to bone marrow aspiration or biopsy are few and are generally related to the use of sedation or restraint. Hemorrhage is an uncommon complication, even in severely thrombocytopenic animals, and severe or unexplained thrombocytopenia is a common indication for marrow evaluation. Peripheral neutropenia is also a common indication for marrow evaluation; however, infection is unlikely because the aspirate, biopsy, or both is performed as a sterile procedure. The potential complications associated with hemorrhage or infection are minimal and should not dissuade the clinician from evaluating the marrow if indications to do so are present.

With the possible exception of a Petri dish or watch glass, most hospitals will have the necessary materials for bone marrow aspiration and biopsy. These include aspiration or biopsy needle, sedation or anesthesia, microscope slides, anticoagulant, scalpel blade (no. 11, no. 13), Petri dish or watch glass, 12-cc syringe, hematocrit capillary tubes, 2% lidocaine, and surgical scrub.

77.1 BONE MARROW ASPIRATION

Three types of aspiration needles are available: (1) the Illinois sternal, (2) the Jamshidi, and (3) the Rosenthal. These are available in 15-and 18-gauge sizes, 1 to 1½ inches in length. The 18-gauge needles are typically used in cats and small dogs, whereas the 15-gauge needles are reserved for dogs greater than 20 pounds. The Illinois sternal needles have a removable plastic cap (designed to hold the stylet in place during placement of the needle) and a removable needle guard. However, the plastic cap and needle guard necessitate the use of gas sterilization. The Jamshidi needles are stainless steel, durable, and may be heat sterilized; however, they lack a removable cover or needle guard.

The use of adequate sedation or general anesthesia will greatly facilitate the collection of bone marrow. Many authors describe collection with nothing more than a local anesthetic, and this may be all that is necessary or permissible in stoic animals or those at a high risk of anesthetic complications. Aspiration is a painful procedure, however, and a struggling or anxious animal will likely interfere with collection of an adequate sample. Sedation or anesthesia is suggested.

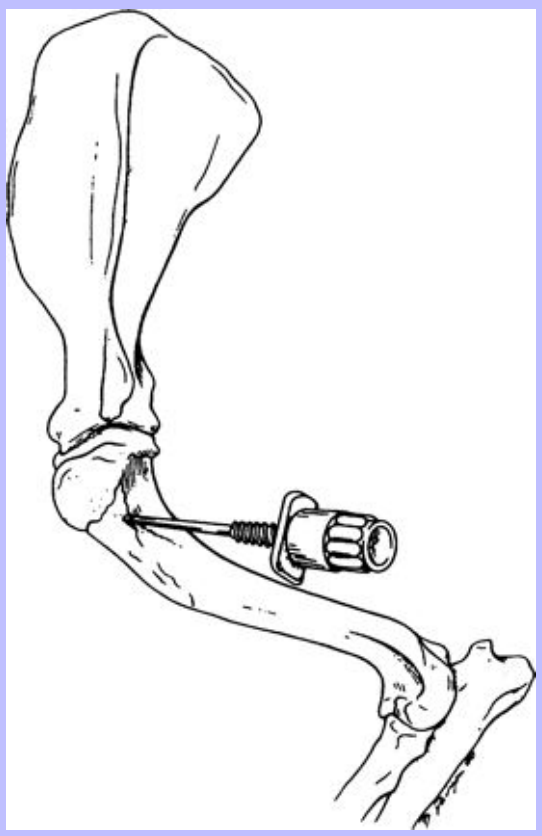
The use of an anticoagulant, although not necessary, is recommended and allows for the preparation of high-quality slides. It also allows time to complete the procedure before slides need to be prepared. Anticoagulant can be prepared by injecting 0.35 cc of sterile saline into a 3-ml lavender top tube containing EDTA, withdrawing the solution, and then reinjecting it into a second EDTA tube. This should yield approximately 0.5 cc of a 2.5% EDTA solution. Alternatively, a 5% solution of EDTA may be prepared using the dry reagent by a local or compounding pharmacy. The dry reagent is inexpensive and available through many pharmaceutic companies.

This is a practical and recommended alternative for hospitals that regularly perform bone marrow aspiration. A volume of 0.5 to 1.0 ml is recommended per collection.

Three sites are commonly used for the collection of bone marrow: (1) the proximal humerus, (2) the iliac crest, and (3) the trochanteric fossa. The proximal humerus is an easily accessible site in dogs and cats of all sizes. It has little overlying tissue and provides a fairly large area for placement of the needle. Its disadvantages include its proximity to the head and the thick, rounded cortex. The greater tubercle is easily palpated, and the needle is inserted into the flat area of the craniolateral aspect of the humerus distal to the greater tubercle. The needle is inserted perpendicular to the long axis of the humerus (Figure 77-1).

The iliac crest is easily accessible in thin dogs or those in good body condition, as well as in large cats. It should be avoided in large or obese animals because it may be difficult to palpate or to seat the needle due to a large amount of overlying tissue. The iliac crest is the widest and most dorsal aspect of the wing of the ilium (Figure 77-2). The trochanteric fossa may be used in cats or small dogs. The trochanteric fossa is medial to the greater trochanter. The greater trochanter is palpated, and the needle inserted medial to it (into the trochanteric fossa). The needle is inserted parallel to the long axis of the femur (see Figure 77-2). The trochanteric fossa is generally avoided in well-muscled or obese animals due to a significant amount of overlying tissue.

Figure 77-1 The needle is inserted perpendicular to the long axis of the humerus. (From Grindem CB: Bone marrow biopsy and evaluation, *Vet Clin North Am Small Anim Pract* 19:669, 1989.)



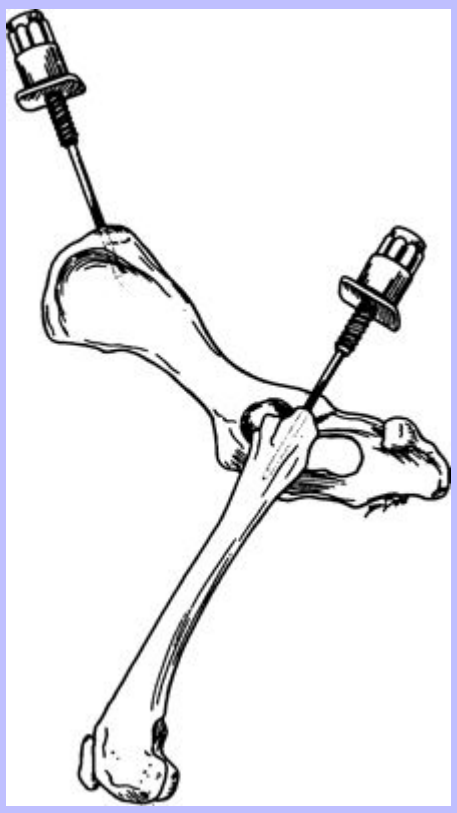
After sedation the animal is placed in lateral recumbency for collection from the proximal humerus, or it can be placed in either lateral or sternal recumbency for collection from the iliac crest. In nonsedated animals, lidocaine is used to block the surgically prepared site, beginning with the periosteum. The needle is then slowly withdrawn while blocking the overlying tissues and finally the skin. The sterile aspiration needle, scalpel blade, and 12-cc syringe are placed on the sterile glove field. Sterile gloves are worn, and 0.3-to 0.5-cc of anticoagulant is drawn into the 12-cc syringe that is then placed again on the sterile field. A small stab incision is made in the skin. The incision only need be wide enough for the aspiration needle.

The site of collection can be localized using one hand. The aspiration needle should be firmly seated in the palm of the hand and the needle held securely between the thumb and index finger. The plastic needle guard on the Illinois sternal needle has a small lip on which the thumb and index finger can be placed to grip the needle securely and to apply firm pressure. A tendency exists to hold the needle as if it were a pen. This should be avoided because it does not allow sufficient pressure to be applied to advance the needle through the cortex. In addition, if using the Jamshidi aspiration needle, pressure should be applied to the top of the stylet to prevent it from being dislodged while placing the needle. This is accomplished by holding it firmly in the palm of the hand.

286

287

Figure 77-2 The needles are inserted medial to the greater trochanter and parallel to the long axis of the femur. (From Grindem CB: Bone marrow biopsy and evaluation, *Vet Clin North Am Small Anim Pract* 19:669, 1989.)



The aspiration needle is placed through the stab incision down to the periosteum. With the needle seated on the bone, firm clockwise-counterclockwise rotational pressure is applied to advance the needle. Frequently a slight decrease in resistance occurs when the needle enters the marrow cavity. When approaching the proximal humerus in cats, the needle may suddenly "pop" into the marrow cavity. When the needle has been properly positioned, it should feel very firmly seated, as might a nail in a block of wood. During advancement, the needle may occasionally and suddenly slide off the cortex into the surrounding soft tissue. This is especially common when approaching the proximal humerus and to a lesser degree the iliac crest. The needle will be freely movable in the subcutaneous tissues and not be firmly seated. Should this occur, the clinician should simply withdraw the needle to the level of the cortex, again seat the needle, and begin rotational pressure. When approaching the iliac crest, it is useful to have an assistant place counterpressure against the distal femur at the level of the stifle.

Once the needle is seated, the clinician should remove the top (if using an Illinois sternal needle) and stylet and place them on the sterile field. Next, a 12-cc syringe should be attached. While holding both the aspiration needle and syringe with one hand, the clinician should make several firm aspirations by rapidly pulling the plunger back. Marrow can appear after the first attempt at aspiration; however, several attempts could be necessary before marrow appears in the syringe. A total volume of 1 or 2 cc is collected if possible. If anticoagulant has been used, the syringe is removed from the needle and gently rocked to mix the marrow and anticoagulant. The sample may then be set down and the needle removed before preparing slides. Should no marrow appear in the syringe after vigorous aspiration, the syringe is removed from the needle and the stylet replaced. The needle is then advanced slightly using the same pressure with which it was placed, and aspiration is reattempted. Occasionally while approaching the iliac crest, the needle may be advanced too far into the opposite cortex. Unsuccessful attempts at aspiration will result. The needle should then be slightly withdrawn before again attempting aspiration.

After mixing the marrow and anticoagulant, the sample is expelled into a Petri dish or watch glass. The Petri dish or watch glass may be gently shaken or tilted to allow visualization of the marrow spicules. Marrow spicules appear as small, irregular white or gray particles that may adhere slightly to the dish or glass. These are collected using a hematocrit capillary tube or pipette. Only a small amount of sample needs to be collected in the capillary tube to prepare an adequate slide. The sample is placed on one end of a glass slide. A second slide is overlain on the bottom slide and the sample permitted to spread briefly between the slides. Digital pressure on the top slide is typically not necessary and is discouraged because cell lysis can result. The top slide is then smoothly but rapidly pulled down the length of the bottom slide and the sample air-dried.

If anticoagulant is not used, the slide must be prepared immediately after successful aspiration. Bone marrow clots very rapidly, and a clotted sample will not allow adequate slides to be prepared. As soon as marrow appears in the syringe, negative pressure is released and both the aspiration needle and syringe are removed. It is important to have several clean glass slides laid out prior to collection. The clinician should rapidly place a few drops of sample near the top of each of the slides. An assistant should then follow closely, preparing slides as the clinician goes down the row. It is difficult to prepare several slides by oneself because the marrow is likely to clot before the smears can be prepared. Several slides should be prepared and submitted. The preparation of 12 to 15 slides should result in several diagnostic slides and would permit additional testing or special staining should this be necessary to identify a poorly differentiated leukemia. In addition, accurate interpretation of the marrow is dependent upon the findings of a concurrent complete blood count (CBC), and a CBC (or current CBC results) should always be submitted with the aspirates.

77.2 BONE MARROW BIOPSY

Bone marrow biopsy is indicated if repeated attempts at aspiration are unsuccessful, if evaluating for metastatic neoplasia, or if evaluating lytic bone lesions resulting from neoplasia, inflammation, or infection. Unsuccessful

aspiration resulting in a dry tap may result from myelofibrosis, myelophthisis, hypoplasia or aplasia, or technical error. Bone marrow may be collected immediately after aspiration and may be collected from the same site or a distant site. Collection from separate sites may increase the likelihood of identifying metastatic neoplasia. Concurrent aspiration and biopsy is beneficial in that aspirated samples may occasionally be insufficient, necessitating histologic evaluation. Additionally, marrow biopsy immediately after aspiration may prevent the need for an additional anesthetic procedure should the aspirates be insufficient for a diagnosis.

Patient preparation, sites of collection, and approach are similar to those described for aspiration. Biopsy is considerably more painful, and good sedation or (preferably) anesthesia should be used. Jamshidi bone marrow biopsy needles are 11 to 13 gauge and 3 to 4 inches long. The 13-gauge needles are typically used in cats and dogs less than 20 lb. Due to the larger size of these needles, the wing of the ilium may be too thin to be used in cats or very small dogs.

The biopsy needle is seated on the cortex and advanced using the same clockwise-counterclockwise rotational pressure that is used to place the aspiration needle. It is beneficial to lay the index finger along the shaft of the needle while advancing the needle to stabilize it while it is rotated. With the needle firmly imbedded, the stylet is removed and the needle is advanced an additional inch or more using the same rotational pressure to collect an adequate sample. The biopsy fragment must be broken loose using several 360-degree twists in both directions, and the needle is withdrawn. The biopsy fragment is pushed out the top of the needle in a retrograde fashion using the wire that accompanies the needle. The biopsy needle is tapered, and attempting to push the sample out the tip will crush it and damage the sample. The collection of a sufficient sample will allow the core to be sectioned and part submitted for culture if an infectious process is suspected. The biopsy fragment is typically submitted in formalin; however, consulting the surgical pathology service may be beneficial because other fixatives are occasionally preferred. Biopsy samples should not be submitted in the same packaging as cytology preparations because the formalin vapors can interfere with the staining quality of cytologic preparations.

78 CHAPTER • 78 Brain Biopsy

Peter J. Dickinson

Richard A. LeCouteur

Neoplastic, vascular, infectious, or inflammatory diseases of dogs and cats frequently result in focal brain involvement. In affected animals, results of ancillary diagnostic investigations, such as cerebrospinal fluid (CSF) analysis and electroencephalography, may be within normal limits or may provide only "indirect" evidence of the presence of a brain lesion. The use of computed tomography (CT) and magnetic resonance imaging (MRI) has enabled accurate detection of many focal brain lesions. Although CT and MRI are sensitive in determining location, extent, and relationships to adjacent structures of brain lesions, both have limited specificity. Non-neoplastic lesions (such as those seen in association with infectious, inflammatory, or vascular diseases) may mimic the CT or MRI appearance of a neoplasm. In most instances, results of CT or MRI provide only a broad list of differential diagnoses for a focal brain lesion. An accurate histologic diagnosis of an intracranial lesion is critical before recommending a specific management or treatment strategy, and the need remains to obtain an intraoperative neuropathologic diagnosis from tissue samples obtained from the lesion.

78.1 OPEN BRAIN BIOPSY

Open brain biopsy may be appropriate in certain clinical situations in which cortical architecture needs to be preserved, for leptomeningeal sampling, for superficially located lesions, and when a decompressive craniectomy with good cortical visualization may be helpful in addition to obtaining a biopsy sample.

For superficial brain lesions, a craniectomy is performed, the dura is opened, the lesion is located, and a specimen of affected brain is excised using a no. 11 scalpel blade. For more deep-seated brain lesions, freehand fine needle (22 gauge) aspiration, or Tru-Cut® biopsy (using a 14-gauge Tru-cut biopsy needle, Travenol Laboratories Inc., Deerfield, IL), CT-guided freehand Field-Lee needle biopsy (using a 13-gauge Field-Lee brain biopsy needle, V. Mueller, Chicago, IL), or ultrasound-guided Menghini needle brain biopsy techniques (using a 16-gauge Menghini biopsy needle, Miltex Corp., Lake Success, NY) have been reported for use in dogs after a limited craniectomy.

Although open brain biopsy techniques usually are accompanied by low morbidity and mortality, these techniques are no longer recommended for deep-seated brain lesions. Stereotactic brain biopsy procedures are preferred, as they have been shown to work safely and effectively in a consistent manner in a large number of cats and dogs.

78.2 STEREOTACTIC BRAIN BIOPSY

With the advent of CT and MRI, and the development of CT-guided stereotactic frames, closed stereotactic brain biopsy has become the standard of care in people. Essentially all closed methods rely on the three-dimensional CT-generated coordinates identifying the lesion location. These coordinates are used to plot the optimal trajectory and depth needed for a biopsy needle to reach a target and obtain a diagnostic tissue sample.

Technical impediments exist to the direct application of most human stereotactic systems to dogs and cats. Most commercially available systems use a cumbersome head-frame, designed specifically for the human skull, and require dedicated, expensive computer software for the planning phase. Several different systems for image-guided stereotactic brain biopsy have been reported for use in dogs and cats.

Stereotactic biopsy begins with proper patient selection. The possibility of non-neoplastic disorders such as infection, cerebral infarction, or vasculitis, must be considered and investigated with other tests in appropriate patients prior to biopsy. When the differential diagnosis list is long and may include neoplasms and inflammatory lesions, the appropriate handling of tissue samples should be discussed with a neuropathologist in advance of the procedure. All patients should be tested for coagulation parameters (prothrombin time [PT], partial thromboplastin time [PTT]) prior to the procedure and should have a platelet count greater than 100,000. Patients should not receive aspirin products for 1 week before surgery.

General anesthesia is required for stereotactic brain biopsy. Biopsy generally is done on the CT-scanner table. For those lesions not well identified on CT images, MRIs that demonstrate a lesion may be used for comparison to localize the lesion on CT images, using well-defined anatomic landmarks (e.g., lateral ventricles). Axial CT images are used to define the CT coordinates of reference markers and the biopsy target. Dorsal or sagittal images may be used for trajectory planning. An entry point should be selected that is associated with a low risk for neurologic deficit or hemorrhage (e.g., avoidance of dorsal sagittal sinus). Ependymal puncture should be avoided where possible. A small craniotomy (2-to 4-mm diameter) is made by means of a twist drill, the dura mater is punctured with an 18-gauge needle, and biopsies may be done with a side-cutting aspirator biopsy needle (using a T 19. S biopsy needle, Ohio Medical Instruments, Cincinnati, OH) with a 10-mm side opening. On average, two or three specimens are removed. It is important to biopsy several regions of the intracranial lesion using a single trajectory.

The intraoperative goal should be to confirm by means of smear or touch preparations whether tissue satisfactory for an eventual diagnosis has been obtained. A specific histologic diagnosis may require routine formalin fixation and paraffin embedding of the biopsy tissue. At the conclusion of the biopsy procedure, the needle is withdrawn in increments to assess any possibility of hemorrhage. In the case of hemorrhage, blood should be permitted to egress from the needle spontaneously until the bleeding stops. An immediate postoperative CT scan should be obtained.

Although stereotactic brain biopsy is minimally invasive (compared with open biopsy techniques) and designed for low risk, complications may rarely occur. Morbidity may include seizures, hemorrhage, new neurologic deficits, brain infection, tumor seeding, and lack of a definitive diagnosis.

78.2.1 Handling the Intraoperative Specimen

The intraoperative specimen must be processed rapidly and carefully to provide timely and accurate diagnostic information. For large specimens, cytologic analyses (touch imprints, smears) may be done in conjunction with frozen sections. Cytologic analyses alone may be done in situations where access to frozen sections is difficult or when the biopsy specimen is small.

The clinician can make a smear (or “squash”) preparation by placing a small fragment of tissue at one end of a standard glass microscope slide. The end of another glass slide is placed over the tissue, mild pressure is applied to the slides, and the slides are gently and rapidly pulled apart to produce a smear. The slides are fixed immediately in 95% alcohol and stained with a rapid hematoxylin and eosin stain. Other techniques include fixation of the specimen in alcohol followed by toluidine blue, Giemsa, or Papanicolaou staining, or air-drying the specimen prior to Romanovsky or Wright's staining.

The clinician may take touch imprints by pressing a glass slide briefly to the surface of the fresh (unfixed) biopsy specimen. Small fragments first may be blotted to remove excess blood or fluid. The slides are fixed and stained in a similar manner to the smear preparations.

Frozen sections provide superior architectural detail for the intraoperative interpretation of biopsy specimens. They are done by placing carefully oriented tissue fragments on a cryostat chuck and freezing them in a viscous freezing medium (such as OCT), either within the cryostat with use of coolant spray and a metal heat extractor or by snap freezing in super-cooled isopentane or 2-methylbutane. Frozen sections are cut and thaw mounted on glass slides. They may be either fixed immediately in alcohol or air-dried before fixation. The sections then are stained with a rapid hematoxylin and eosin stain.

With results of one of the rapid tests outlined previously, a decision may be made regarding the need for further biopsy specimens to define the exact nature of the lesion (e.g., if results from an initial specimen are inconclusive) or the need for additional specimens for completion of specialized techniques (e.g., culture and sensitivity testing for a suspected inflammatory or infectious disorder).

Most intracerebral biopsy specimens may be safely fixed in 10% neutral buffered formalin and processed for hematoxylin and eosin staining. Small samples (1 to 2 mm) may be adequately fixed in 1 to 2 hours, whereas larger specimens may require overnight fixation. If any doubt exists as to the appropriateness of the fixative, a neuropathologist should be consulted immediately. Although technical improvements in immunohistochemical staining permit accurate assessment of samples after formalin fixation and paraffin embedding, assessment of ultrastructural detail using electron microscopy requires fixatives containing glutaraldehyde.

78.3 CONCLUSION

Treatment options based on empiric observations of brain lesions in dogs and cats may compromise clinical outcome. Regardless of lesion location, size, or appearance, a histologic diagnosis is necessary for optimal treatment. Although stereotactic brain biopsy techniques require specialized equipment and instrumentation, they should be considered a standard option in the diagnostic workup of dogs or cats with definable brain lesions on CT or MRI.

79 CHAPTER • 79 Muscle and Nerve Biopsy

Peter J. Dickinson

Richard A. LeCouteur

Biopsy of muscle and nerve is an essential consideration in the diagnosis and therapy of neuromuscular diseases in small animals. Examination of the specific components of the motor unit, as well as of sensory and autonomic nerves, permits definition and classification of the underlying pathology.

79.1 MUSCLE BIOPSY

Conventional biopsy and formalin fixation techniques, as used with most organ systems, severely limit the quantity and quality of information that may be obtained from muscle specimens. The development of specialized enzyme histochemical techniques, using frozen skeletal muscle biopsy specimens, has greatly increased the understanding both of normal muscle and of the underlying pathologic processes of many neuromuscular diseases.

290

79.1.1 Selection of Muscle

The selection of a muscle for biopsy is guided by a number of criteria:

1. The muscle should be affected by the disease process but should not be end-stage. This choice may be based on electrophysiologic data, including abnormal electromyographic (EMG) results and clinical abnormalities suggesting muscle involvement (atrophy, hypertrophy, apparent pain, weakness).
2. The muscle should be easily identified surgically, with low associated morbidity, and with fibers oriented in a single direction.
3. Specimens should be harvested from muscles for which there is previous interpretive experience. Standard muscles include the lateral head of the triceps brachii (distal third), vastus lateralis (distal third), cranial tibial (proximal third), and temporalis muscles. Biopsy specimens from both a thoracic and a pelvic limb muscle, or other distant locations, are necessary to permit diagnosis of generalized neuromuscular disease.
4. Muscle biopsy specimens should be harvested from a site remote to tendinous insertions and aponeuroses.
5. Specimens should be free of artifacts induced by previous disease, intramuscular injections, and EMG needle insertion.
6. Some specialized procedures may require biopsy specimens from specific muscles or regions within muscles. For example, diagnosis of congenital myasthenia gravis is based on the demonstration of decreased numbers of acetylcholine receptors in biopsies of external intercostal muscle.

79.1.2 Open Muscle Biopsy Procedure

Open biopsies are done most often under general anesthesia following electrodiagnostic investigations. After routine surgical preparation, the skin and fascia overlying the muscle are incised, allowing visualization of the

orientation of the myofibers. A sample for fixation is harvested first. Two incisions are made with a No. 11 scalpel blade, parallel to the direction of the myofibers and approximately 2 cm long, 0.25 cm apart, and 0.5 cm deep. Specialized muscle clamps are placed at either end of the incised strip of muscle (to minimize myofiber contraction), and the isolated muscle is freed from the surrounding muscle with a scalpel blade or scissors. This specimen is immersed immediately in fixative, usually glutaraldehyde (either sodium phosphate–buffered glutaraldehyde or Karnovsky's fixative). Clamps may be removed after 24 hours following fixation. If a specialized muscle clamp is not available, the specimen may be sutured to the wooden stem of a cotton-tipped applicator. Samples for freezing and routine histochemical staining (approximately 0.5 to 1 cm in cross section and 1 to 1.5 cm long) may be harvested from adjacent muscle. It is not necessary to maintain these specimens in a stretched position. Handling of the specimen should be kept to a minimum to reduce artifact. Wound closure is routine. External dressings are not necessary. Complications (infection, hematoma) are uncommon and usually are the result of animals interfering with the biopsy site. Collection of a muscle biopsy specimen may be contraindicated in patients with significant coagulopathies.

79.1.3 Percutaneous Muscle Biopsy Procedure

Percutaneous needle or punch muscle biopsy is not recommended routinely due to the limited size and poor orientation of the biopsy specimens obtained.

79.1.4 Specimen Processing and Transport

Ideally, muscle biopsy specimens should be frozen immediately or transported to specialized laboratories for processing and interpretation. Specimen blocks are mounted on thin cork squares using tissue-embedding media, with the muscle fibers oriented vertical to the cork, and frozen for approximately 20 seconds in isopentane (2-methylbutane) cooled to approximately −150°C in liquid nitrogen. Proper freezing of the sample is critical for preservation of morphologic detail and prevention of artifacts. Frozen blocks may be stored in airtight containers at −80°C or in liquid nitrogen storage vessels. For biopsy specimens that are to be transported to specialized laboratories for processing, one fact cannot be overemphasized: *the quality of the information that will be obtained depends on the quality of the biopsy specimen that arrives at the laboratory*. Before a biopsy procedure is performed, the laboratory's specific instructions for selection, handling, and transportation of the specimen should always be obtained. Nonfrozen specimens should be wrapped in saline-moistened swabs that have been thoroughly wrung dry; the specimens then should be placed in an airtight container and maintained at 4°C using cold packs. The specimen container should be wrapped in a layer of newspaper to insulate it from the cold packs to prevent partial freezing of the specimen. Specimens should be shipped so as to reach the laboratory within 30 hours and should not arrive at the laboratory during a weekend. Muscle specimens to be used for biochemical analysis, such as carnitine quantitation, and glutaraldehyde-fixed specimens may be transported in a container separate from the chilled biopsy specimen. Many laboratories request that 5 cc of the animal's serum be shipped with the muscle biopsy specimen.

79.2 NERVE BIOPSY

79.2.1 Selection of Nerve

As with muscle selection, certain guidelines should be followed in the selection of a nerve for biopsy:

1. The nerve should be affected by the disease process, as evidenced by abnormal results on electrophysiologic investigations or by neurologic abnormalities in areas innervated by the nerve (atrophy, hypotonia, hyporeflexia, paresis, sensory deficits).

2. If the disease process is generalized, a nerve should be selected that (1) is easily biopsied with low morbidity, (2) has established normal electrophysiologic and morphometric data available, and (3) innervates a muscle that may be routinely biopsied.

Biopsy of the mixed (motor/sensory/autonomic) common peroneal nerve is recommended when generalized neuromuscular disease is suspected. This nerve is relatively easy to identify and biopsy because it is flat and contains prominent fascicles. Other mixed nerves that may be biopsied easily are the tibial nerve (pelvic limb) and the ulnar nerve (thoracic limb). When a predominantly sensory neuropathy is suspected, biopsy of cutaneous sensory nerves, such as the caudal cutaneous antebrachial nerve or the caudal cutaneous sural nerve, may be appropriate. Biopsy of nerve roots via laminectomy may be necessary when pathology is restricted to the most proximal portions of the peripheral nervous system. If both dorsal and ventral nerve roots are affected, biopsy of the dorsal nerve root is preferred. Biopsy of cranial nerves is infrequently done, largely due to the inaccessibility of these nerves.

79.2.2 Nerve Biopsy Technique (Common Peroneal)

The common peroneal nerve may be palpated on the lateral aspect of the distal femur just caudal to the proximal tibia. A 6 to 8 cm incision is made over this region, exposing the fascia of the biceps femoris muscle. After the nerve has been palpated through the fascia, a small incision (4 to 5 cm) is made in the fascia while the fascia is elevated with a pair of rat-toothed forceps to prevent inadvertent damage to the nerve. The nerve may be seen as it passes over the lateral head of the gastrocnemius muscle. A 5-0 or 6-0 silk suture is placed through the caudal one fourth to one half of the nerve at the proximal end of the biopsy site, allowing minimal gentle traction as a 3 to 4 cm fascicular biopsy is excised using fine iris scissors. Severely diseased nerves may be markedly reduced in size and may appear almost translucent. Care should be taken to dissect as much fat and fascia from around the nerve as is possible. Wound closure is routine. External dressings normally are not required. Some animals may exhibit proprioceptive deficits, with knuckling of the distal pelvic limb on the side of the biopsy. This usually resolves within 3 to 4 days, and long-term deficits are uncommon.

290
291

79.2.3 Nerve Specimen Processing

The nerve should be placed immediately into fixative (usually glutaraldehyde). Contraction artifact is minimized by (1) pinning the nerve at either end to a piece of balsa wood; (2) suturing the nerve at either end onto the wooden stem of a cotton-tipped applicator; or (3) suspending the nerve in fixative with a stainless steel weight. The sample then may be transported to the laboratory in a sealed screw-top bottle. A nerve specimen also may be frozen in liquid nitrogen if specialized biochemical analysis is required. Specimens collected in this manner may be used for plastic embedding, teased fiber preparations, or electron microscopy.

80 CHAPTER • 80 Buccal Mucosal Bleeding Time

Catharina Brömel

Examination of the patient with a suspected bleeding disorder includes assessment of vascular response and platelet function with formation of the platelet plug (primary hemostasis) and of the coagulation cascade leading to formation of fibrin and stabilization of the plug (secondary hemostasis). Persistent hemorrhage from superficial cutaneous injuries and mucosal surfaces (nasal, gingival, gastrointestinal, genitourinary) and formation of petechiae or ecchymoses are characteristic indicators of abnormalities in primary hemostasis. Primary hemostasis can be evaluated through quantitative measures (platelet estimate from blood smear, platelet count, mean platelet volume) and qualitative measures (von Willebrand factor [vWF] concentration and in vitro platelet function tests, such as aggregometry, aperture closure time, and flow cytometry). The buccal mucosal bleeding time (BMBT) is an in vivo, easily performed screening test for evaluation of primary hemostasis in dogs and cats.

Abnormalities in secondary hemostasis can cause hematomas, hemarthrosis, and bleeding into the pleural and peritoneal cavities. These abnormalities are identified by coagulation screening tests (prothrombin time, activated partial thromboplastin time, activated coagulation time, fibrinogen), proteins induced by vitamin K absence or antagonism (PIVKA), and individual coagulation factor assays.

Determination of the BMBT requires two people and can generally be performed without sedation in dogs. The materials needed are (1) a bleeding time device, such as the Simplate II R (Organon Teknika Corp., Durham, North Carolina), shown in Figure 80-1; (2) a gauze strip approximately 5 cm wide; (3) circular filter paper; and (4) a stopwatch.

The animal is placed in lateral recumbency. The upper lip facing the examiner is everted to expose the buccal mucosa, and the gauze strip is tied around the maxilla and mandible to cause moderate venostasis of the buccal mucosa (in sedated cats, the gauze strip can be tied through the open mouth around the cranium). The tear-away tab (see Figure 80-1) of the single or dual-blade spring-loaded bleeding time device is removed. The device is placed evenly against the exposed mucosal surface rostral to the gauze, with care taken to avoid visible blood vessels. The trigger is depressed, resulting in one or two standardized 5 mm by 1 mm mucosal incisions. The stopwatch is started at the time of trigger activation, and the device is removed from the mucosa. The filter paper is used to blot the blood in 5 second intervals about 2 mm from the incision; care is taken to avoid disrupting platelet plug formation by touching the incision (Figure 80-2). The blood should be prevented from reaching the animal's mouth, because this causes agitation. Blotting and the stopwatch are stopped upon complete cessation of hemorrhage, when blood is no longer absorbed by the filter paper. The BMBT is the time elapsed between mucosal incision and cessation of hemorrhage. If two incisions are made, bleeding generally stops at the same time at both sites. If not, the time should be recorded when the first incision ceases to bleed.

Published reference ranges for the BMBT are 1.4 to 3.5 minutes in dogs and 1.5 to 2.5 minutes in cats. For clinical purposes in dogs, a BMBT of less than 4 minutes is considered normal.

BMBT measurement is not indicated in animals with thrombocytopenia (less than 70,000/μL), because an abnormal result would be expected. Other causes of a prolonged BMBT are von Willebrand's disease (vWD), thrombocytopathies, and vascular disorders. Impaired platelet adhesion and aggregation are present in vWD, a hereditary deficiency of vWF that is reported in various dog breeds but is rare in cats. In a patient with a normal plasma vWF concentration and absence of thrombocytopenia, a prolonged BMBT suggests a defect in platelet function that can be congenital or acquired. Inherited thrombocytopathies (intrinsic platelet function defects) are rare. They include disorders of platelet membranes (e.g., Glanzmann's thrombasthenia in otter hounds and Great Pyrenees

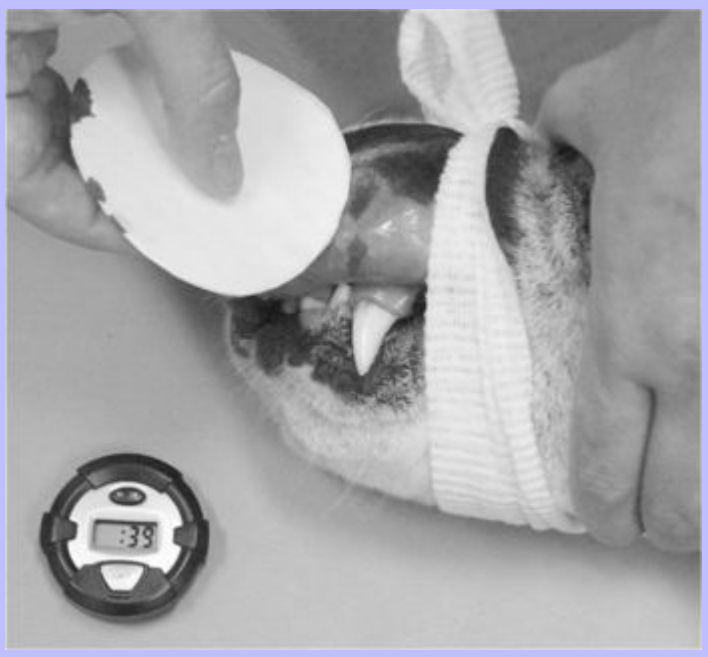
dogs) and disorders of platelet secretion (e.g., spitz and basset hound thrombopathy and platelet granule storage pool deficiency in American cocker spaniels and feline Chédiak-Higashi syndrome). These defects have been associated with a prolonged BMBT. However, not all conditions or agents that cause a platelet dysfunction are reported to result in an abnormal BMBT. 292

Figure 80-1 Disposable bleeding time device (Simplate II R). *Top,* Entire device. *Bottom,* Device with front cover removed, after tear-away tab has been removed and trigger pressed.

Acquired thrombocytopathies are seen in uremic animals, in whom the prolonged BMBT is primarily due to defective platelet adhesion. Platelet aggregation is not consistently altered in uremic animals. Uremic toxins are

thought to play a role in the pathogenesis of this condition. A prolonged BMBT was noted after infusion of dextran 70 in dogs. Nonsteroidal anti-inflammatory agents interfere with platelet function through inhibition of cyclooxygenase 1 (COX-1), leading to decreased synthesis of thromboxane A2, a plateletaggregating and vasoconstricting factor. Aspirin was found to prolong the canine BMBT. Indomethacin did not prolong the BMBT in dogs; the same results were found for the weak COX-1 inhibitors carprofen and meloxicam. Reports on ketoprofen have been conflicting. Acquired thrombocytopathies associated with dysproteinemias and with disseminated intravascular coagulation (DIC) are thought to result from platelet coating by paraproteins and fibrin degradation products. Other causes of a prolonged BMBT include infectious diseases (feline retrovirus–induced thrombocytopathy, canine leishmaniasis and ehrlichioses e.g., *Ehrlichia canis, Ehrlichia platys*), myeloproliferative diseases, and vasculopathies, e.g., vasculitis and inherited vascular defects. Coagulation factor deficiencies do not produce an abnormal BMBT because functional primary hemostasis leads to the formation of an unstable platelet plug; however, rebleeding can occur.

Figure 80-2 Determination of the buccal mucosal bleeding time in a dog.



The BMBT is a quick, useful cage-side test for evaluation of primary hemostasis. It requires minimal preparation and few materials, and it is fairly noninvasive, safe, cost-effective, and easy to perform. Results are available immediately, which allows efficient presurgical screening and repeated evaluation to assess response to treatment. The test can be used as a complement to in vitro function tests, which may not fully reflect platelet function in vivo. However, the BMBT procedure is affected by iatrogenic variables that could normalize the result. Reports on sensitivity and specificity for the detection of primary hemostatic disorders vary. A normal result does not eliminate a diagnosis of vWD or a platelet function defect, especially if the degree of dysfunction is mild. No correlation was found between the BMBT and plasma vWF concentration in dogs. The BMBT test is not standardized (e.g., degree of venostasis) and not reproducible. For any two readings in the same dog, the BMBT may differ by up to 2 minutes with one observer or between two observers. However, it is a valuable tool for the initial assessment of the patient with a suspected bleeding disorder, together with the signalment, medical history (e.g., congenital versus acquired

thrombocytopathy), drug history, physical examination findings, and results of other hemostatic, biochemical, and hematologic parameters.

81 CHAPTER • 81 Jugular Catheterization and Central Venous Pressure

Darlene L. Riel

Catheterization of the jugular vein is a common method of achieving central venous access. Of the four general categories of intravenous access devices (winged needle, over-the-needle, through-the-needle, and multilumen catheters), the through-the-needle and multilumen catheters are favored for jugular catheterization. These catheters are available in a variety of lengths and diameters.

81.1 THROUGH-THE-NEEDLE CATHETERS

Through-the-needle catheters are catheters that are passed through a needle. The catheter is packaged in a protective plastic sleeve to prevent contamination. After catheter placement, the needle is withdrawn and a needle guard is applied to prevent trauma to the dog or cat and to protect the catheter from shearing.

81.2 MULTILUMEN CATHETERS

Multilumen catheters have two to five separate lumens in one catheter and are available in both the over-the-needle and through-the-needle designs. They are useful for administering two or more continuous infusions at the same time and/or for monitoring central venous pressure. Catheter placement is accomplished with the aid of a guide wire and a vein dilator.

81.3 JUGULAR CATHETERIZATION

81.3.1 Supplies and Patient Preparation for All Catheters

The catheterization supplies (Box 81-1) are gathered and arranged so as to be ready for use on a clean tray or countertop close to the patient. An appropriate-size catheter for the dog or cat is selected. The tip of the jugular catheter should reach the vena cava, close to the right atrium. The length to which the catheter should be inserted is determined by measuring from the expected catheter insertion site to the caudal edge of the triceps muscles.

81.3.1.1 Box • 81-1 Jugular Catheterization Supplies

Clippers and antiseptic preparation solutions

Through-the-needle catheter or multilumen catheter kit

Antimicrobial ointment

Sterile 2 × 2 gauze sponge

Heparinized saline syringes

Surgical drapes, if necessary

Sterile gloves

Small utility surgical set

Suture material

Injection cap (or caps) or T-port

Bandage material

Tape

Proper positioning of the dog or cat, usually in lateral recumbency, is crucial. An assistant should extend the patient's head and direct the front limbs caudally. The assistant should hold off the vein by pressing into the thoracic inlet. Placement of a bag of fluids, a sandbag, or rolled towels under the neck may help stabilize the vein. If the vein is not properly stabilized, it may roll laterally or crumple longitudinally. Hair should be clipped wide enough to prevent contamination during the catheterization procedure. Aseptic technique is used, and the site is prepared as would be a surgical site. Sterile drapes should be used if necessary.

81.3.2 Through-the-Needle Catheterization Technique

The operator should first inspect the through-the-needle catheter to make sure the catheter is retracted back into the needle and is not visible at the needle bevel. Grasping the needle firmly, with the needle bevel up, the operator inserts the needle through the skin and advances it subcutaneously parallel to the vein for at least 1.25 cm before it is introduced into the vein. Venipuncture is confirmed when a flash of blood is seen within the catheter. The operator then advances the needle well into the vein, holds the needle with one hand, and threads the catheter with the other hand by pushing the catheter hub within the protective plastic sleeve until the catheter hub is advanced into the needle hub. Pressure is applied at the catheter puncture site; the needle is backed out from the skin, and the plastic sleeve is disconnected from the needle. The needle is secured with a needle guard. If a wire stylet is present, it is removed from the catheter. The catheter then is capped with an injection cap or T-port. Placement is confirmed by successful aspiration of blood, and the catheter is then flushed with heparinized saline. The catheter is sutured close to the insertion site, and care is taken not to kink the catheter. The insertion site is covered with a sterile dressing. Finally, the catheter is secured with a stabilizing wrap.

81.3.3 Multilumen Catheter Technique

All the “pigtail” ports of the multilumen catheter are flushed with sterile heparinized saline, and injection caps are applied to all the ports *except* the most distal one. A No. 11 scalpel blade is used to make a full-thickness stab incision large enough to accommodate the vessel dilator (too small an incision makes it difficult to pass the dilator). The catheter introducer (usually an over-the-needle style catheter) is inserted, and the guide wire is fed through the catheter introducer and into the jugular vein. A length of wire is left exposed that is equivalent in length to the multilumen catheter. It is important that the operator control the wire so as to prevent contamination outside the sterile field and to prevent the wire from slipping down the jugular vein. The catheter introducer is then withdrawn from the vein over the guide wire, leaving the guide wire in the vein. The vein dilator is threaded over the guide wire and advanced into the jugular vein to its full length. Some resistance is expected, and the dilator may need to be rotated or twisted to insert it into the jugular vein. Digital pressure is applied to minimize bleeding, and the dilator is removed from the vein and then withdrawn over the guide wire. *Care must be taken not to remove the guide wire!* The catheter is threaded over the guide wire until the operator can grasp the guide wire from the open pigtail injection port. The operator holds the guide wire and advances the catheter into the jugular vein to the predetermined length. Once the catheter is in place, the guide wire is removed, leaving the multilumen catheter in the vein. An injection cap is placed on the pigtail of the distal port, air is aspirated, and the port is flushed with heparinized saline. The catheter is then sutured in place, and the insertion site is covered with a sterile dressing. Finally, the catheter is secured with a stabilizing wrap.

293
294

81.4 CENTRAL VENOUS PRESSURE MEASUREMENT BY WATER MANOMETER

Central venous pressure (CVP) is a luminal pressure measurement taken from the intrathoracic portions of the cranial vena cava. The accepted normal range for CVP is 0 to 10 cm H_2O.

81.4.1 Supplies Needed for Central Venous Pressure Measurement

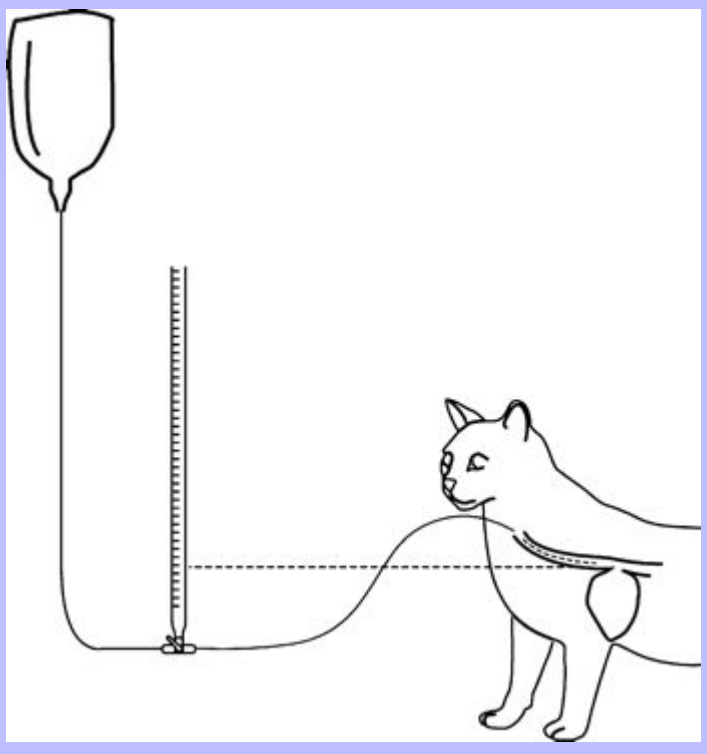
A catheter with the tip properly placed in the intrathoracic vena cava is required. The materials needed include a sterile bag of fluids with an attached fluid administration set, an intravenous fluid extension set, a three-way stopcock, and a water manometer.

81.4.2 Procedure

The dog or cat should be positioned in lateral or sternal recumbency. A water manometer is placed in the fluid line via a three-way stopcock and the extension set (Figure 81-1). The fluid administration set and the extension set are primed with sterile fluids from the fluid bag while the stopcock is in the “Off” position to the water manometer. There must be no air bubbles in the fluid lines. The primed extension set is attached to the patient's catheter. The stopcock at the bottom of the manometer should rest on the table or cage floor. The administration set is opened, again with the stopcock in the “Off” position to the manometer, to allow fluid to flow into the patient's catheter, thus ensuring that the catheter is patent. If fluid does not flow freely into the patient's catheter, a valid CVP measurement will not be obtained. Next, the stopcock is turned so that the “Off” position is now to the patient. The fluid will now fill the manometer, which is allowed to fill about three-quarters full. The stopcock then is turned “Off” to the fluids, allowing a pathway only from the fluid-filled manometer and the patient's catheter.

The level of fluid in the manometer falls until the hydrostatic pressure of the column of fluid reaches equilibrium with the hydrostatic pressure of the blood at the end of the catheter. Therefore it is essential to know where the catheter tip lies in relation to the manometer fluid column. When the animal is in lateral recumbency, the cranial vena cava lies near the midline, and the manubrium is a good reference point. When the animal is in sternal recumbency, the cranial vena cava is about at the level of the point of the shoulder or the scapulohumeral joint. With the stopcock resting on the tabletop or cage floor, a *zero reference point* is determined by a horizontal line drawn between the manometer and the appropriate external anatomic landmark (manubrium or scapulohumeral joint). The centimeter mark where the horizontal line intersects the manometer is the zero reference point. A carpenter's level fastened to a taut string is an excellent guide for the horizontal line from the anatomic landmark to the manometer. The difference between the equilibrium point reading and the zero reference point is the CVP measurement. For example, if the initial reading is 15 cm H_2O (where the fluid level stopped falling) and the zero reference point is 10 cm H_2O (horizontal line drawn between the external anatomic landmark and the manometer), the CVP is 5 cm H_2O. The presence of a well-placed, unobstructed catheter can be verified by the fluid column in the manometer, which will slightly oscillate up and down as the animal's heart beats or as the animal breathes. Readings are taken between ventilatory excursions. Trends in central venous pressure are more informative than single values. Each time a CVP measurement is obtained, the patient should be in the same recumbent position. The goal is to be consistent in taking the readings and to monitor the trends.

Figure 81-1 Setup for central venous pressure (CVP) assessment.



82 CHAPTER • 82 Cerebrospinal Fluid Collection, Myelography, and Epidurals

Scott M. Anderson

82.1 CEREBROSPINAL FLUID COLLECTION

Cerebrospinal fluid (CSF) can be collected from the cerebellomedullary (CM) cistern or from the lumbar subarachnoid space. A larger volume of fluid is more easily obtained from the former, with less risk of iatrogenic hemorrhage.

82.1.1 Cerebellomedullary Cistern Collection

With the animal under general anesthesia, the operator clips and prepares the region for aseptic sample collection. If elevated intracranial pressure is suspected, the dog or cat is hyperventilated.

The animal is placed in lateral recumbency, with the neck flexed so that the long axis of the head is perpendicular to the spine. The spine and median plane of the head should be parallel to the table. Care should be taken to avoid hyperflexion of the neck, which can partially occlude the endotracheal tube and increase intracranial pressure by reducing jugular venous flow.

The midline is identified through palpation of the occipital crest. On the midline, just ahead of a line between the cranial edge of the wings of the atlas, a 22-gauge, 3.75 to 7.5 cm styletted spinal needle is inserted perpendicular to the long axis of the spine. In thick-skinned animals, a stab incision is made in the skin at the needle entry site so that the needle does not plunge into the spinal cord after being forced through the skin.

The needle is advanced slowly, in 1 to 2 mm increments. A pop and decreased resistance may be felt as the needle penetrates the dura. In cats and smaller dogs, this may be difficult to feel. The stylet then is withdrawn, and the operator checks for CSF flow. If none is seen, the stylet is replaced and the needle again is advanced in 1 to 2 mm increments, with the operator checking each time for CSF flow. If the needle strikes the occipital bone, it is “walked” off the caudal edge of the bone until it enters the CM cistern.

If no CSF flow is seen after further advancement, the operator should remove the stylet and withdraw the needle slowly, observing for CSF flow. If two unsuccessful attempts are made at CM cerebrospinal fluid collection, the operator should consider performing a lumbar tap rather than risking trauma to the cervical spinal cord.

If whole blood flows from the needle at any time, the needle should be withdrawn and the procedure repeated using a fresh needle.

Once CSF flow is seen, 0.5 to 2 mL is collected, depending on the animal's size, and the pressure is measured if desired. The jugular veins may be occluded to increase CSF flow. Aspiration with a syringe should be avoided, because this increases the risk of blood contamination. Only as much CSF as needed should be collected; removing a large volume of CSF may increase the risk of brain herniation (shift in intracranial contents), which is often fatal.

Blood in the CSF may be iatrogenic or pathologic. If blood is seen, the stylet is replaced for 1 minute, and sample collection is then resumed. Often the bleeding will have diminished. Iatrogenic hemorrhage often decreases as the fluid is collected. Therefore the first and second portions of the sample must be collected in

separate tubes. If the degree of blood contamination is severe, an ethylenediamine tetra-acetic acid (EDTA) tube may be used to prevent clotting. Red blood cell contamination does not significantly correlate with the nucleated cell count or protein concentration.

If fluid analysis cannot be performed immediately, the addition of 30 μL of autologous serum per 250 μL of CSF has been shown to help preserve the structure of the cells in refrigerated CSF for up to 48 hours. If this process is used, a sample of unaltered CSF should also be submitted for determination of the protein concentration and total cell count.

If no flow can be obtained, the dog or cat may have suffered a brain herniation that is obstructing CSF flow. Attempts at CSF collection should be discontinued and hyperventilation instituted.

82.1.2 Lumbar Collection

For lumbar CSF collection, the animal is placed in lateral recumbency, with the hind legs pulled forward to flex the lumbar spine. A median or paramedian needle insertion site may be used. For a median puncture, the needle is inserted perpendicular to the spine just cranial to the L6 dorsal spinous process. For a paramedian placement, the needle is inserted slightly caudolateral to the L6 dorsal spinous process. The needle then is directed cranioventrally at an angle parallel to the plane of the dorsal intervertebral articulation (approximately 45 degrees to the spine). Fluoroscopy is helpful in confirming needle position.

The needle is advanced into the spinal canal. Aspiration of CSF from the dorsal subarachnoid space avoids needle-induced trauma to the spinal cord and is preferable, but obtaining fluid from this level is more difficult than obtaining it from the ventral subarachnoid space. Once the needle is felt to pass the articulation, the operator withdraws the stylet to check for CSF flow. If none is seen, the stylet is replaced and the needle is advanced in 1 to 2 mm increments, with the operator checking for CSF flow after each advance. Alternatively, the needle can be advanced until the tip contacts bone, and CSF then is withdrawn from the ventral subarachnoid space. The pathologist must be informed of the collection site: lumbar CSF has a slightly higher protein concentration and fewer cells than CSF collected from the CM cistern.

If no CSF is obtained, the needle is withdrawn in 1 mm increments, with the operator observing for CSF flow. If none is seen, collection at the L4 to L5 level can be attempted.

82.2 MYELOGRAPHY

Myelography (radiography after subarachnoid injection of a contrast medium) may be performed by either cervical (CM cistern) or lumbar injection. Cervical injection allows more contrast medium to flow cranially into the cerebral ventricular system. In addition, a lesion causing severe cord swelling or compression may not allow the contrast medium to pass, resulting in only the cranial edge of the lesion being outlined. Lumbar injection, however, can be performed under pressure, forcing contrast medium past the lesion to outline the entire lesion and the full length of the spinal cord. For these reasons, a lumbar injection site is preferred.

295

296

The needle is placed as described above for CSF collection. Lumbar injection is typically done in the ventral subarachnoid space, because it can be difficult to position the needle tip in the dorsal subarachnoid space. Fluoroscopic guidance facilitates proper needle placement. CSF is collected prior to injection of the contrast media, because the CSF protein concentration and neutrophil count typically increase after myelography.

Use of a nonionic contrast medium (iohexal or iopamidol, 180 to 240 mg/mL) is advised. Metrizamide should not be used, because it poses a higher risk of complications, including seizures. A test injection of 0.2 mL of contrast

medium should be performed, with fluoroscopic or radiographic confirmation that subarachnoid injection has occurred. The needle hub and injection set should be filled with contrast medium prior to commencing injection; this minimizes the appearance bubbles in the subarachnoid space, which may hamper interpretation.

Epidural leakage of contrast medium obscures the subarachnoid dye columns. If this is seen, the operator should withdraw the needle 1 to 2 mm and perform another test injection. If this does not produce opacification of the subarachnoid space, the operator should consider withdrawing the needle and selecting another injection site. Further incremental withdrawal could result in contrast medium being injected into the spinal cord parenchyma, with deleterious results.

After cervical injection and needle removal, the front half of the dog or cat is elevated to maximize the flow of contrast medium into the thoracic and lumbar subarachnoid space; lateral and ventrodorsal spinal radiographs are then obtained. Oblique views and dynamic studies may be helpful in some cases.

Transient exacerbation of neurologic impairment may be seen after myelography, particularly in large breed dogs, dogs with degenerative myelopathy, and dogs with chronic neurologic conditions. This usually resolves within a few days.

82.3 EPIDUROGRAPHY

Because the subarachnoid space typically does not extend to the lumbosacral junction, myelography is an unreliable means of assessing lesions caudal to L5. For this area, magnetic resonance imaging (MRI) scans are preferred. If MRI is not available, epidurography may be performed.

The tail base and dorsal sacral region are clipped and aseptically prepared. At any level from S3-CD1 through CD4-CD5, a 22-gauge, 2.5 to 7.5 cm styletted spinal needle is inserted on the midline perpendicular to the spine. With the needle tip on the floor of the spinal canal, 0.15 to 0.2 mL/kg of contrast medium is injected. With the needle in place, flexed, neutral, and extended lateral radiographs of the lumbosacral region are obtained. Supplemental injections of 0.1 mL/kg are given as needed for follow-up views. The needle then is removed, and a ventrodorsal radiograph is obtained.

Epidurography has no significant complications.

82.4 EPIDURAL ANESTHESIA

Epidural anesthesia may be administered as a single dose or may be given continuously through an indwelling catheter. To administer a single dose, a 20-to 22-gauge, 2.5 to 7.5 cm needle is inserted on the midline, perpendicular to the spine and slightly caudal to the L7 dorsal spinous process. A pop and decreased resistance are felt as the needle passes through the interarcuate ligament.

To verify that the needle tip is in the epidural space, sterile saline solution can be injected. There should be no resistance to injection if the needle tip has been properly placed. Alternatively, 3 to 4 mL of air may be injected. The bubbles produced do not significantly decrease the efficacy of the local anesthetic to be injected.

If CSF flow is obtained, the needle tip is in the subarachnoid space. This is uncommon, because the subarachnoid space typically does not extend to the L7 to S1 level. In this situation, a second attempt may be made to insert the needle into its proper epidural location. Alternatively, subarachnoid injection of a reduced dose of anesthetic may be performed (1 mL/10 kg body weight; that is, 50% of the epidural dose).

If blood flow is obtained, the needle should be withdrawn and another attempt made at proper placement. A local anesthetic should not be injected in this situation. Intravascular injection is contraindicated due to the risk of toxicity.

The selected local anesthetic can now be administered. Details of specific agents and dosages are beyond the scope of this chapter, but in general, approximately 1 mL/5 kg body weight is administered, to a maximum of 20 mL. For cesarean section, 1 mL/6 kg is reported to be sufficient. The anesthetic should be warmed to body temperature and injected over a 1-minute interval to minimize discomfort.

For continuous epidural anesthesia, a 17-or 18-gauge, 7.5 cm Touhy or Crawford needle is inserted and directed 30 degrees cranial, rather than perpendicular to the spine. The bevel is directed cranially. The catheter is advanced through the needle at least 3 cm into the epidural space, or farther, to the desired level in the lumbar or thoracic spine. If the catheter cannot be advanced, the operator injects a small amount of saline solution while again attempting to advance the catheter. If this fails, the needle and catheter are withdrawn simultaneously; if the catheter is withdrawn alone, it could be severed by the needle tip. If this occurs, most authors agree that surgery to retrieve the catheter fragment is not indicated.

Paresis of the nictitating membrane (the sympathetic innervation of which originates from T1 to T3) indicates blockade of spinal sympathetic outflow due to thoracic epidural anesthesia. This may produce hypotension, Horner's syndrome, and hypoglycemia. If the agent affects the cervical spinal cord, respiratory muscle paralysis can occur. In these cases, the thorax, neck, and head are elevated to decrease forward flow of the anesthetic agent and the patient is ventilated if necessary.

Other reported complications of epidural anesthesia include infection, seizures, insufficient or delayed onset of anesthesia, circulatory depression, Schiff-Sherrington–like reflexes, unilateral hind limb paresis, and partial anesthesia of the tail and perineum.

83 CHAPTER • 83 Veterinary Diagnosis of Bacterial, Fungal, and Viral Disease

Janet E. Foley

83.1 INDICATIONS FOR TESTING

Infectious disease testing may be performed for a number of reasons; for example, to identify the etiology of an inflammatory disease, to follow up on a dog or cat with an infectious disease, to obtain an isolate for further testing (such as for antibiotic susceptibility), or to determine the risk of transmission of an infection to other animals or to people. Tests and interpretation vary, depending on the clinician's intent, therefore it is helpful to clarify the purpose for testing in each case. For example, if the goal is to determine whether an animal poses a risk to an immunocompromised human member of a household, it would be important to document active infection; thus culture or antigen-based tests would be used, not serology. It is important to evaluate test results in the context of the whole patient evaluation; documenting the presence of a pathogen does *not* prove that the pathogen is the cause of the animal's clinical signs.

83.2 TYPES OF TESTS: PROS, CONS, AND LIMITATIONS

Tests for infectious agents are either direct or indirect (Figure 83-1). *Direct tests* detect a pathogen, its nucleic acids, or its antigens. These tests include culture, polymerase chain reaction (PCR), antigen tests, and direct visualization. Direct methods may either document living (active) infection or may pick up an infection that no longer is active. Only culture documents that the infection is active at the time of sample acquisition, although cytology or histopathology can be suggestive. PCR or antigen tests may remain positive after effective treatment has been initiated; that is, after the target agent has died. For example, the blood of a bacteremic animal could be PCR positive for bacterial DNA for a few days after administration of antibiotics and after the animal has become culture negative. *Indirect tests* seek evidence of exposure to a pathogen by evaluating host response; these tests consist primarily of serology for specific host antibodies.

Good tests should be *sensitive* (high likelihood of detecting the infectious agent) and *specific* (low likelihood of a positive result if the agent is not present). Culture often is insensitive but highly specific. Bacterial culture often is negative in samples from animals recently started on antibiotics, and some agents may require days to weeks to grow in vitro. However, culture should be highly specific, depending on how well “positives” are further characterized in the laboratory. Culture has the additional advantages of providing an isolate for testing antibiotic, antifungal, or antiviral agents, molecular epidemiologic studies, and possible experimental infections. Culture sensitivity depends on sample handling (discussed below). *Many agents cannot be cultured,* therefore alternative methods for these organisms are critical and may be useful for improving sensitivity even for agents that can be cultured.

The “most direct” test is direct visualization, which also is insensitive, sometimes like looking for a needle in a haystack. Inflammation may be helpful in directing the attention of the clinical pathologist or microbiologist to the area containing organisms. Gram stains are useful in bacterial processes, because culture virtually always underestimates the number and diversity of bacteria, whereas a semiquantitative Gram stain can reveal both. Special stains, such as silver-based stains or calcofluor white (a fluorescent stain), can enhance spirochetes, some bacteria, fungi, and other organisms. Immunohistochemical stains use monoclonal or polyclonal antibodies raised against the pathogen to target areas in tissue where a pathogen is present, coupled with a technique for flagging the pathogen (usually either a fluorescent dye or a chemical chromogen).

PCR is emerging as a diagnostic powerhouse for bacterial, fungal, and viral infectious diseases. PCR is an iterated biochemical reaction performed in a *thermal cycler,* a machine that cycles repeatedly through a temperature series, so that a few target DNA fragments in a sample can yield millions of copies. Millions of same-size DNA fragments can be visualized on an electrophoretic gel. The trick to PCR is to find primers to start the reaction that anneal to a particular target and only that target. Thus *Hemobartonella felis* (now *Mycoplasma hemofelis*) primers should anneal only to *M. hemofelis* DNA and feline coronavirus primers only to feline enteric coronavirus (FECV) cDNA. There are several *universal primers,* which anneal to all bacteria or all filamentous fungi. After PCR is performed, the resulting fragment can be sequenced and the results checked against a data base to identify the bacterium or fungus present in the sample.

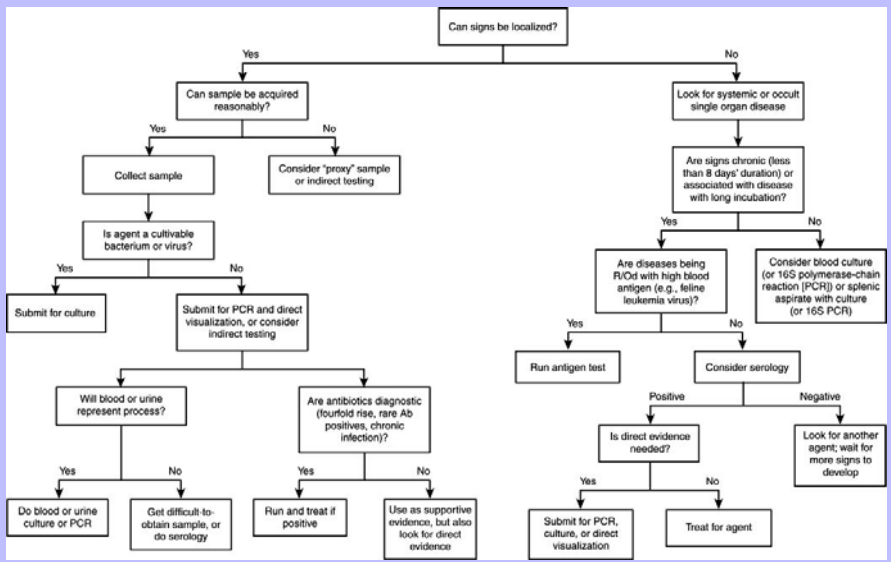
Even carefully designed PCR reactions occasionally have been found to amplify nontargets (when by chance, some other organism has a region of DNA to which the primers anneal), therefore it is important to verify PCR results with DNA sequencing, a DNA probe, a second PCR in another region of DNA, or some other method. Two other limitations of PCR are the feasibility of obtaining sufficient quality RNA or DNA from the clinical sample and inhibitors in the sample. RNA in viruses such as FECV, canine distemper, and others is prone to RNAse degradation and must be kept as cold as possible and processed rapidly in a laboratory using special techniques to protect the RNA. Delays in sample handling increase the rate of false-negative PCR results. DNA is more stable and can be shipped dried, frozen, at room temperature, in paraffin-embedded tissue, and so forth. Some pathogens are harder to "crack," in terms of obtaining DNA, particularly mycobacteria and many fungi. Blood, feces, ascitic fluid, ticks, and other samples have inhibitors that can make the reaction less sensitive. Also, PCR can become cross-contaminated with DNA in the laboratory, therefore positive results should be trusted only if the laboratory has excellent quality control and makes stringent use of negative controls.

Antigen tests are available for a few veterinary pathogens associated with high levels of antigen in a sample; some of these pathogens are feline leukemia virus (FeLV), *Cryptococcus neoformans,* and canine parvovirus. In other infections, such as feline immunodeficiency virus (FIV), antigen is insufficient to make such a diagnostic modality feasible.

297

298

Figure 83-1 Algorithm for the diagnosis of bacterial, fungal, and viral diseases.



298

Antibody testing has several advantages. The sample typically is serum, which may be easier to obtain than, for example, tissue, and animals may remain seropositive for months after exposure, providing a larger window for testing. However, this large window may be a drawback as well, because the animal remains seropositive long after infection has resolved. In diseases that do not resolve (e.g., FIV), antibody testing documents infection; however, in other diseases, such as ehrlichiosis, serology only documents previous exposure. Serology has two other drawbacks: there is no detectable immunoglobulin G (IgG) early in infection (up to 10 to 14 days), and vaccines induce cross-reacting seropositivity in some diseases, such as feline herpesvirus, calicivirus, and canine parvovirus. Twofold or fourfold rises in titer over 2 to 4 weeks are helpful for documenting recent infection in some diseases (and are part of the human case definition for ehrlichiosis) but are not helpful in others (e.g., feline infectious peritonitis [FIP]). Negative titers in a disease process that has been ongoing for at least 2 weeks are extremely informative in terms of ruling out some infections.

83.3 SAMPLE COLLECTING, HANDLING, AND SUBMISSION

The packaging and transport of samples depend on the tests to be run. The requirements are:

- *Direct visualization, pathology, or immunohistochemistry:* Rapid transport, room temperature, and room air (unless formalin fixed)
- Virus isolation, PCR, or antigen and antibody tests: Frozen
- Aerobic and fungal culture: Cooled with room air
- Anaerobic or microaerophilic bacteria: Cooled with special atmospheres

Although each institution has a different configuration of laboratories, infectious disease diagnosis could involve clinical pathology, virology, immunology, microbiology, parasitology, biochemistry, and/or molecular biology. Clinicians should verify, through contact with the laboratory, how much sample and what paperwork are required to route the sample to all desired laboratories.

84 CHAPTER • 84 Urogenital Diagnostic Procedures

S. Dru Forrester

84.1 CYSTOCENTESIS

Cystocentesis is indicated to collect urine for diagnostic evaluation and also to temporarily decompress the urinary bladder in animals with urethral obstruction. Obtaining urine from the urinary bladder bypasses contamination from the lower urogenital tract and is the preferred technique when samples are to be submitted for bacterial culture. When performed correctly, cystocentesis is a safe procedure. In most dogs and cats, a 22-gauge, 1.5-inch needle attached to a 12-mL syringe is used. For large or obese dogs, a 22-gauge, 3-inch spinal needle may be needed. If the urinary bladder cannot be palpated, ultrasound guidance is helpful for localizing it.

Cystocentesis can be done with the dog or cat standing or in dorsal or lateral recumbency. The bladder is palpated to determine the site for puncture. Usually the needle is inserted into the ventral or ventrolateral aspect of the urinary bladder. Hair can be clipped over the site and the skin prepared aseptically. However, in almost all situations this is unnecessary, and alcohol can simply be used to wipe the skin over the puncture site. The urinary bladder is immobilized with one hand, and the other hand is used to insert the needle through the abdominal wall (Figure 84-1). If the urinary bladder contains a small amount of urine or if cystocentesis is done therapeutically, the needle should be inserted near the urinary bladder neck, rather than at the apex, so that urine can be removed continually as the urinary bladder becomes smaller. Urine is aspirated by pulling back on the plunger to create negative pressure. If urine is not obtained, the needle is not redirected; rather, the needle is removed from the abdomen and the procedure is begun again. Excessive pressure on the urinary bladder during and immediately after aspiration should be avoided to prevent leakage of urine into the abdominal cavity.

Figure 84-1 During cystocentesis the urinary bladder is immobilized with one hand while the other hand is used to insert the needle into the urinary bladder and aspirate urine.

If the urinary bladder cannot be palpated and ultrasound is not available, cystocentesis can be done "blindly." Although this technique may not be as effective, it can be attempted if a dog or cat cannot be hospitalized during the day or is likely to void frequently due to pollakiuria. The pet is positioned in dorsal recumbency, and a puncture site is selected on the midline, halfway between the umbilicus and pelvic brim (this is often the point where alcohol pools when dripped onto the area in female dogs). In male dogs, the penis and prepuce should be retracted laterally so that the needle can be inserted into the abdomen on the midline. Urine is aspirated as described above. If a sample is not obtained, the needle is removed and aspiration is attempted at a site just cranial or caudal to the original puncture. If urine is not obtained after a total of three attempts, cystocentesis should be delayed until the urinary bladder can be palpated.

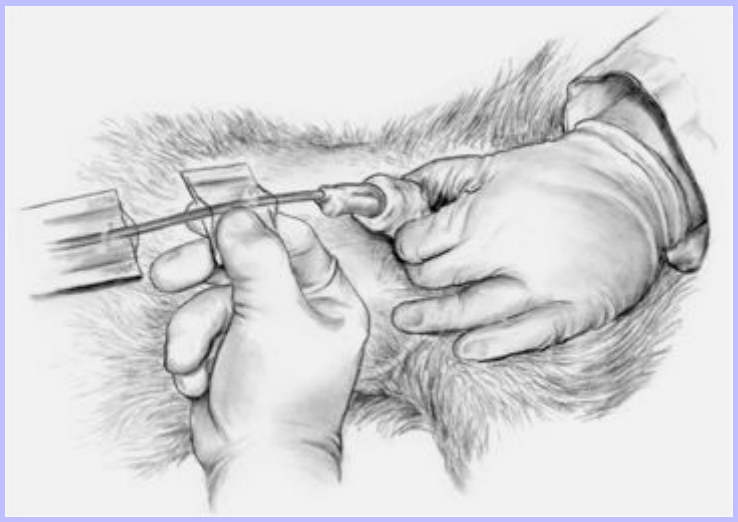
84.2 URETHRAL CATHETERIZATION

Transurethral catheterization is indicated to collect urine for analysis or bacterial culture (primarily in male dogs), to measure urine output, to inject radiographic contrast material, and to relieve urinary retention secondary to functional or anatomic urethral obstruction. Potential complications include iatrogenic urinary tract infection (more likely in females) and urethral or urinary bladder trauma. Catheterization should always be performed aseptically using a sterile catheter. Flexible catheters (e.g., rubber) are appropriate for the collection of urine for diagnostic purposes and are less traumatic than polypropylene catheters. Urethral catheters with an inflatable balloon near the tip (e.g., Foley catheters) are useful for indwelling catheterization in female dogs. Catheters are available in a variety of sizes and lengths. Catheter diameter is most often expressed in French (F) units (3F = 1 mm). For male dogs, depending on the animal's size, catheter diameters of 3.5 to 5F (<10 kg), 8 to 10F (10 to 25 kg), and 10 to 12F (>35 kg) are appropriate. Catheters ranging from 5 to 14F are adequate for most female dogs.

Male dogs should be restrained in lateral recumbency, and an assistant should retract the prepuce to expose the penis. The tip of the penis should be cleansed with a mild antiseptic solution. The length of catheter needed to reach from the distal end of the penis to the neck of the urinary bladder should be estimated; this helps avoid overinsertion of the catheter, which could damage the urinary bladder mucosa. The tip of the catheter should be lubricated with a sterile, water-soluble lubricant from a single-use packet. The urinary catheter should be maintained in sterile condition during catheterization; this may be accomplished by using a sterile hemostat, wearing sterile gloves, or using a cut portion at the end of the catheter package to advance the catheter (Figure 84-2). The tip of the catheter is inserted into the external urethral opening and gently advanced. Some resistance may occur as the catheter is advanced through the area of the os penis and again at the ischial arch. If the catheter has been inserted to the appropriate level and urine is not observed, a syringe is attached to the catheter to aspirate urine. After urine collection, the catheter is gently removed from the urethra.

Urethral catheterization is more technically difficult in female dogs, and sedation may occasionally be helpful in some cases (e.g., with small or fractious dogs). Catheterization may be performed using a speculum (e.g., human nasal speculum, otoscope cone) to visualize the urethral orifice or blindly, with or without digital palpation. Selection of technique depends on the preference and experience of the clinician and the temperament of the dog or the size of the vagina. It is helpful to insert a lubricated, sterile, metal stylet or 3.5F polypropylene catheter through the lumen of the Foley catheter to increase its rigidity and facilitate its passage. The stylet should be advanced to the tip of the Foley catheter to prevent it from exiting the eye of the catheter and causing urethral damage during placement.

Figure 84-2 Urethral catheterization of a male dog. A portion of the catheter's package is used to aseptically advance the catheter through the urethra.



Female dogs are most easily catheterized while standing or in sternal recumbency with the rear legs hanging over the end of a table; an assistant should hold the tail to one side. Excessive hair around the vulva should be clipped, if necessary, and the area should be cleansed with antiseptic soap. A lubricated tuberculin syringe is inserted into the vagina, and 0.25 to 0.5 mL of local anesthetic (e.g., 0.5% lidocaine or topical ophthalmic anesthetic) is instilled in the area of the urethral orifice (approximately 3 to 5 cm cranial to the vulvar opening). While sterile conditions are maintained, the tip of the catheter is lubricated with water-soluble lubricant.

For the visual technique, the vaginal speculum is lubricated and the tip is gently inserted dorsally through the vulva and then directed cranially to avoid the clitoral fossa. The blades of the speculum are opened gently so that the urethral orifice can be visualized. The handles of the speculum should be directed dorsally so that they do not interfere with visualization. A sterile glove is worn to pick up the catheter; the tip is inserted through the urethral orifice, and the catheter then is gently advanced into the urinary bladder. If the catheter is to remain in place, air or saline is injected to inflate the balloon at the catheter tip.

For the digital technique, the person passing the catheter should wear sterile gloves. A lubricated index finger is inserted into the vagina, and the urethral orifice is palpated. The other hand is used to insert the catheter ventral to the finger in the vagina; the catheter is guided ventrally on the midline so that it enters the urethral orifice (Figure 84-3). If a finger cannot be inserted into the vagina, the catheter can be passed blindly. After the catheter has been inserted through the vulva, it is directed ventrally along the midline of the vestibular floor and advanced cranially. If resistance is encountered, the catheter has most likely advanced past the urethral orifice to the cervix. If this occurs, the catheter is withdrawn and the procedure is repeated. If urine is not noted from the catheter, a syringe is attached and urine is obtained through aspiration.

Figure 84-3 Urethral catheterization of a female dog. An index finger is placed over the urethral orifice to guide the catheter ventrally into the urethra.

84.3 ASPIRATION/BIOPSY OF UROGENITAL MASSES

Tissue specimens may be obtained from urogenital masses (i.e., vagina, prostate gland, urethra, and urinary bladder) for cytologic and histologic evaluation by a variety of methods, including endoscopy, ultrasound-guided aspiration, and catheter-assisted biopsy. Catheter-assisted biopsy can be performed without the need of special diagnostic equipment. Sedation may be helpful in fractious dogs. The location of the mass should be confirmed by physical examination or diagnostic imaging studies (e.g., ultrasound, contrast urethrography). As described above, a flexible urinary catheter with side openings (eyes) on the distal end should be passed into the urinary bladder and all urine removed. The tip of the catheter should then be withdrawn to the level of the mass (Figure 84-4). The location of the catheter tip can be confirmed by digital palpation per rectum or by radiographs if a radiopaque catheter is used. A 12-mL syringe containing sterile saline is attached, and all but 1 mL is injected through the catheter. The plunger is pulled back to create negative pressure, and mucosal pieces are aspirated into the side openings of the catheter. If the mass is located in the prostate gland, vigorous palpation of the prostate per rectum during aspiration may facilitate collection of prostatic tissue.

Figure 84-4 Passage of a flexible rubber catheter through the urethra of a male dog to aspirate tissue samples from a mass at the trigone of the urinary bladder.

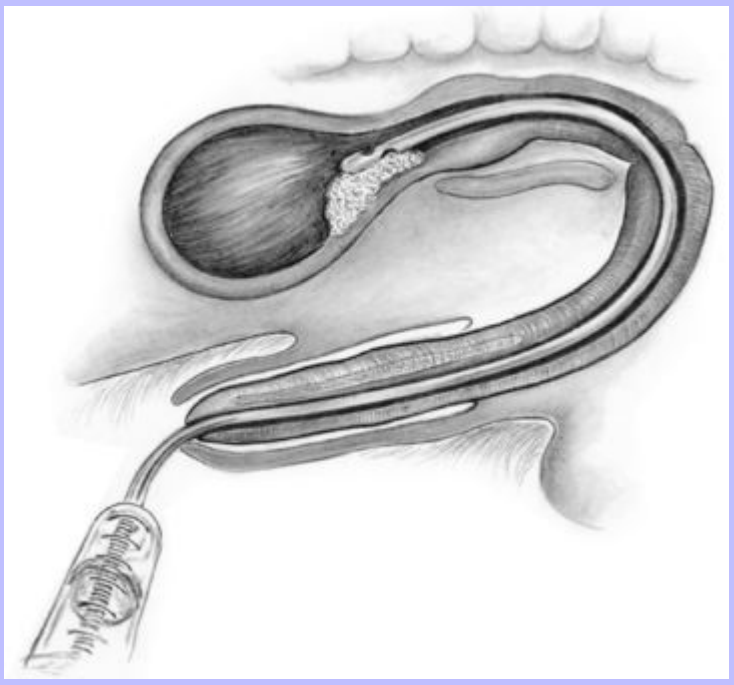


Figure 84-5 Urethroscopy of female Labrador retriever with incontinence since birth. Note the urethral lumen *(white arrow)* and the ectopic ureter entering the urethra *(black arrow)*. (Courtesy Dr. Patti Sura, Virginia Tech.)

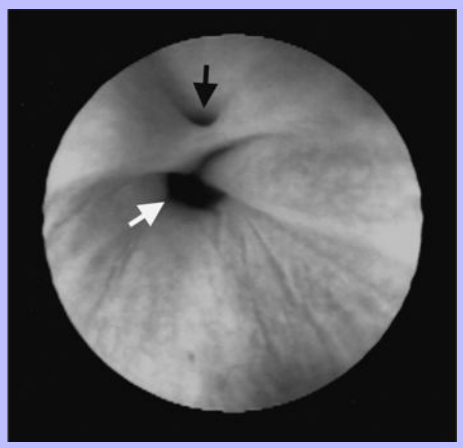


After the sample has been collected, negative pressure is released and the catheter is removed from the urethra. The tip of the catheter is placed in a vial, and additional saline is injected through the catheter to remove tissue samples. Any solid pieces of tissue should be placed in formalin and submitted for histologic evaluation. The remaining saline, containing small fragments of tissue, should be evaluated cytologically.

84.4 CYSTOSCOPY

Cystoscopy may be indicated for the evaluation of dogs or cats with hematuria, signs of lower urinary tract inflammation, recurrent urinary tract infections, urinary bladder or urethral masses, urolithiasis, and urinary incontinence. Procedures that can be performed include visualization of the urethral and urinary bladder mucosa, collection of tissue samples from masses or other lesions, removal of uroliths, collection of urine from individual ureters for diagnosis of renal hematuria or pyelonephritis, and identification and location of ectopic ureters (Figure 84-5). Rigid or flexible cystoscopes can be inserted through the urethra of female dogs and cats; however, only flexible endoscopes can be used in males.

301

302

Cystoscopy is performed under general anesthesia with the dog or cat in lateral or dorsal recumbency. Hair should be clipped around the vulva, and the area should be gently scrubbed with antiseptic solution. Sterile gloves should be worn to assemble the cystoscope. The tip of the cystoscope is lubricated and then gently inserted into the vestibule. Sterile saline is infused through the fluid port of the cystoscope to distend the mucosa and allow visualization of the urethral orifice (Figure 84-6). The scope then is inserted through the urethral orifice and advanced slowly, allowing the urethra to be distended so that it can be examined thoroughly. After the cystoscope has been advanced into the urinary bladder, urine is drained completely and the bladder is distended with sterile saline. The entire urinary bladder mucosa should be examined. It may be helpful to examine the urinary bladder when it is distended at low pressure and also at high pressure. After cystoscopy an antimicrobial (e.g., ampicillin) should be given for 5 days to prevent urinary tract infection secondary to bacterial contamination.

Figure 84-6 Urethral orifice on the ventral floor of the vagina in a female dog undergoing cystoscopy.

85 CHAPTER • 85 Cytology of Internal Organs

Amy L. MacNeill

A. Rick Alleman

Cytologic evaluation of internal organs is a powerful diagnostic technique. It is imperative that samples be collected and processed properly and that a well-maintained microscope is used. This chapter briefly describes proper sample handling and some diseases of internal organs that can be diagnosed cytologically.

85.1 ASPIRATE COLLECTION AND PREPARATION

Ultrasonography is recommended to guide sample collection and to monitor the dog or cat for bleeding. It is possible to obtain some samples without sedation. Aspiration of internal organs must be considered a sterile procedure. The center of large masses should be avoided, because this area is often necrotic. Multiple samples should be taken so that different areas of the lesion are represented. If fluid is collected, some should be smeared directly onto a slide, and the rest should be saved for determination of cell counts and protein content and concentration. If the fluid is bloody, it should be placed in an ethylenediamine tetra-acetic acid (EDTA) tube. Also, cytologic examination of touch preparations from nonfixed biopsy samples can be informative.

If generalized splenomegaly or hepatomegaly is detected, blinded aspiration can be performed but is not recommended. The animal should be placed in dorsal recumbency. A 6-to 12-cc syringe is attached to a 20-to 22-gauge, 1.5-inch needle. The needle is introduced into the caudodorsal aspect of the spleen or liver to avoid piercing the diaphragm. The plunger is pulled back to create 1 cc of vacuum. The needle position is carefully redirected within the organ. The pressure on the plunger is released, and the needle is withdrawn. The sample is placed near the frosted edge of a clean slide and smeared by placing a second slide flat onto the sample slide and pulling the second slide from the frosted edge to the open edge of the sample slide in one continuous, smooth motion. The weight of the second slide is sufficient to smear the sample. It is important not to pull the sample off the end of the slide.

Once a sample has been collected, it should be air dried and stained for cytologic examination. New methylene blue and Romanowsky-type stains are commonly used. If a slide is sent to a laboratory, it should be shipped separately from histology samples.

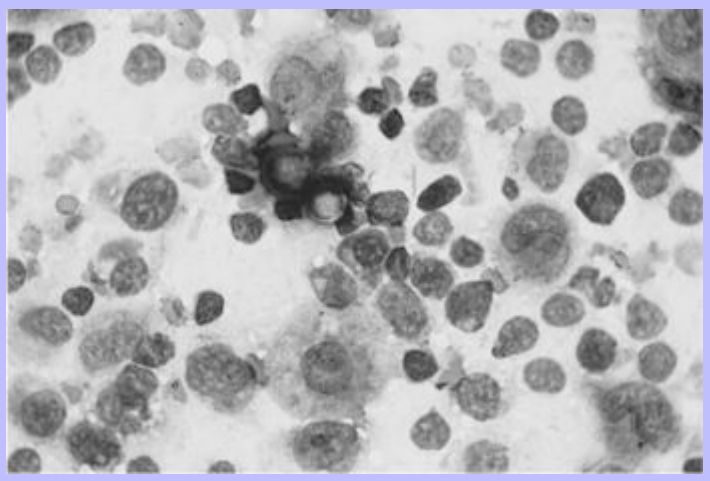
85.2 THORACIC ORGAN CYTOLOGY

85.2.1 Pulmonary Aspirates

Aspirates from normal pulmonary tissue tend to be hemodilute and contain low numbers of respiratory epithelial cells and macrophages. Inflammation caused by most bacterial agents is purulent, whereas fungal infections cause pyogranulomatous disease. Culture is recommended with most inflammatory samples. Several specific fungal diseases can be diagnosed cytologically, including blastomycosis (Figure 85-1). Carcinomas tend to exfoliate as sheets of epithelial cells with visible cell junctions, basophilic cytoplasm, and round nuclei. Acinar structures or punctuate cytoplasmic vacuoles may be observed with adenocarcinomas (Figure 85-2). Metastatic carcinomas can rarely be distinguished from primary lung tumors. As with most malignant lesions, features such as anisocytosis, anisokaryosis, prominent nucleoli, an increased nuclear to cytoplasmic ratio (N:C), mitotic figures, coarse chromatin, and multinucleation must be observed for diagnosis. Also,

inflammation can cause epithelial cells to have characteristics of malignancy; neoplasia, therefore, often cannot be reliably diagnosed if inflammation is observed.

Figure 85-1 Blastomycosis. Several round organisms, approximately 15 µm in diameter and having a nonstaining capsule, are characteristic of *Blastomyces* infection. Infiltrating macrophages and lymphocytes are also noted. (Wright-Giemsa stain, ×250.)



85.2.2 Heart-Based Tumors

Echocardiography and anesthesia are necessary to obtain aspirates of heart-based masses. Hemangiosarcomas exfoliate poorly and are hemorrhagic with low numbers of basophilic, spindle-shaped cells with large pleomorphic nuclei, multiple prominent nucleoli, and other features of malignancy. Erythrophagia may be noted within neoplastic cells and macrophages. Neuroendocrine tumors, including chemodectomas and aortic body tumors, contain aggregates of pale blue cytoplasm with indistinct cell borders that are associated with round “naked” nuclei (Figure 85-3). Minimal characteristics of malignancy are seen with large heart-based masses because these tumors tend to be benign.

Figure 85-2 Adenocarcinoma, lung. Epithelial cells arranged in an acinar structure are pictured. Note the marked anisokaryosis and prominent nucleoli. (Wright-Giemsa stain, ×250.)

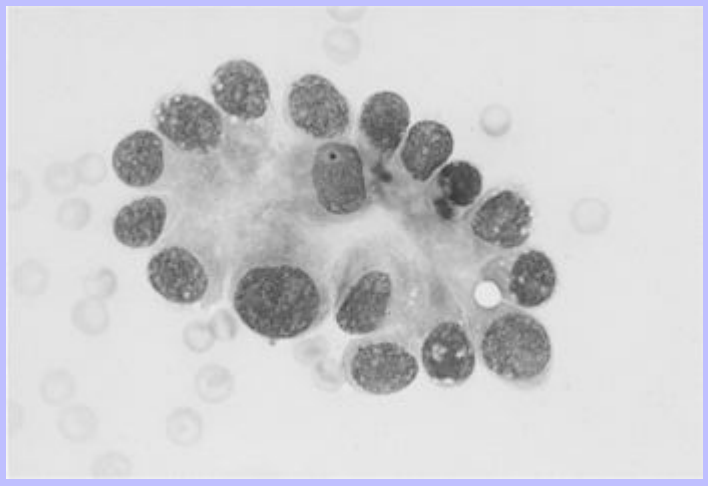


Figure 85-3 Heart-based neuroendocrine tumor. Round “naked” nuclei with single prominent nucleoli can be seen. (Wright-Giemsa stain, ×250.)

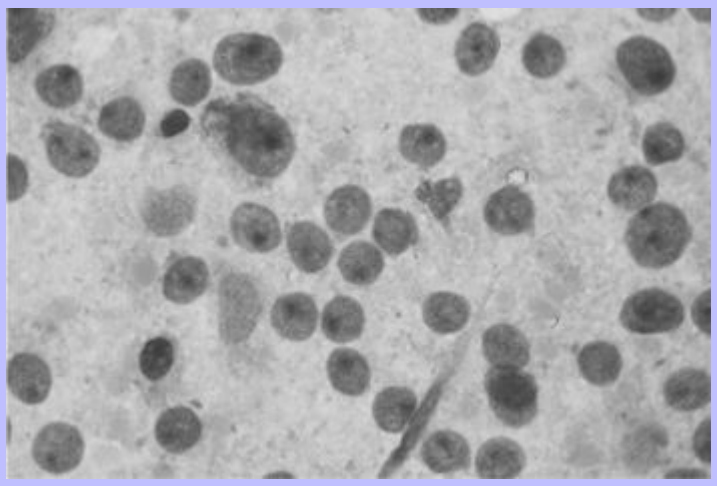

85.2.3 Thymus

Thymic enlargement can be caused by a thymoma or thymic lymphoma. Thymomas contain large clusters of thymic epithelial cells, large numbers of small lymphocytes, low numbers of intermediate to large lymphocytes, and mast cells (Figure 85-4). Thymic epithelial cells have a moderate amount of blue-grey cytoplasm and single round nuclei. Eosinophilic material may be associated with the cells. Thymic lymphomas have a predominant

population of intermediate or large lymphocytes with scant, deeply basophilic cytoplasm, round to pleomorphic nuclei, and prominent nucleoli.

85.3 ABDOMINAL ORGAN CYTOLOGY

85.3.1 Liver

Normal hepatocytes are large cells that occur in clumps with distinct cytoplasmic borders and abundant, basophilic cytoplasm (Figure 85-5). The nuclei are round and contain a distinctive, large, single nucleolus. 303
Vacuolar degeneration is a common cytologic finding and is classified as either glycogen or lipid accumulation. 304
Glycogen accumulation appears as a diffuse cytoplasmic clearing that is most prominent in the periphery of the cytoplasm (Figure 85-6). Glycogen accumulation is seen in dogs with steroid hepatopathy, nodular hyperplasia, or idiopathic vacuolar degeneration. Hepatocytes with lipid accumulation contain discrete, clear cytoplasmic vacuoles (Figure 85-7). Severe lipid degeneration is almost exclusively seen in cats with hepatic lipidosis syndrome. However, mild to moderate lipid degeneration can be seen as a secondary response to diseases such as diabetes mellitus, pancreatitis, cholangiohepatitis, or hepatic lymphoma. Hepatic cholestasis is characterized by the presence of dark blue bile pigment within the cytoplasm of hepatocytes or in casts between adjacent hepatocytes. This is a common finding in hepatobiliary disorders and precedes the onset of icterus.

Figure 85-4 Thymoma. A cluster of thymic epithelial cells with a moderate amount of cytoplasm and large round nuclei are shown. Several small lymphocytes, low numbers of large lymphocytes, a neutrophil, and a mast cell are also present. (Wright-Giemsa stain, ×250.)

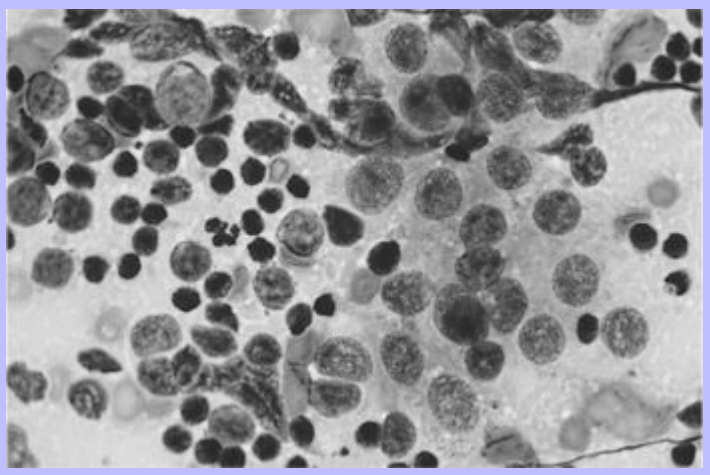

Figure 85-5 Normal liver. Hepatocytes have abundant cytoplasm, round nuclei, and single prominent nucleoli. (Wright-Giemsa stain, ×250.)

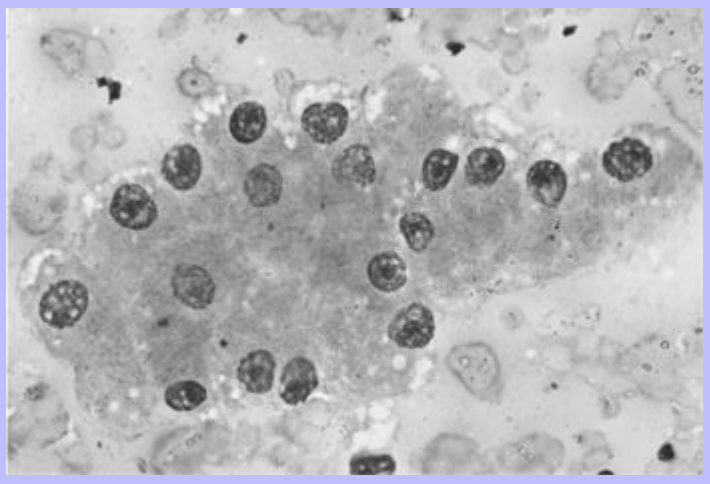

Due to the focal nature of many inflammatory lesions, cytologic identification of inflammatory liver disease may be difficult. Tumors commonly found in the liver include hepatocellular carcinoma (HCC), bile duct carcinoma, lymphoma, and hemangiosarcoma. The diagnosis of HCC is made when anaplastic cells with differentiation toward mature hepatocytes are aspirated from a hepatic mass. These cells have a cytoplasm similar to that of hepatocytes with nuclear features of malignancy, particularly a high N:C, anisokaryosis, and extremely prominent nucleoli. Bile duct carcinomas contain dense clusters of epithelial cells that are smaller than hepatocytes and have a very high N:C and scant, basophilic cytoplasm. Nuclear features of malignancy are usually present with the exception of nucleoli.

Figure 85-6 Steroid hepatopathy. Indistinct cytoplasmic vacuoles concentrated at the borders of hepatocytes indicate excess glycogen storage in the liver. (Wright-Giemsa stain, ×250.)

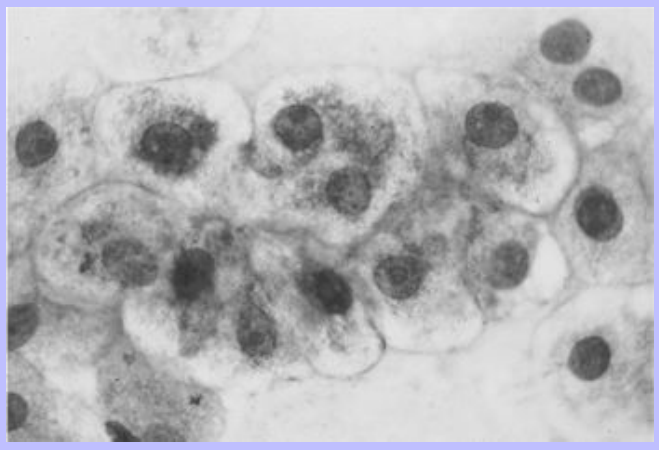

Figure 85-7 Hepatic lipidosis. The cytoplasmic vacuoles observed with lipid accumulation in the liver are large and distinct. (Wright-Giemsa stain, ×125.)

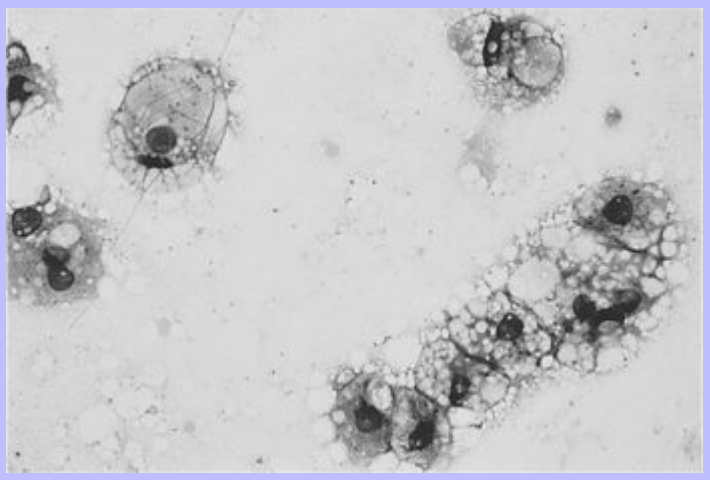

85.3.2 Spleen

Aspirates from normal spleen are hemodilute with clusters of splenic reticular elements, large numbers of small lymphocytes, moderate numbers of intermediate to large lymphocytes, and low numbers of plasma cells and mast cells. Common cytologic diagnoses associated with generalized splenomegaly are extramedullary hematopoiesis (EMH) and lymphoma. EMH may be observed when the peripheral demand for erythroid or myeloid cells exceeds production in the bone marrow. All stages of erythroid and myeloid precursors, as well as megakaryocytes, can be present. Splenic lymphoma is difficult to diagnose due to the mixed population of lymphocytes in a normal spleen. If a monomorphic population of either intermediate or large lymphocytes makes up greater than 70% of the cells, splenic lymphoma can be suspected. The most common cause of splenic nodules is nodular hyperplasia, which is indistinguishable from normal spleen when aspirated. Hemangiosarcomas, hemangiomas, or hematomas cause large hemorrhagic splenic nodules that can be difficult to differentiate cytologically.

85.3.3 Intestinal Tract

Intestinal aspirates tend to be poorly cellular with low numbers of epithelial cells. Lymphocytes may be seen due to lymphoid tissue associated with the intestine. Inflammatory bowel disease and lymphoma also have lymphocytes. In all of these cases, small lymphocytes can predominate, which prevents a definitive cytologic diagnosis. However, large granular lymphoma is easily diagnosed cytologically. Infectious diseases may also be observed. Figure 85-8 is an example of intestinal pythiosis. Intestinal carcinomas contain dense clusters of epithelial cells with deeply basophilic cytoplasm, round to pleomorphic nuclei, prominent nucleoli, an increased N:C, and other features of malignancy. Acinar formation is observed with adenocarcinomas (Figure 85-9).

85.3.4 Kidney

Aspirates of enlarged kidneys require anesthesia and ultrasonography. Renal aspirates are hemodilute with rare clusters of renal tubular epithelial cells that have abundant blue cytoplasm, distinct cell borders, and round nuclei. Clear cytoplasmic vacuoles may be seen. A diagnosis of lymphoma is made if increased numbers of lymphocytes are observed. Inflammatory lesions may be purulent or pyogranulomatous and should be cultured. Renal carcinomas are rare.

304

305

Figure 85-8 Pythiosis, intestine. *Pythium* organisms cause severe pyogranulomatous inflammation with increased numbers of eosinophils. Septate branching hyphal structures stain black with silver stain. (Grocott's methenamine silver [GMS] stain, ×250.)

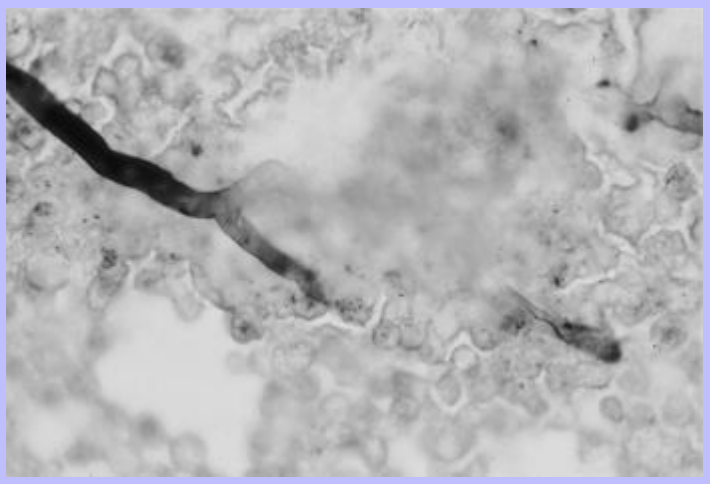

Figure 85-9 Adenocarcinoma, intestine. A cluster of intestinal epithelial cells with distinct cell borders, variably sized nuclei, an increased N:C, and multiple nucleoli are shown. Acinar formation is observed. (Wright-Giemsa stain, ×250.)

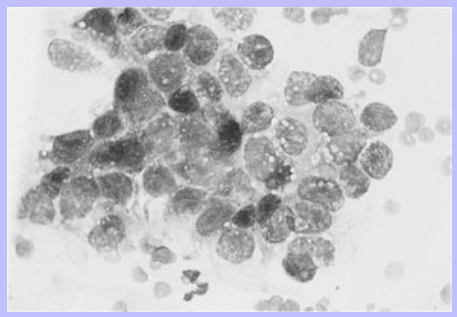


86 CHAPTER • 86 Cytology of the Skin and Subcutaneous Tissues

Deborah C. Bernreuter

Cytology should be regarded as a *rapid screening test* to determine if a biopsy, culture, or surgical excision is necessary. Quite often cytologic examination is the only test needed to arrive at a diagnosis, prognosis, and treatment plan. A representative cytologic sample at least can yield a short list of possible diagnoses. If the cytologic evaluation is not completely diagnostic, a biopsy is required to rule out or to confirm various differential diagnoses. When the cytologic results are considered in conjunction with the patient's history; the location, description, and duration of the lesion; the physical examination results; diagnostic imaging findings; and other laboratory determinations, the list of differential diagnoses becomes quite short.

86.1 REQUIRED EQUIPMENT

The following equipment is required for obtaining an adequate representative sample for cytologic evaluation:

- 22-gauge needle (21-to 23-gauge needles also can be used)
- 12-cc syringe
- Unused glass slides, preferably with frosted ends for ease of labeling
- Lavender-top tube (for fluid)
- Sterile swab (for fistulous tracts and mucous membranes) and saline
- Paper towel (for impression smears)

If the cytologic evaluation is to be done in-hospital, a good quality, well-maintained binocular microscope, a “quick” type of Romanowsky stain, and distilled water are also required.

86.2 PROCEDURE FOR SAMPLE COLLECTION

86.2.1 Samples from Solid Masses or Fluid-Filled Lesions

For solid masses and fluid-filled lesions, a 22-gauge needle on a 12-cc syringe is usually used to collect and transfer cells or fluid (or both) to several glass slides. Sedation or anesthesia can be used if required to reduce risk and unnecessary pain. Local anesthesia is not used on superficial lesions, because the pain associated with aspiration of a sample is no greater than the pain felt during injection of the local anesthesia. Skin preparation is the same as that required for a venipuncture or an injection. If the lesion will also be sampled for micro-biologic culture, surgical preparation should be done on the collection site.

Before the sample is collected, four glass slides should be made ready to receive it. This minimizes clotting of the sample in the needle, which can occur while slides are located to receive the sample. It is not necessary to submit more than four smears; even a single smear can be adequate if it is representative.

The needle is attached to the syringe while the plunger is depressed. One hand is used to grasp the lesion firmly to stabilize it, and the other hand is used to insert the tip of the needle deep into the mass. Inserting the needle

deeply into the mass yields a larger sample than inserting the needle only superficially. When the tip of the needle is in a representative location, the plunger of the syringe is pulled back as far as possible and *held* for a few seconds. *The plunger is never pumped!* The pumping action that is useful in the collection of bone marrow samples is harmful for cells in all other anatomic sites. It causes excessive tissue damage, and encourages bleeding and clotting (release of tissue thromboplastin). The direction of the needle within the mass should be changed only when the needle has been almost completely withdrawn so as to avoid excessive tissue destruction and subsequent lysis of cells, which would occur with an attempt to change the direction of the needle while it is still embedded in the mass. Aspiration can be done in two or three different orientations in the mass to collect the most representative sample. The hub of the needle where it is attached to the syringe must be watched; *blood must not be allowed to flow into the syringe*. Blood dilutes a previously representative sample and causes clotting. If blood appears while the plunger is withdrawn, the plunger (and thus the vacuum pressure) is released immediately. A needleful of cells is sufficient to make a dozen smears if necessary.

Only after the vacuum in the syringe has been released is the needle removed, first from the lesion and then from the syringe. A small amount of air is then drawn into the syringe, the needle is reattached, and the plunger is rapidly advanced *while the needle's tip is close to a glass slide* (i.e., not from a great height). In this way, the sample is expelled onto the slide intended, and it does not inadvertently shed a few cells onto the adjacent slide. On several occasions this author has identified misdiagnoses made because a few tumor cells or organisms were inadvertently sprayed onto adjacent slides, which, because they grossly appeared to be unused slides, were then used to prepare smears from a different patient. When slides are prepared to receive cytology samples, they should not be placed close to each other, to avoid overspray.

86.2.2 Liquid Samples

If the sample is liquid, only one drop of sample should be placed on each slide so that when the sample is smeared *rapidly* to make a feathered edge (and thus a monolayer of cells), *the entire smear will be one half to three fourths the length of the slide*. If too large a drop is accidentally expelled onto a slide, the excess is immediately reaspirated into the syringe. It is helpful if an assistant who can make a feathered edge is available to smear out the drop of sample as soon as one is placed on a slide, while additional drops are being placed on additional slides. If the sample consists of a large amount of fluid, a couple of feathered edge smears are made, and the remaining fluid is expelled into a lavender-top tube. *Watery fluid* is smeared correctly by raising the angle between the sample slide and the spreader slide to 50 to 60 degrees and smearing very quickly. *Thick fluid* is smeared to a monolayer by lowering the angle to 25 to 30 degrees and smearing slightly more slowly. Normal blood is smeared with a 45-degree angle. Any remaining fluid should be expelled into a lavender-top tube and mixed well to avoid clotting so that accurate cell counts can be attained and smears of concentrated cells can be prepared. The ethylenediamine tetra-acetic acid (EDTA) in the lavender-top tube is the preservative of choice for accurate cell morphology. Heparin can distort cells. Both the fresh smears and the fluid are submitted to the laboratory. At the laboratory, some of the fluid can be placed in a cytocentrifuge for production of concentrated smears. Cytocentrifuges concentrate the cells directly onto a small area of a glass slide, which is especially useful with fluids of low cellularity. In addition, some of the fluid can be centrifuged and a drop of sediment (or buffy coat smear, if the sample is very hemorrhagic) can be prepared, stained, and examined.

86.2.3 Semisolid Samples

If the sample is semisolid, another slide should be placed flat on top of the sample and the two slides should be gently pulled apart to make monolayers on both slides. With either the direct smear or the “pull” technique, *all smears should be thin enough to air dry within 1 minute*. The smears should be double-checked to ensure that they are completely dry before they are encased in a slide holder for transportation to a laboratory.

An *impression smear* can be useful with a biopsy sample. Before the biopsy sample is placed in formalin, its cut surface can be blotted with a paper towel to remove surface blood and tissue fluid and then touched to a glass slide several times to make an impression smear.

86.2.4 Samples from Mucous Membranes of the Vagina, Conjunctiva, and Mouth and from Fistulous Tracts

For sampling the mucous membranes of the vagina, conjunctiva, or mouth or for sampling fistulous tracts, a sterile swab moistened with saline can be used to swab the lesion. If the lesion is already moist, the saline is not needed. The tissue is swabbed, and the swab then is *rolled* onto a glass slide. *Never rub the swab on the slide;* it causes disruption of the cells.

86.3 COMMON MISTAKES TO AVOID IN COLLECTION AND PREPARATION OF CYTOLOGY/FLUID SAMPLES

The following common mistakes should be avoided in sample collection and preparation:

1. *Pumping the syringe plunger during collection*. This causes tissue destruction and lysis of cells and also increases the risk of clotting due to release of tissue thromboplastin.

2. *Using a syringe with a capacity of less than 10 cc*. If the syringe is too small, the vacuum pressure it creates is too weak, and the sample is often too small for adequate evaluation.

3. *Placing too large a sample on one slide*. If the drop of sample is too large, the consequences are (1) the largest cells are pushed off the end of the smear, resulting in a nonrepresentative sample; (2) a monolayer is not formed, and the smear will be too thick for evaluation; and (3) thick smears dry slowly, causing cell lysis and distortion.

4. *Failing to smear out the sample*. A drop of sample left in one place on the slide dries slowly, causing lysis, and forms a thick jumble of cells, which cannot be evaluated. If two cells are on top of each other, neither can be evaluated. If excessive cell fragility is present (as in some lymphomas and other tumors), the cells might not be able to survive smearing, and a biopsy would be necessary for evaluation.

5. *Refrigerating the smears*. When smears are placed in slide holders and then refrigerated, the ambient humidity from the room air in the holder condenses, causing droplets of water to fall onto the smears. Water is hypotonic and causes cell lysis; only a homogeneous, proteinaceous background is observed on cytology.

6. *Placing the slides in the slide holder before they are completely dry*. Slow drying causes lysis of cells. If cells are lysed and then placed near an ice pack while liquid, the cells crystallize into shapes of long spears, preventing evaluation.

7. *Submitting samples for cytology or fluid analysis without including the signalment, patient history, and other physical findings, as well as the anatomic location, a description, and the duration of the lesion.* Without these other parameters, only a description, not an interpretation, is possible.

8. *Submitting fluid without EDTA*. Fluid is always submitted for analysis in an EDTA tube, and a fresh smear is submitted as well for accurate cell counts (without clots).

86.4 DETERMINING THE CHOICE OF CYTOLOGY OR BIOPSY

The choice of cytology or biopsy depends on the type and location of the lesion. For discrete masses in the intradermal and subcutaneous tissues, a fine needle aspiration biopsy is often diagnostic. It is useful for identifying the mass as a site of inflammation, a cyst, or a solid tumor. In addition, if the lesion is a site of inflammation, the etiology (e.g., bacteria, fungal elements, yeast, parasites, or keratin debris from a ruptured epithelial cyst) can often be observed. Bacteria can be identified as cocci, rod shaped, spirochetes, possible anaerobes, mycobacteria, or a mixed population, which can be helpful in choosing an appropriate class of antibiotic while awaiting results of a culture and sensitivity test. If Gram stain is also available, additional samples can be used to determine Gram positivity or negativity. If the lesion is a solid tissue tumor, an experienced cytologist can further classify it as epithelial or mesenchymal in origin and list any criteria of malignancy observed. If it is a round cell tumor, cytology is often sufficient for diagnosis.

306
307

If the lesions are vesicular, however, such as pemphigus lesions, cytology is not useful. Instead, an intact vesicle (or at least the edge of a vesicle if none is intact) is gently excised, and the tissue is placed in formalin for biopsy. For other superficial lesions (e.g., ulcers) that are not associated with a mass, a biopsy of the edge of the lesion is usually more helpful than cytology. If a dermal mass has an ulcerated surface, impression smears of the lesion will contain only the secondary inflammatory cells and organisms; they will not be representative of the primary lesion underneath. For this reason, an aspirate of the deeper layers of the mass would probably be more representative.

87 CHAPTER • 87 Ear Flushing

Kinga Gortel

Most cases of acute otitis externa in cats and dogs can be managed by treatment with topical medications and ear cleaning administered by owners. There are, however, many instances in which in-clinic ear flushing is essential for the successful resolution of otitis. The most common indication for ear flushing is failure of owner-administered therapy to clear an infection within a reasonable period (2 to 4 weeks). Ears containing exudate that cannot be removed by simple cleaning respond poorly to topical medications, which are unable to reach the target tissue and pathogens. Another common indication is the presence of purulent exudate associated with Gram-negative bacteria, such as *Pseudomonas*. Ear flushing is also recommended when there is a suspicion of otitis media, a foreign body, or otic neoplasia.

Ear flushing allows evaluation of the ear canal and tympanic membrane, and myringotomy if necessary. It permits cleaning of the tympanic bulla and its sampling for culture and cytology. It also facilitates removal of foreign bodies and visualization and sampling of masses.

Complications from ear flushing are infrequent in dogs but more common, although usually transient, in cats. These include vestibular symptoms, deafness, Horner's syndrome, and facial nerve paralysis. The possible need for myringotomy to fully evaluate and treat a diseased ear should be explained to the owner. Owners are often unaware that the tympanic membrane usually heals after myringotomy. Ear flushing, however gentle, during another anesthetic procedure should be avoided unless the owner has been forewarned of possible side effects. It is important to understand the anatomy of the external and middle ear, because it may be severely altered by chronic inflammation.

If ear canal stenosis, glandular hyperplasia, or edema prevent passage of an otoscope tip, ear flushing should be postponed until the canal can be rendered more accessible by a 1-to 2-week course of topical and systemic corticosteroids (e.g., prednisone, 1 mg/kg given orally daily for dogs). If severe stenosis persists, surgical intervention is more likely to result in a favorable outcome than ear flushing and medical therapy.

Sedation suffices for ear cleaning only when minimal exudate is present; general anesthesia is required for full cleaning or myringotomy. An endotracheal tube with an inflated cuff is used to prevent lower respiratory tract contamination via the auditory tubes.

Bulla radiographs or computed tomography is recommended prior to the ear flush when otitis media is suspected. These procedures allow evaluation of otic structures, including the bulla.

Various ear flushing techniques utilizing hand-held and video-otoscopes have been described. The procedure should allow removal and sampling of exudate in the outer ear canal, a myringotomy if needed, and sampling and cleaning of the bulla.

Ear flushing in dogs utilizing a hand-held otoscope may be performed as follows. While the patient is prepared for anesthesia, swabs for culture and cytology are collected from each ear. The ear canals are then filled with a mild ceruminolytic ear cleaner. Once the dog has been anesthetized and intubated, an ear bulb syringe and warmed irrigation saline solution are used to gently remove the exudate and ear cleaner. All the ceruminolytic agent must be removed from the ear canal to prevent irritation. The ear canal must not form a tight seal with the bulb syringe in order to avoid tympanic rupture. A new bulb syringe should be used for each patient. Once the flushing yields clear fluid, the canal can be suctioned with an 8 French polypropylene catheter (cut to the desired length) on a 12-cc

syringe introduced through the otoscope. The tip of the catheter may be heated over a flame to smooth sharp edges. The ear should then be examined, and flushing should continue via the catheter until the canal appears clean. Repeated flushing, suctioning, and re-evaluation may be needed. An ear curette can be used to remove tenacious exudate, and grasping tools, such as alligator forceps, can be used to remove hair, wax balls, or foreign bodies. Finally, the ear canal should be thoroughly suctioned.

Ear flushing in cats is performed similarly. Pretreatment with a ceruminolytic agent is not recommended due to the higher incidence of complications from ear flushing in this species.

Video-otoscopy facilitates ear flushing procedures and permits documentation. Video-otoscopes provide greater magnification and resolution than hand-held units. Working channels allow simultaneous flushing and visualization. In contrast, when a hand-held otoscope is used, the visual field may be obscured by instruments and fluids.

Also, the stream of saline from the flushing catheter can be directed more effectively at adherent material using a video otoscope. A relatively simple technique uses a 5 French polypropylene catheter attached to a 20-cc syringe. An assistant flushes warmed saline solution in pulses while the tip of the catheter is moved within the ear canal by the operator. Pretreatment with a ceruminolytic agent and cleansing with an ear bulb syringe are still helpful but less necessary. Alternatively, a three-way stopcock may be attached by intravenous tubing to a 1 L bag of saline solution for flushing and to a syringe or suction apparatus for removing saline from the ear. A dual-port attachment may also be used for simultaneous infusion and suction.

After thorough cleaning, the area of the tympanic membrane can be evaluated. Obliteration of the tympanum in cases of chronic otitis is common but may be confusing unless one has extensive experience in observing the normal location of this structure. If the otoscope tip has been advanced as far as possible and the tympanum is not seen, it is likely absent. The intense light source in video-otoscopy may make the lining of the tympanic cavity appear reflective and white, confusing the operator by its similarity to the tympanum. If the tympanum is absent or partially ruptured, material from the middle ear is obtained by passing two sterile swabs into this area, preferably through a sterile otoscope cone. The first swab is cultured, and the second is used for cytologic evaluation. The middle ear cavity should be gently flushed to remove exudate or ceruminolytic agent.

Diagnostic and therapeutic myringotomy should be performed if otitis media is suspected, because the tympanum is frequently intact despite a middle ear infection. Otitis media should be suspected in cases of chronic, relapsing, or unremitting otitis, when the tympanum appears abnormal, when neurologic signs are present, or when radiographic evidence is present. Myringotomy allows collection of samples from, and thorough flushing of, the middle ear. After the ear canal has been cleansed and dried, the myringotomy incision may be made using a 5 French polypropylene catheter, an open-ended tomcat catheter, or a calcium alginate swab or with a short CO_2 laser pulse. The incision should be made in the caudoventral quadrant of the tympanic membrane to minimize the damage to the tympanic germinal epithelium and middle ear structures. The middle ear should be sampled and flushed as described above, using a catheter passed through the myringotomy incision.

Essential to the successful outcome of the ear flush is the ability to keep the ear clean, therefore topical and oral antimicrobial agents should immediately be initiated based on cytology. Once or twice daily ear cleaning by owners is prescribed, and a 1 week follow-up is scheduled. Saline solution may be used in an ulcerated ear or immediately after myringotomy. Oral corticosteroids are recommended to facilitate at-home treatment and to reduce the production of inflammatory exudate in painful or ulcerated ears. At the 1 week follow-up, topical and oral antimicrobial agents may be changed, based on the culture results, and a more effective ear cleaner prescribed.

88 CHAPTER • 88 Ear Vein Blood Glucose Monitoring

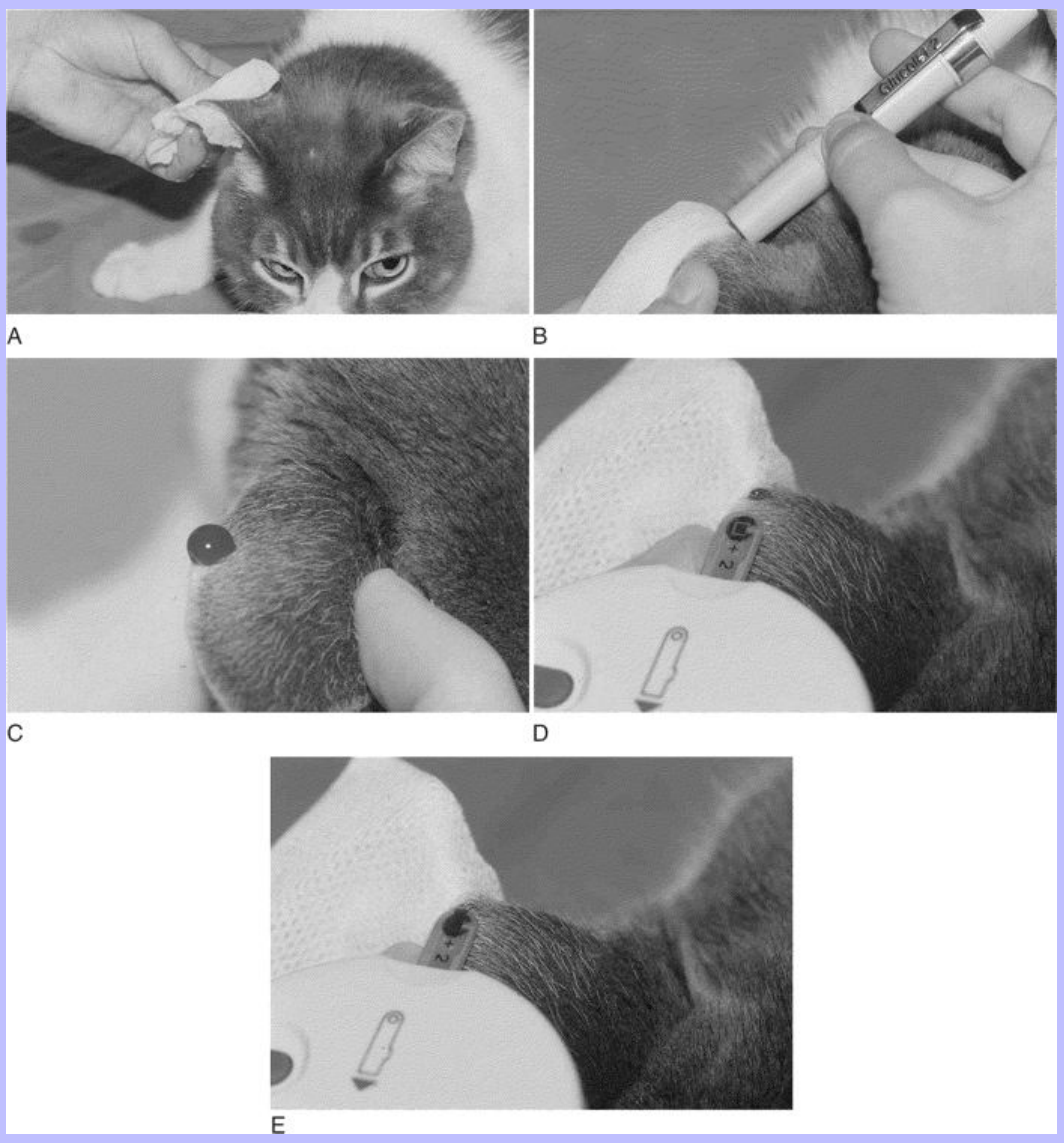
Melanie D. Thompson

In dog and cats with diabetes mellitus, owner observation of clinical signs and in-hospital evaluation of serial blood glucose curves are common methods both of assessing glycemic control and of determining the dosage and type of insulin to be used and the frequency of administration. For these blood glucose curves, affected dogs and cats are typically hospitalized and blood samples are collected at 1-or 2-hour intervals by means of direct venipuncture of a peripheral vein. Hospitalization, restraint for blood sample collection, and venipuncture have all been associated with stress hyperglycemia (especially in cats), and some hospitalized pets may not eat. This can complicate interpretation of the resulting blood glucose curve.

Most human diabetics perform self-monitoring of blood glucose concentrations using a portable blood glucose meter (PBGM) and capillary blood, which is collected by pricking a fingertip with a lancet device. Portable blood glucose meters are being used more frequently to generate serial blood glucose curves in diabetic dogs and cats. These meters are inexpensive, require only a single drop of blood for analysis, and provide results rapidly. In addition, the results obtained with these meters have been shown to correlate with those obtained by reference laboratories. When only a small amount of blood is required for analysis, use of an ear vein for blood sampling can minimize patient discomfort, preserve the integrity of peripheral veins, and decrease the need for physical restraint during sample collection. Recent studies have shown that the marginal ear vein nick technique is a reasonable alternative to venous blood collection for serial measurement of blood glucose concentrations. Studies have also shown good correlation between the glucose concentration of capillary and venous blood. Two methods of capillary blood sampling from the ear of dogs and cats are described here. Both methods are fast and easy to perform.

The first technique utilizes conventional lancet devices designed for pricking the fingertips of human beings. A device with a variable needle depth should be chosen. This allows the appropriate depth to be selected in order to provide an adequate amount of blood for the test (dogs usually require greater depth compared to cats). Although any portion of the inner pinna can be sampled, the marginal ear vein (MEV) usually results in the best sample. First the MEV is identified, then a warm, damp gauze sponge (or warm washcloth) is applied to it to increase perfusion as needed (Figure 88-1, *A*). A thin film of Vaseline can be placed over the sampling site in longhaired pets to allow the drop of blood to form without dissipating into the fur. The automatic lancing device should then be placed over the vein (Figure 88-1, *B*); the ejected needle will nick the ear, causing a drop of blood to form (Figure 88-1, *C*). The person performing the test should place a folded gauze sponge between the ear and the individual's finger to avoid an inadvertent nick. The PBGM with the test strip already inserted is then applied to the drop of blood to measure the blood glucose concentration (Figure 88-1, *D* and *E*).

Figure 88-1 **A,** A warm, damp gauze sponge is applied to the ear vein to increase perfusion. **B,** The automatic lancing device is placed over the ear vein. Note that the gauze is folded so that the individual performing the test does not inadvertently get nicked. **C,** After the ejected needle nicks the ear, a drop of blood will form. **D,** The PBGM with the test strip already inserted is applied to the drop of blood. **E,** The drop of blood is aspirated by capillary action into the reaction chamber after contact with the test strip.

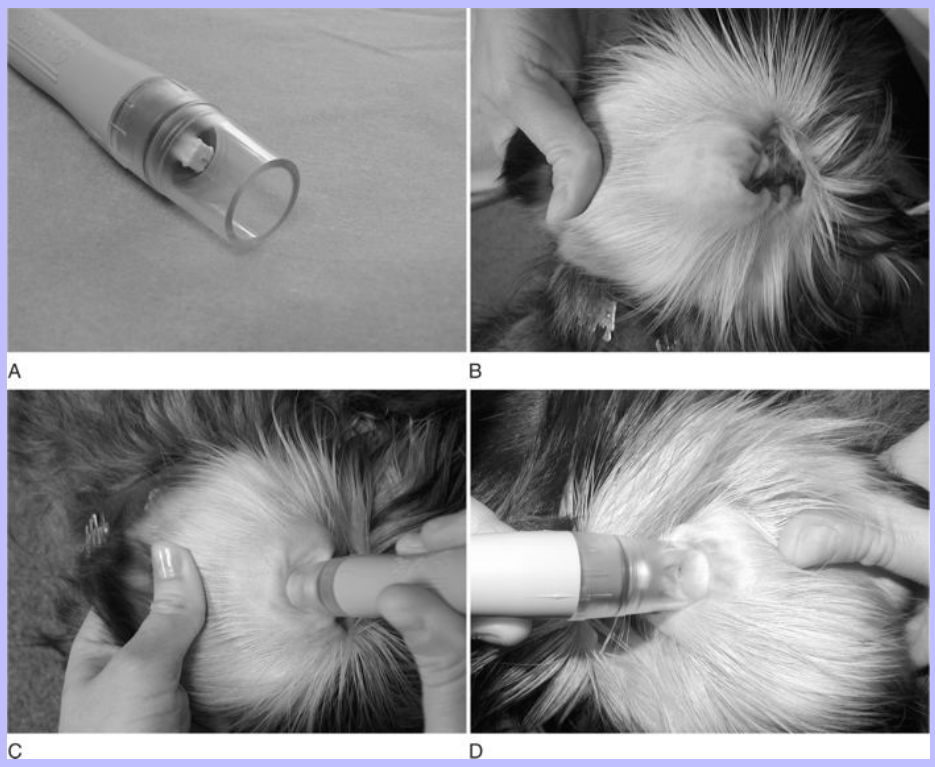


The second technique utilizes a vacuum lancing device, the Microlet Vaculance (Bayer Diagnostics, Tarrytown, New York), to facilitate collection of an adequate drop of blood (Figure 88-2, *A*). The device was designed to allow blood collection from body sites other than the fingertips in human beings. It also has variable needle depth. This technique allows sampling of the inner pinna in dogs and cats. The tip of the ear is held between the thumb and index finger, and the surface of the pinna is held flat by the rest of the fingers (Figure 88-2, *B*). The lancet device then is set on a nonhaired area of the ear. An airtight seal between the device and the ear is obtained by pushing the outer ear against the device with the tip of one finger. The entire edge of the endcap must be in contact with the skin (Figure 88-2, *C*). The site is lanced by pressing the plunger cap down until it comes to a complete stop. While pressure is maintained between the endcap and the skin, the plunger is slowly released. This creates a negative pressure, and the skin slightly bulges up into the endcap. The negative pressure is maintained until there is an adequate drop of blood (Figure 88-2, *D*). When an adequate drop of blood has formed, the plunger is pressed three fourths of the way down to release the vacuum and remove the device. The PBGM with the test strip already inserted is then applied to the drop of blood to measure the blood glucose concentration.

309

310

Figure 88-2 **A,** The Microlet vaculance (vacuum lancing device). **B,** The tip of the ear is held between the thumb and index finger. The surface of the pinna is held flat by the rest of the fingers. **C,** The lancet device is set on a nonhaired area of the ear. The outer ear is pushed against the device to form an airtight seal. **D,** After lancing the ear, pressure is maintained and the plunger is slowly released. Negative pressure causes the skin to bulge up into the endcap.



Clinicians should be aware that there are some important limitations to the use of a PBGM. In particular, several factors can affect the accuracy of the blood glucose concentrations obtained with these meters, including the level of training of the user, whether the meter is properly maintained, whether appropriate quality control checks are performed, whether the animal has any concurrent diseases, and the hematocrit of the animal. All PBGMs overestimate the blood glucose concentration of anemic animals. Dehydration results in falsely lower blood glucose concentrations. Other factors may also affect results, such as altitude, environmental temperature and humidity, hypotension, hypoxia, and the triglyceride concentration.

The Bayer Glucometer Elite (Bayer Diagnostics) is one of the easiest PBGMs to operate. It has no buttons to press. The meter automatically turns on when the test strip is inserted and turns off when the test strip is removed. It requires only 2 μL of blood, which is automatically aspirated by capillary action into the reaction chamber after contact with the test strip. The result is displayed in 30 seconds. It is important that the operator make sure the test strip is filled to the mark, because this meter starts the measuring process even if the test strip chamber is only partially filled with blood; this can result in an erroneously low blood glucose value.

A PBGM that is simple to operate should be chosen. Portable blood glucose meters are constantly being improved, and the result is greater precision, faster measurement, decreased blood volume, and decreased operator dependence. It is important to become familiar with the PBGM and perform routine maintenance. With practice, veterinarians, veterinary technicians, and veterinary students can become proficient in the techniques outlined here, and errors can be minimized. Ear vein sampling can become the routine method of generating serial blood glucose curves in the hospital. These techniques can also be taught to clients for home monitoring of blood glucose concentrations.

Owners also can be directed to web sites dedicated to diabetic pets, which contain information on home monitoring of glucose. In the search field, type “home monitoring of diabetic pets.”

89 CHAPTER • 89 Echocardiography

Marie-Claude Bélanger

Cardiac ultrasonography has become a powerful diagnostic tool in the noninvasive evaluation of the size, structure, function, and blood flow dynamics of the canine and feline heart. This chapter is designed to guide the practitioner through veterinary transthoracic echocardiography.

89.1 BASICS OF CARDIAC ULTRASONOGRAPHY

Propagation of sound waves is favored by fluids and soft tissue and inhibited by bone, metal, and air. The operator must therefore obtain a suitable air-free window between the ribs of the animal and ventral to the lungs. A *window* is described as a transducer location or region where the heart contacts the intercostal muscles, allowing adequate imaging of cardiac structures.

The basic idea of any ultrasound technique is that the probe emits a pulse of sound that penetrates the target tissue. A portion of that emitted ultrasound goes through the organ and is lost; another portion is reflected back to the probe. If considerable sound is reflected back (as occurs with the myocardium, for example), the structure is said to be *hyperechoic;* a hyperechoic structure appears on the screen as a whiter image. When very little of the sound is reflected back (as with blood or blood vessels), the structure is *hypoechoic* and appears dark on the screen.

Echocardiographic transducers are made of piezoelectric crystals that generate sound waves, which travel in cycles. The frequency of a probe is determined by the number of cycles sent out per minute. High-frequency transducers emit more cycles per time unit and thus have shorter wavelengths. These transducers reflect sound from smaller structures and therefore produce better image definition and resolution, but less tissue penetration, than low-frequency transducers.

Figure 89-1 **A,** Typical examination setting for echocardiographic studies in veterinary medicine. Rectangular or circular cutouts allow the transducer to be introduced from the bottom of the scanning table. **B,** The animal is held in lateral recumbency with the shaved thoracic window over the hole. The examiner is scanning from the right parasternal location.

89.1.1 Equipment

The quality of images obtained from echocardiographic studies depends on the sophistication and technology of the ultrasound machine, the skill and experience of the operator, and the individual patient's characteristics. Echocardiograms can be obtained from an upright position, but lateral recumbency on a table with an opening that allows examination from beneath the animal is optimal, because this arrangement creates a larger echo window. Sector scanning transducers are recommended for cardiac studies in veterinary medicine, because the small intercostal space of our patients limits the size of the available acoustic windows. The choice of transducer is directed by the size of the patient, because tissue penetration is inversely proportional to the frequency of the probe. In other words, the higher the frequency of the probe, the less the tissue penetration. Cats and small dogs usually require a 7.0 MHz transducer. A 5.0 MHz probe is appropriate for most dogs. For very large dogs, a 3.5 MHz transducer may be required to obtain optimal tissue penetration.

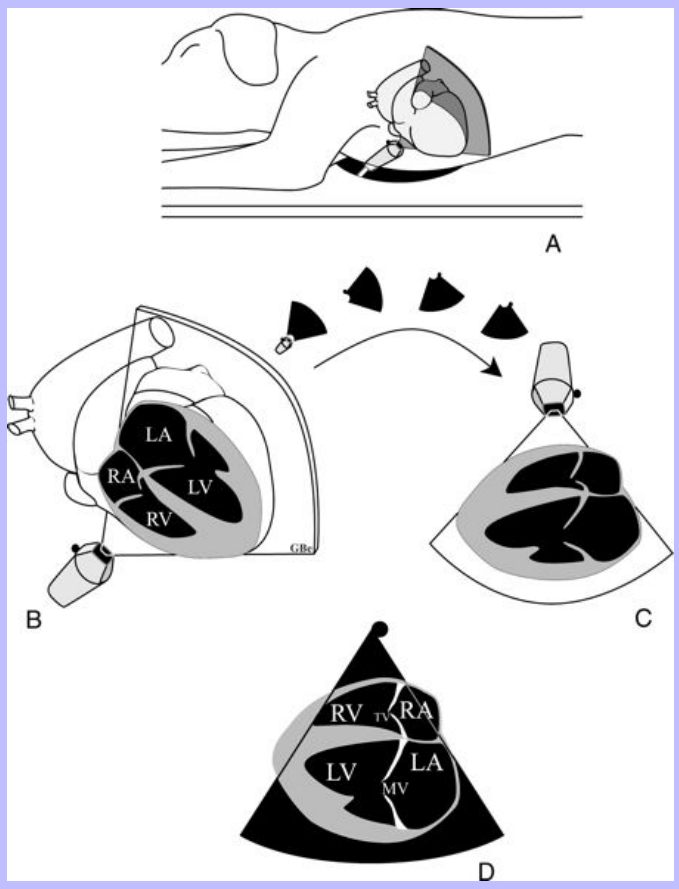
89.1.2 Technique

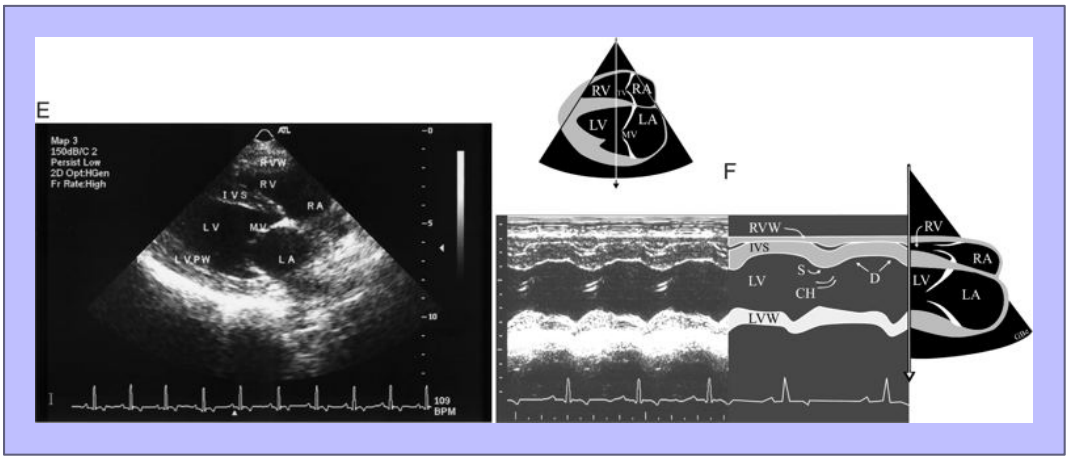
In animals, the hair is usually clipped to improve skin contact and image quality, and coupling gel is applied over the right or left precordial impulses. However, shaving may not be required for dogs with very short hair. Also, one should always warn breeders before shaving a show dog! Application of alcohol or water can sometimes replace the coupling gel; either of these provides good but briefer contact. The animal is restrained in lateral recumbency on a special table with an imaging opening (Figure 89-1). The patient's forelimbs should be gently pulled cranially by a technician to keep the elbows out of the acoustic window. The probe is placed 311
on the prepared area and twisted, tilted, or slid as needed to find a good window for optimizing the quality of 312
images from the cardiac structures. A complete echocardiographic study includes two-dimensional (2-D), M-mode, and Doppler examinations.

An echocardiogram can usually be performed in animals with minimal or no chemical restraint. On the other hand, sedation has the advantage of minimizing stress and poor image quality in squirmy patients. Low doses of ketamine hydrochloride (2 to 5 mg/kg given intravenously [IV] or intramuscularly [IM]), alone or with midazolam (0.1 to 0.2 mg/kg given IV or IM), can be used on asymptomatic fractious cats. A combination of butorphanol (0.2 mg/kg IM) and midazolam (0.1 to 0.2 mg/kg IM) is a good alternative when one wishes to avoid the positive chronotropic effect of ketamine or when sedation is necessary in a cat with congestive heart failure. An opiate (buprenorphine, 0.0075 to 0.01 mg/kg IV) with acepromazine (0.03 mg/kg IV) can be helpful in uncooperative dogs. Oxymorphone (0.05 mg/kg IM) with midazolam (0.2 mg/kg IM) is the protocol used by the author when sedation is needed in a cardiac dog, although other options are also utilized.

The potential influence of the sedation used must be considered in the interpretation of echocardiograms. For example, an increased heart rate, a decreased left ventricular (LV) internal diameter in diastole, an increased septal and left ventricular wall thickness, and a decreased fractional shortening are observed in most cats sedated with ketamine. Also, the potentially hazardous side effects of some sedatives must be considered in the decision on whether to chemically restrain a compromised cardiac patient.

Figure 89-2 **A,** Typical positioning of the animal for visualization of the right parasternal long axis view. In the dog, the long axis of the heart is parallel to an imaginary line connecting the shoulder to the xiphoid. **B,** Spatial orientation of the right parasternal location, long axis four-chamber view. **C,** Spatial orientation of the right parasternal location, long axis four-chamber view as observed on the ultrasound monitor. **D,** Illustration of the different cardiac structures observed with this window. **E,** Real-time 2-D image of the right parasternal location, long axis four-chamber view. **F,** Corresponding M-mode image obtained from this window. The heart is seen as it fills and empties (diastole and systole). *CH,* Chorda tendineae; *D*, diastole; *IVS,* interventricular septum; *LA,* left atrium; *LV,* left ventricle; *LVPW,* left ventricular posterior wall; *MV,* mitral valve; *RA,* right atrium; *RV,* right ventricle; *RVW,* right ventricular wall; *S*, systole; *TV*, tricuspid valve.





89.2 NORMAL CARDIAC ULTRASONOGRAPHIC EXAMINATION

89.2.1 2-D Echocardiography

Two-dimensional echocardiography is used to evaluate the cardiac structural changes resulting from congenital defects or cardiac diseases. It produces a real-time anatomic evaluation of the heart throughout the cardiac cycle. A complete 2-D study involves imaging of all valves and great vessels, as well as the relative size and wall thickness, of the cardiac chambers.

89.2.1.1 Common 2-D Echocardiographic Positions

The animal is first imaged from its right side. The transducer is placed on the right side of the chest wall just dorsal to the sternum at the fourth or fifth intercostal space. This typical position is called the right parasternal location. The views routinely performed from the right parasternal location are the long axis four-chamber view, the long axis left ventricular outflow view, and the different short axis views described in Figures 89-2 and 89-3. Conventionally, echocardiographic views are named from the positioning of the transducer and the structures that are examined (e.g., right parasternal long axis view). The right and left parasternal positions are used most often, but a multitude of planes can be obtained to better visualize a distinct part of the heart. The subcostal or subxiphoid position is an example of another window used to specifically evaluate the left ventricular outflow tract (LVOT) in the dog. The long axis view is obtained by an imaging plane that transects the heart parallel to its long axis from apex to base; a perpendicular imaging plane is performed to obtain the short axis view (see Figures 89-2 to 89-4). Technically, this means that the short axis views can be obtained from the long axis views by a 90-degree rotation of the probe.

312
313

The second half of the echocardiographic study consists of the left-sided views. As opposed to the right parasternal location, there are two acoustic windows on the left side. The left cranial parasternal views are obtained at the level of the fourth intercostal space, and the left caudal (apical) parasternal views are best visualized from the fifth to sixth intercostal spaces (see Figure 89-4). Table 89-1 presents useful tips for optimizing the imaging of the canine and feline heart in some situations.

Table • 89-1 Tips for Optimizing Small Animal Echocardiography

REQUIREMENT/PROBLEM	OPTIMAL IMAGING
The view required is the right parasternal long axis view.	Make sure the dot on the probe points toward the shoulder of the animal.
The view required is the right parasternal short axis view.	Make sure the dot on the probe points toward the elbow of the animal.
Structures from the right side of the heart are difficult to image.	Image the right side of the heart from the left parasternal location.
A specific cardiac structure is difficult to visualize.	Remember the three ways the probe can be moved: twisting, tilting, and sliding.
The right parasternal location must be used in a brachycephalic breed.	Position the probe closer to the sternum than is done in other breeds.
Optimal image of one extremity of the heart (apex or base) cannot be obtained.	Slide one intercostal space cranially or caudally.
Horizontal lines with a hazy image are observed.	Add coupling gel to improve poor transducer contact.
Resolution of the structures in the lateral field is decreased.	Decrease the overall gain.
Near-field resolution is poor in very small patients.	Change to a higher frequency probe.

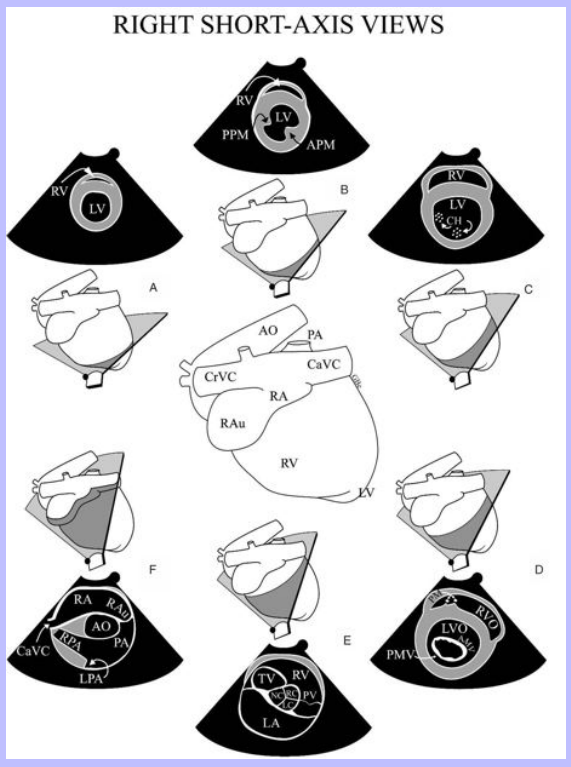
89.2.2 M-Mode Echocardiography

The term *M-mode* refers to real-time *motion-mode*. M-mode echocardiography is used to evaluate the phasic motion of the cardiac structures during the cardiac cycle. M-mode echocardiography complements the 2-D echocardiogram, because it has a higher sampling rate, which allows good resolution of rapidly moving structures. It is especially useful for recording subtle changes in wall and valve motion and for performing accurate measurements of chamber diameters and wall thicknesses. The M-mode image is viewed on a video screen, on which the depth of the structures is plotted on the *Y* axis and time is shown on the *X* axis. Only the structures transected by the cursor are seen on the M-mode images. The steerable cursor scrolls across the heart, and the associated changes in thickness or position of the structures are recorded on the screen as the heart fills and contracts (see Figure 89-2, *F*).

313

315

Figure 89-3 Standard 2-D echocardiographic study obtained from the right parasternal transducer location; short axis views are at the level of the apex **(A),** the papillary muscles **(B),** the chordae tendineae **(C),** the mitral valve **(D),** the aorta **(E),** and the pulmonary arteries **(F).** *AMV,* anterior mitral valve cusp; *APM,* anterior papillary muscle; *CaVC,* caudal vena cava; *CH,* chorda tendineae; *CrVC,* cranial vena cava; *LA,* left atrium; *LC*, left coronary aortic cusp; *LPA,* left pulmonary artery; *LV,* left ventricle; *LVO,* left ventricular outflow; *NC,* noncoronary aortic cusp; *PA,* pulmonary artery; *PM*, papillary muscle; *PMV,* posterior mitral valve cusp; *PPM,* posterior papillary muscle; *PV,* pulmonary valve; *RA,* right atrium; *Rau,* right auricle; *RC,* right coronary aortic cusp; *RPA,* right pulmonary artery; *RV,* right ventricle; *RVO,* right ventricular outflow; *TV,* tricuspid valve. (Modified from Thomas WP, Gaber CE, Jacobs GJ: Recommendations for standards in transthoracic two-dimensional echocardiography in the dog and cat, Echocardiography Committee of the Specialty of Cardiology, American College of Veterinary Internal Medicine, *J Vet Intern Med* 7:247–252, 1993.)



In veterinary medicine, M-mode echocardiography is generally performed only from the right parasternal location. The usual M-mode echocardiogram includes an evaluation of the left ventricle (see Figure 89-2, *F*) and of the mitral valve and aortic root (Figure 89-5). As recommended by the American Society of Echocardiography (ASE), end-diastolic measurements are taken at the onset of the QRS complex, and end-systolic measurements are taken at the level of the maximal excursion of the interventricular septum. The *leading edge method* is used; that is, the measurements of each echo line are made beginning at the edge that is closest to the transducer. The sonographer should be aware that a tremendous potential exists for artifactual measurements when the M-mode image is obtained in a suboptimal plane (e.g., tangential slices).

The left ventricular M-mode study provides absolute measurements of the left ventricular walls and chamber during systole and diastole. It can be performed using the right parasternal long axis four-chamber view (see Figure 89-2, *F*) or the right parasternal short axis view at the level of the papillary muscles (see Figure 89-3, *B*). Tables 89-3, 89-4, and 89-5 describe the normal M-mode echocardiographic values used in cats and dogs. These M-mode measurements are also used to evaluate the left ventricular systolic function by calculation of the ejection phase indices (as described later in the chapter under Evaluation of Cardiac Function).

89.3 DOPPLER ECHOCARDIOGRAPHY

Spectral and color flow Doppler imaging techniques are used to evaluate blood flow velocity and direction in the heart and great vessels. The transducer generates ultrasound waves, which are reflected off the red blood cells. The change in frequency between the sound transmitted by the transducer and the sound received by it is called the *Doppler shift* (Δf). Because velocity = frequency × wavelength, the magnitude of the Doppler shift is directly proportional to red blood cell (RBC) velocity:

$$\Delta f = \frac{2f_0 \times V \times \cos\Theta}{C}$$

Where f_0 is the frequency transmitted by the transducer; V is the flow velocity of RBC in meters per second (m/sec); Θ is the intercept angle; and C is the speed of sound in blood (1540 m/sec).

Doppler echocardiography assesses the direction and velocity of blood flow. Blood moving toward the transducer creates a positive frequency shift encoded in red on color Doppler and is displayed above the baseline of spectral Doppler. Blood flow moving away from the transducer is blue and is inversely displayed as a negative flow profile under the baseline (Figure 89-6).

89.3.1 Spectral Doppler

Cardiac spectral Doppler study uses imaging planes that align the sound beam along the blood flow. A marker is represented on the cursor line that corresponds to the sampling volume or *gate* where the flow is interrogated. The parallel beam positioning is in contrast to the M-mode, in which the beam is oriented in a perpendicular manner to visualize the cardiac structures. When Doppler studies are performed, care must be taken to align the Doppler beam with the jet flow (intercept angle <20 degrees) to minimize underestimation of the flow velocity.

Flow signals are displayed with time on the horizontal axis and velocity on the vertical axis. Two types of spectral Doppler are used clinically, *pulsed wave (PW) Doppler* and *continuous wave (CW) Doppler*. An intermediate between PW and CW Doppler, called *high pulse-repetition frequency (HPRF),* is another type of spectral Doppler, one that is used less frequently. Spectral Doppler is helpful in the assessment of pressure

gradients, intracardiac chamber pressure, regurgitant fractions, shunt ratios, valve area, effective orifice area, and cardiac output.

In veterinary medicine, spectral Doppler is often used to calculate *instantaneous pressure gradients* (ΔP) across a stenotic area or regurgitant valve. The maximal pressure gradient is calculated from the maximal flow jet velocity *(v)* using the modified Bernoulli equation:

$$(\Delta P) = 4v^2$$

The peak pressure gradient, along with the determination of the effective orifice area and other 2-D and M-mode echocardiographic findings, is used in the clinical assessment of the severity of stenosis.

89.3.2 Pulsed Wave Doppler

PW Doppler uses a single crystal transducer that transmits and receives the Doppler signal. Short pulses of ultrasound are produced, and the returning echoes from a specific sample volume are analyzed. The main advantage of PW Doppler is the possibility of interrogation of the direction, velocity, and spectral characteristics (laminar versus turbulent) of the blood flow from a distinct anatomic region of the heart or blood vessels. Laminar flows are characterized by the similitude of the velocities within the flow profile, which creates a Doppler signal with less disparity in velocity and little spectral broadening (see Figure 89-6). 315
Turbulent flow profiles are broad, and the area under the curve is filled in because the transducer is receiving 318
many frequency shifts associated with variable velocities. The disadvantage of PW Doppler lies in a maximal measurable velocity, called the *Nyquist limit,* that cannot be exceeded because of a limited pulse-repetition frequency. In other words, PW Doppler is only accurate when measuring low velocities.

Figure 89-5 Standard M-mode views obtained at the level of the mitral valve *(A)* and the aortic valve *(B)*. **A,** The mitral valve is seen as an M shape. During rapid ventricular filling (early diastole), the mitral valve is forced to open up toward the interventricular septum. As ventricular filling progresses, the pressure in the left atrium equalizes with the left ventricular pressure and the mitral leaflets move toward each other. The mitral leaflets open again during atrial contraction. Closure of the mitral valve occurs after atrial systole. **B,** During diastole, the line in the middle of the aorta represents the closed aortic cusps. During systole, the aortic valve opens toward the walls of the aorta, remains open during the systolic ejection of blood, and then rapidly closes at the end of systole. *AO,* Aorta; *AOV,* aortic valve; *D,* diastole; *IVS,* interventricular septum; *LA,* left atrium; *LV,* left ventricle; *LVW,* left ventricular wall; *MV,* mitral valve cusp; *RA,* right atrium; *RV,* right ventricle; *RVW,* right ventricular wall; *S,* systole.

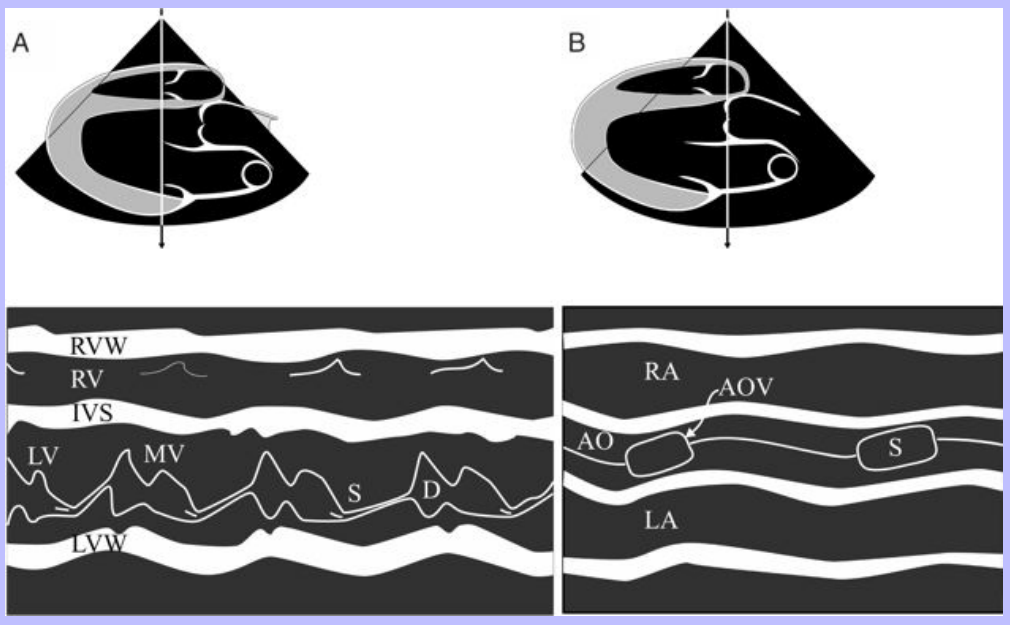

Figure 89-6 Normal left ventricular systolic outflow signal measured from the apical five-chamber view with PW Doppler.

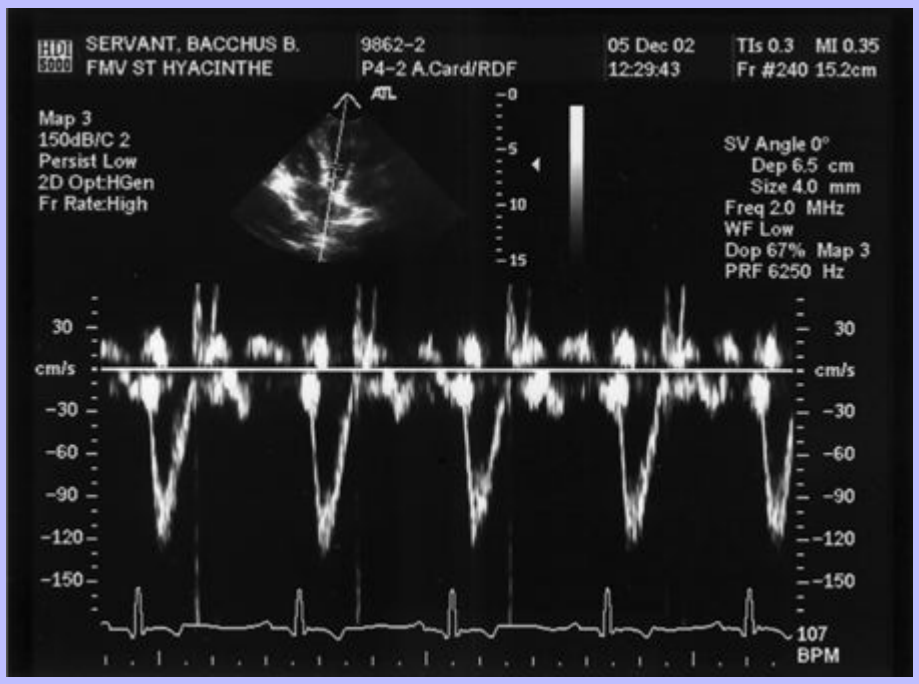


PW Doppler is very useful in the evaluation of valvular blood flow patterns. Diastolic flows across the atrioventri-cular valves have similar patterns, which are characterized by an initial high-velocity signal associated with the rapid ventricular filling known as the *E wave*, followed by a lower velocity signal produced by the atrial contraction, or *A wave* (Figure 89-7). The flow patterns across the semilunar valves are characterized by a rapid acceleration during ejection followed by a more gradual deceleration. The variance of these valvular flow patterns is studied to identify different valvular diseases as described elsewhere. Table 89-6 describes the normal values for valvular spectral doppler echocardiographic velocities in dogs and cats.

318

319

89.3.3 Continuous Wave Doppler

CW Doppler uses dual crystals for simultaneous transmission and reception of the Doppler signal. Very high velocity flows can be recorded with CW Doppler, because there is no Nyquist limit. The disadvantage of CW Doppler is that the specific location and characteristic of flow cannot be documented, because all velocities are measured along the cursor line.

PW and CW Doppler, therefore, are complementary, and both techniques are used to accurately describe the location, quality, and maximal velocity of an abnormal flow jet.

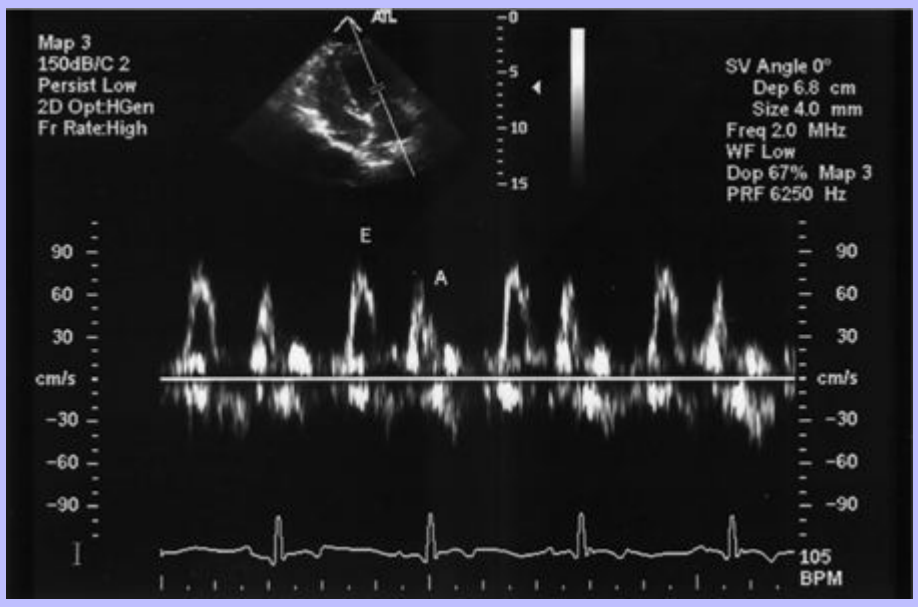
89.3.4 Color Flow Doppler

Color flow Doppler is a form of PW Doppler. Its primary clinical use is the detection of flow disturbances. The Doppler shift is encoded with a color map, which usually uses red, blue, and green to produce other color shades such as cyan, yellow, and white. Conventionally, blood moving away from the probe is blue, whereas blood moving toward the probe is red. This color map configuration is called the BART display (Blue/Away and Red/Toward). Color Doppler is very helpful for appropriately aligning with flow jets, searching for modest insufficient jets, describing the size and shape of regurgitant jets, identifying areas of turbulent flow, and confirming some cardiac shunts seen on 2-D echocardiograms. Turbulent flow is characterized by disparate velocities within the sampled area, which appears as a disorganized flow with a mosaic pattern. Several transducer positions and planes are used to find the optimal color flow imaging of a specific cardiac structure.

89.4 SPECIAL ECHOCARDIOGRAPHIC TECHNIQUES

Other echocardiographic techniques can provide useful information in the imaging of the canine and feline heart. These techniques include transesophageal and three-dimensional (3-D) echocardiography. Although useful in the clinical setting, these imaging methods have limited application in veterinary medicine, because they require expensive equipment. Transesophageal echocardiography requires general anesthesia, which increases the time and cost of the procedure.

Figure 89-7 Spectral Doppler recording of a normal mitral flow obtained from the left apical position with the PW Doppler gate located in the left ventricular inflow tract. The E point represents the rapid ventricular filling. The A wave corresponds to the atrial contraction.



Contrast echocardiography is another useful imaging method in the clinical evaluation of the cardiovascular system. It now is mostly used when Doppler echocardiography is unavailable. Microbubbles (obtained from the agitation of a syringe filled with 3 to 10 mL of physiologic saline) can be injected in a peripheral vein to assist in the diagnosis of right-to-left intracardiac shunting. The microbubbles reflect ultrasound and do not cross pulmonary or systemic capillaries, and they are reabsorbed by the pulmonary capillaries. In a normal patient, therefore, microbubbles injected into the cephalic vein stay on the right side of the heart. When right-to-left shunting is present, microbubbles are also observed in the left side of the heart.

89.5 EVALUATION OF CARDIAC FUNCTION

89.5.1 Cardiac Size and Chamber Dilatation

Cardiac chamber dimensions are determined by M-mode echocardiography and sometimes by 2-D echocardiography. Table 89-2 summarizes the most common etiologies for anomalies in chamber size.

The *E point to septal separation (EPSS)* is a very useful parameter in the assessment of left ventricular dilatation and systolic dysfunction. EPSS measures the distance from the maximal opening of the mitral valve (E point) to the endocardial aspect of the interventricular septum (Figure 89-8). In the normal heart, the mitral valve opens in diastole, and its anterior leaflet almost contacts the interventricular septum. In dilated hearts with decreased contractility (e.g., dilated cardiomyopathy), the mitral valve does not reach the septum. Reports in human medicine have shown that the size of the left ventricle alone does not alter the EPSS unless systolic dysfunction is present.

The *left atrial to aortic ratio (LA: Ao ratio)* is used to estimate the degree of left atrial enlargement. It compares the M-mode diameter of the left atrium in systole to the diameter of the aorta in diastole. This ratio is best obtained from the right parasternal short axis view but may also be evaluated from the right parasternal long axis view. The M-mode LA: Ao method has often been criticized because of the subjectivity of the cursor placement. This method underestimates left atrial size if the cursor does not reach the body of the left atrium. Conversely, it overestimates the relative left atrial size if a tangential plane of the aorta is performed. The reported LA: Ao ratio in normal dogs and cats is less than 1.3.

Table • 89-2 Common Etiologies for Anomalies in Cardiac Chamber Size

ANOMALY	ETIOLOGY
Left ventricular dilatation	Volume overload
	Mitral regurgitation
	Right-to-left shunting
	Aortic insufficiency
	Dilated cardiomyopathy
	High output stage
	Hyperthyroidism
	Anemia
Left ventricular reduction	Volume depletion
	Severe dehydration
	Hypoadrenocorticism
	Hypovolemic shock
	Inadequate blood return to the left heart
	Dirofilariasis
	Tetralogy of Fallot
Left ventricular hypertrophy	Pressure overload
	Aortic stenosis
	Hypertension
	Hypertrophic cardiomyopathy
	Infiltrative myocardial disease
Right ventricular dilatation	Volume overload
	Tricuspid regurgitation
	Atrial septal defect
	Dilated cardiomyopathy
Right ventricular reduction	Cardiac tamponade
	Volume depletion
Right ventricular hypertrophy	Pressure overload
	Pulmonic stenosis
	Tetralogy of Fallot
	Cor pulmonale
	Pulmonary hypertension
	Dirofilariasis
	Feline hypertrophic cardiomyopathy
	Feline restrictive cardiomyopathy
Left atrial enlargement	Chronic degenerative mitral valve disease
	Dilated cardiomyopathy
	Left-to-right shunting
	Mitral stenosis
	Mitral dysplasia
Right atrial enlargement	Tricuspid regurgitation/dysplasia
	Dilated cardiomyopathy
	Dirofilariasis
	Right-to-left shunting
	Tricuspid stenosis
	Cor pulmonale
	Pulmonary hypertension

Rishniw reported a more accurate 2-D echocardiographic method for estimating left atrial size in adult dogs. This method measures the LA: Ao ratio from the right parasternal short axis view of the aorta and left atrium when the aortic valve is closed. The internal diameter of the aorta is measured along the commissure between the noncoronary and right coronary aortic valve cusps after aortic valve closure (Figure 89-9). The left atrial

internal diameter is measured from a line parallel to the commissure between the noncoronary and left coronary aortic valve cusps to the distant margin of the left atrium. A LA: Ao ratio greater than 1.6 suggests left atrial dilation.

89.5.2 Left Ventricular Volumes

Many experimental models and formulas have been described in the canine patient to assess left ventricular volumes (LVV) by use of M-mode and 2-D echocardiography. Left ventricular end-diastolic and end-systolic volumes can be estimated by the Teichholz method; the bullet method; or the disk summation method (i.e., Simpson's rule). The disk summation method is considered the more accurate echocardiographic method in veterinary medicine. The Teichholz method is considered the more accurate M-mode method in the assessment of LVV, but one must realize that much of the volumetric estimates calculated from only one-dimensional measurements are less accurate, especially with an abnormal heart. The Teichholz method calculates the volume as follows:

$$LVV_{ES} = \frac{7(ESD^3)}{2.4 + ESD} \qquad LVV_{ED} = \frac{7(EDD^3)}{2.4 + EDD}$$

Where *ESD* is the left ventricular internal dimension at the end of systole, *EDD* is the left ventricular internal dimension at the end of diastole, LVV_{ES} is the left ventricular volume at the end of the systole, and LVV_{ED} is the left ventricular volume at the end of the diastole. This formula takes into consideration that the short axis of the left ventricle widens more than the long axis when the heart dilates.

Because of the inaccuracy of M-mode calculations for ventricular volumes in the diseased heart, the American Society of Echocardiography recommends the use of 2-D methods involving fewer geometric assumptions, such as the disk summation method (Figure 89-10). This method is especially more accurate when the heart has an irregular, enlarged, or asymmetric shape, as is the case in many of the canine and feline cardiomyopathies.

89.5.3 Ejection Phase Indices

Ejection phase indices are used to evaluate cardiac performance, especially the left ventricular systolic function. These indices, which are calculated from linear M-mode measurements, include the fractional shortening, the velocity of circumferential fiber shortening, the stroke volume, and the ejection fraction. The *end-systolic diameter,* by itself, is also a good indicator of left ventricular performance and is a more specific index of myocardial contractility than the fractional shortening. Although M-mode methods of volume determination have a poorer correlation with more invasive methods, these indices are still useful in the clinical setting, especially in the normal heart. It should be remembered that these indices are significantly influenced by ventricular loading conditions (preload and afterload).

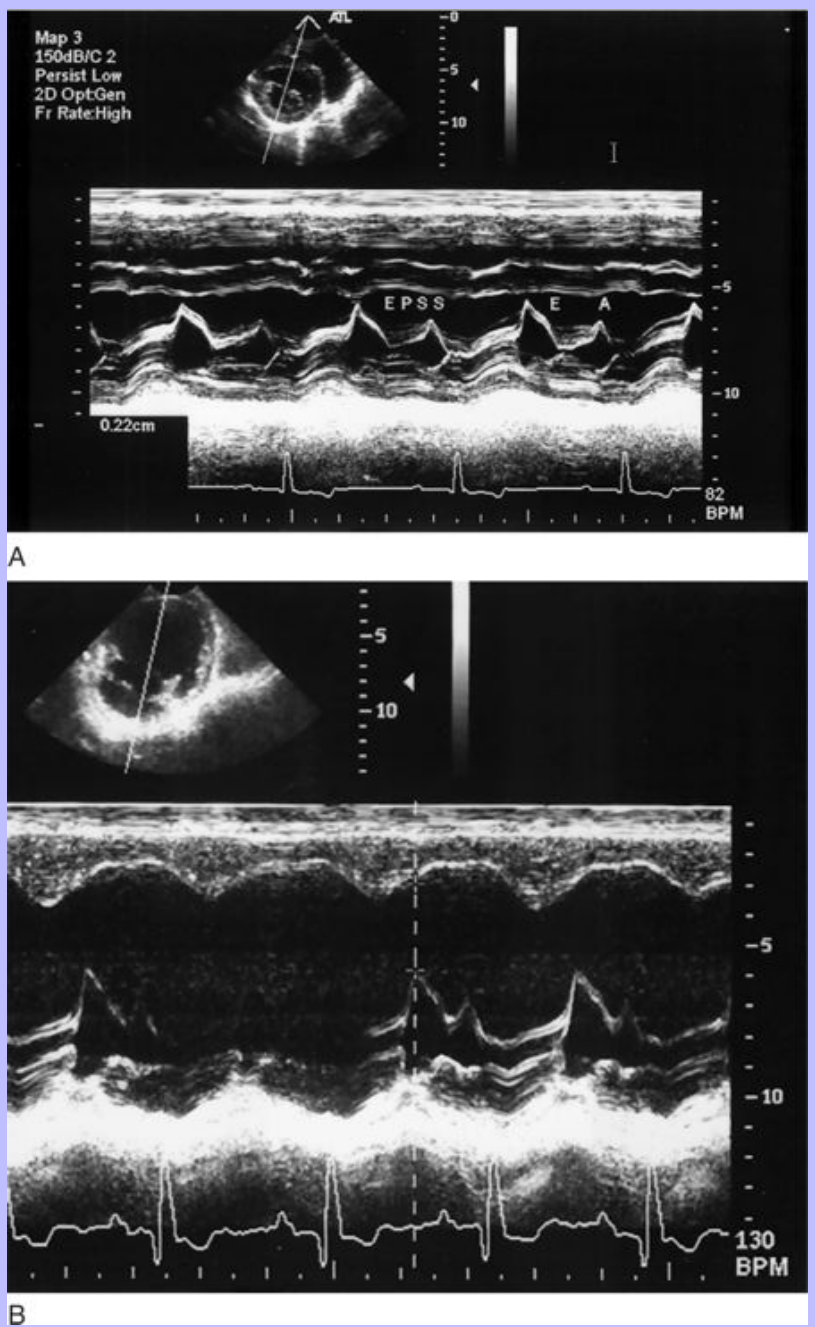
Fractional shortening (FS) is the percent change in diameter of the ventricular cavity from diastole to systole. It provides a rough index of cardiac function. In veterinary medicine, the FS is the clinical index used more commonly in the evaluation of global inotropism and systolic function. Normal values in dogs range from 27% to 48%. FS is calculated as follows:

320

321

$$FS\,(\%) = \frac{EDD - ESD}{EDD} \times 100$$

Figure 89-8 **A,** EPSS measurement in a normal dog. A line is drawn between the interventricular septum and the maximal initial opening of the mitral valve (E point). **B,** Increased EPSS (2.9 cm) in a dog with dilated cardiomyopathy.



where, as noted previously, *EDD* is the left ventricular internal dimension at the end of diastole, and *ESD* is the left ventricular internal dimension at the end of systole. The *velocity of circumferential fiber shortening* (V_{cf}) measures the rate of change in the circumference *(circ)* of the left ventricle during systole. It is calculated as follows:

$$V_{cf}(\text{circ/sec}) = \frac{EDD - ESD}{EDD \times LVET}$$

where *LVET* is the left ventricular ejection time (see Systolic Time Intervals, below). Normal values for V_{cf} are 1.6 to 2.8 circ/sec in dogs and 1.3 to 4.5 circ/sec in cats.

The *stroke volume (SV)* and ultimately cardiac output can be calculated from M-mode measurements or more accurately by Doppler echocardiography (see Hemodynamic Parameters, below). M-mode SV is computed as follows:

$$SV\ (mL) = LVV_{ED} - LVV_{ES}$$

where, as noted previously, LVV_{ED} is the left ventricular volume at the end of diastole, and LVV_{ES} is the left ventricular volume at the end of systole.

The *ejection fraction (EF)* is a rough index of LV cardiomyocyte shortening, because it is the percentage of the LVV_{ED} ejected with each heartbeat. It also corresponds to the 3-D volumetric equivalent of the FS. The EF is the ratio of the left ventricular SV to the LVV_{ED} as calculated here:

$$EF\ (\%) = \frac{LVV_{ED} - LVV_{ES}}{LVV_{ED}} \times 100$$

89.5.4 Systolic Time Intervals

Systolic time intervals (STI) are other indices used in the assessment of global LV function. They are obtained by simultaneous recording of the electrocardiogram (ECG) and M-mode echocardiogram of the aortic valve (Figure 89-11). The following three intervals are routinely measured during systole:

321
323

- The *pre-ejection period (PEP),* which is the time between ventricular depolarization (initial deflection of the QRS) and the onset of LV ejection, which corresponds to the opening of the aortic valve. PEP represents the isovolumetric contraction time.
- The *left ventricular ejection time (LVET),* which is the time required for aortic valve opening, which is measured from the opening of the aortic valve to its closure. The LVET is determined by the SV and the rate of flow. Generally, improvement of LV systolic performance is characterized by a shortening of the PEP or a decreased isovolumetric contraction time and a prolongation of the LVET, which corresponds to an improved SV.
- The *total electromechanical systole (QAVC),* which is the interval between the beginning of the Q wave and aortic valve closure. In other words, QAVC is the summation of PEP + LVET.

Ao_D, Aortic root diameter in diastole; *EPSS*, E point to septal separation; *FS*, fractional shortening; *IVS_{ED}*, interventricular septal thickness at the end of diastole; *IVS_{ES}*, interventricular septal thickness at the end of systole; *LA_S*, left atrial diameter in systole; *$LVID_{ED}$*, left ventricular internal diameter at the end of diastole; *$LVID_{ES}$*, left ventricular internal diameter at the end of systole; *LVW_{ED}*, left ventricular posterior wall thickness at the end of diastole; *LVW_{ES}*, left ventricular posterior wall thickness at the end of systole.

It should be remembered that STI are affected by heart rate and preload or afterload variations. The PEP/LVET index is therefore recommended because it is less influenced by these loading parameters. Normal values for STI are shown in Table 89-7.

89.5.5 Hemodynamic Parameters

Doppler echocardiography is used to calculate the cardiac output (CO). The cardiac index is the CO indexed for body surface area (BSA), which takes into account body size variation among animals. The BSA is calculated from body weight using the following formula:

$$BSA = (10.1 \times w^{2/3}) \times 10^{-4}$$

where *w* is the body weight in grams. Cardiac output is calculated from the product of the heart rate (HR) and stroke volume:

$$CO = HR \times SV$$

The continuity equation is used to evaluate the CO. This equation is based on the theory of conservation of mass that is applied to fluids, which specifies that flow through a given area of a conduit must equal flow through an adjacent area over a given time. Accordingly, SV ejected through a valvular orifice during systole is equal to the flow that passes through the valve, as expressed by the following equation:

$$SV = A \times VTI$$

Table • 89-5 Normal M-Mode Echocardiographic Values in Cats*

$LVID_{ED}$ (mm)	$LVID_{ES}$ (mm)	LVW_{ED} (mm)	LVW_{ES} (mm)	IVS_{ED} (mm)	IVS_{ES} (mm)	LAS (mm)	Ao_D (mm)	FS (%)	EPSS (mm)
12–18	5–10	3–5	4–9	3–5	5–9	8–13	8–11	30–55	≤ 4

Ao_D, Aortic root diameter in diastole; *EPSS*, E point to septal separation; *FS*, fractional shortening; *IVS_{ED}*, interventricular septal thickness at the end of diastole; *IVS_{ES}*, interventricular septal thickness at the end of systole; *LA_S*, left atrial diameter in systole; *$LVID_{ED}$*, left ventricular internal diameter at the end of diastole; *$LVID_{ES}$*, left ventricular internal diameter at the end of systole; *LVW_{ED}*, left ventricular posterior wall thickness at the end of diastole; *LVW_{ES}*, left ventricular posterior wall thickness at the end of systole.

* These measurement guidelines are based on the author's experience and published data.

where *A* is the cross-sectional area of the orifice calculated from the diameter of that orifice (O) measured by 2-D echocardiography, and *VTI* is the velocity-time integral of the PW Doppler signal across the valvular orifice.

$$A = D^2 \times (\pi/4)$$
$$CO = HR \times D^2(\pi/4) \times VTI$$

Virtually any valve or area in the heart can be used to estimate the CO, but the left ventricular outflow tract and the aortic valve are used most often.

89.5.6 Diastolic Function

Historically, the assessment of diastolic function has received little attention in veterinary medicine. The diastolic function should be evaluated when abnormal ventricular compliance or abnormal diastolic filling patterns are suspected. Doppler echocardiographic study of the transmitral flow profiles (E and A waves) is useful in the characterization of diastolic function. In general, with a decrease in ventricular compliance, the passive filling velocity (E wave) is decreased, and the active atrial contraction velocity (A wave) is increased; thus the E/A ratio is less than 1, representing a delayed relaxation pattern in diastole. This finding has been recognized inconsistently in dogs suspected of having depressed diastolic function. The E/A ratio is even more difficult to evaluate in the cat, owing to its high heart rate, which often causes a fusion of the E and A waves. A *restrictive pattern* has also been described in some cardiomyopathies; in this pattern, the peak E wave velocity is increased and the A wave velocity is decreased. A number of other diastolic indices have been described elsewhere, including the isovolumetric relaxation period, relaxation time index, duration of rapid filling phase, time to peak filling rate, rate of change in LV dimension, and peak rate of ventricular wall thinning in diastole.

89.6 NORMAL VALUES

M-mode measurements vary with body size, body surface area, breed, and sedative drugs used. They are also modified by factors such as fear and stress, which significantly affect heart rate and contractility in veterinary patients. Therefore reported normal values should always be regarded as approximate. Kienle collected values from the literature to establish mean normal M-mode values for dogs ranging from 3 to 68 kg (Table 89-3). Normal dogs generally have values within a range of 10% of either side of the mean. Figure 89-12 shows the typical echocardiography report used in veterinary medicine.

90 CHAPTER • 90 Electrocardiographic (ECG) Techniques

Kelly Anderson-Wessberg

The heart is an electrical field created by the flow of current through individual cardiac muscle cells. These cells are connected by intercalated discs, which allows for rapid spread of electrical activity throughout the heart. The arms and legs are linear extensions of this electrical field. When electrodes are connected to the extremities, an electrocardiograph machine can record electrical activity within the heart.

A *dipole* generates an electrical force by having a positive pole and a negative pole, which are separated by a small distance. The sum of multiple dipoles in the heart is measured at the body surface by the electrocardiograph. The *equivalent dipole theory* assumes that all cardiac cells summate to one dipole on the body's surface.

90.1 LEAD SYSTEMS

Each lead evaluates the heart at a specific angle and in a certain plane. The augmented unipolar leads and the standard bipolar leads relate to the frontal plane. They provide information about current flowing right, left, inferior, and superior (head and tail). Chest leads are in the horizontal plane and provide information about current flowing right, left, anterior, and posterior (ventral and dorsal). Bipolar leads use a positive and a negative electrode on that lead. Unipolar leads use a single electrode and a neutral reference point. The letter V indicates a unipolar lead.

90.1.1 Bipolar Leads

Leads I, II, and III are standard bipolar limb leads (Table 90-1). They were devised by Willem Einthoven in 1902 and were the first fixed lead system to be used. The position of these leads forms an approximate equilateral triangle, called *Einthoven's triangle*.

90.1.2 Augmented Unipolar Leads

Leads aVR, aVL, and aVF are augmented unipolar leads (“a” stands for augmented) (Table 90-2). These leads record only half the voltage of the other leads, and the electrocardiograph must amplify, or augment, the deflections to make the size of the complexes comparable to those of the other leads. Because these leads are unipolar, they have a positive electrode and a neutral reference point. The neutral reference point is the average of the other two limb electrodes.

Table • 90-1 Electrode Placement for Standard Limb Leads

LEAD	POSITIVE	NEGATIVE
I	Left front limb	Right front limb
II	Left hind limb	Right front limb
III	Left hind limb	Left front limb

Table • 90-2 Electrode Placement for Augmented Unipolar Leads

LEAD	POSITIVE ELECTRODE	NEUTRAL REFERENCE POINT
aVL	Left front limb	Right front limb, left hind limb
aVR	Right front limb	Left front limb, left hind limb
aVF	Left hind limb	Right front limb, left front limb

90.1.3 Precordial Chest Leads

In humans, chest leads are used most often for their ability to identify myocardial infarctions. In animals, chest leads are most helpful for identifying P waves not easily seen in other leads; bundle branch blocks; and heart enlargement patterns. Right heart enlargement, in particular, may be identified only through the use of chest leads. In animals, the leads are connected as indicated in Table 90-3. Chest leads are unipolar leads. The neutral reference point is the sum of electrical activity at the left arm (LA), left leg (LL), and right arm (RA). This neutral reference point is essentially the center of the heart.

90.1.4 Other Lead Systems

The orthogonal lead system was designed to measure the heart's electrical activity in three dimensions. This system uses three axes, X, V, and Z, and the three leads are perpendicular to each other. Lead I approximates the X axis; lead aVF approximates the Y axis; lead V_{10} approximates the X axis; lead aN/F approximates the Y axis; and lead V approximates the Z axis. The vectorcardiogram is derived from these leads. This system is not commonly used today because it is cumbersome and usually does not provide additional information.

90.2 RECORDING THE ELECTROCARDIOGRAM

The canine patient is placed in right lateral recumbency. This position is recommended because the majority of reference data were obtained from dogs in this position. Metal tables should not be used, nor should the animal be positioned directly on the ground. With the patient's head to the right, the handler may place the right arm over the patient's neck and the left arm over the hindquarters. The patient's legs are held perpendicular to the body and parallel to each other. It is essential that each pair of limbs remain parallel to each other and that enough space remains between the limbs to avoid contact between limbs or electrodes. Patient movement is restricted without discomfort. Figure 90-1 shows proper patient positioning.

Table • 90-3 Electrode Placement for Unipolar Chest Leads

CURRENT LEAD NAME	ELECTRODE LOCATION	OLDER LEAD NAMES	HUMAN EQUIVALENT
rV_2	Right side, 5th ICS, near sternum	CV_5 RL	V_1
V_2	Left side, 6th ICS, near sternum	CV_6 LL	V_2, V_3
V_4	Left side, 6th ICS, at costochondral junction	CV^6 LU	V_4, V_5
V_{10}	Over dorsal spine of 7th thoracic vertebra	CV_{10}	V_6

ICS, Intercostal space.

Figure 90-1 Proper patient positioning.

The electrodes are attached directly to the skin. It is not necessary to clip the hair or prepare the skin. Electrodes may be alligator clips, adhesive patches, or wire. If alligator clips are used, patient discomfort can be minimized by filing or blunting the teeth and relaxing the spring. Alternatively, a gauze pad can be placed between the alligator clip and the skin. Limp electrodes are placed just proximal to the caudal surface of the elbow (LA, RA) and just proximal to the stifle on the cranial surface of the hind limbs (LL, RL). Chest leads are placed according to their respective locations (see Table 90-3). To maintain electrical contact, the electrodes are saturated with 70% isopropyl alcohol or covered with ECG electrode gel.

A 1-millivolt pulse should be recorded at the beginning of every ECG to ensure standardization. A minimum of three complexes of each lead, at 50 mm/sec, is recorded. A rhythm strip is obtained by recording lead II at 25 or 50 mm/sec. The ECG is labeled with the patient's name and medical record number, the date, and the paper speed.

Inaccurate ECG recordings may lead to misdiagnosis and inappropriate treatment. Improper patient positioning, electrical interference, and breathing artifacts are the most common causes of inaccurate ECG recordings. Small changes in limb or electrode placement can result in significant changes on the ECG. Lead aVL has been shown to be the lead most affected by forelimb malposition. Electrical interference may occur because of loose connections between the alligator clips and cable tips or because of nearby operation of electrical equipment.

In feline patients or dyspneic dogs, an ECG recorded in a sternal position is adequate. If restraining the animal at all presents a danger, a rhythm strip may be obtained in any position. An ECG recorded in a nontraditional position may yet provide vital information, particularly about the rhythm, while avoiding any harm to the patient.

91 CHAPTER • 91 Electromyography and Nerve Conduction Velocity Studies

David Lipsitz

Diseases involving any part of the neuromuscular system (peripheral nerve, muscle, neuromuscular junction) may be clinically identical, and the neurologic examination may not always reveal which part of the neuromuscular system is affected. Electrodiagnostic testing may extend the examiner's capabilities in these disorders, by supplementing clinical findings and localizing lesions within the neuromuscular system. They may also aid in selecting and guiding nerve and muscle biopsies. To avoid movement, discomfort, and lack of cooperation, dogs and cats are usually placed under general anesthesia when examined.

91.1 ELECTROMYOGRAPHY

Electromyography (EMG) is a method for detection and display of insertional, spontaneous, and voluntary electrical activity of skeletal muscles. EMG deals primarily with the electrical activity of a single muscle fiber or groups of muscle fibers. EMG is based upon the inherent excitability of normal skeletal muscle and on changes in this excitability during disease. Normal muscle is electrically and mechanically silent except during voluntary contraction. Denervated muscle fibers and muscle fibers damaged due to primary disease will spontaneously depolarize, causing readily detectable spontaneous activity.

EMG is most useful in defining mononeuropathies, polyneuropathies, and myopathies and for differentiating neurogenic from disuse atrophy. Disuse atrophy and diseases of neuromuscular transmission do not induce EMG abnormalities. EMG abnormalities are not specific for a particular neuromuscular disease, but a distinction can frequently be made based on neurologic examination, distribution of affected muscles, and results of nerve conduction studies. EMG can also be used to select a biopsy site in diseases where only specific muscles are involved, such as masticatory muscle myositis.

The most commonly used EMG electrodes are concentric (coaxial) needle electrodes, which measure the potential difference between a nichrome silver or platinum wire and the surrounding stainless steel shaft. Factors to consider when performing an EMG examination are the amount of electrical interference in the room from extraneous sources (heating pads, electrical outlets) and patient-monitoring equipment. The dog or cat must be properly grounded and the machine set to filter 60 Hz interference and radio interference to obtain proper recordings. The sensitivity of the EMG examination can be increased by performing multiple insertions into a specific muscle group and by examining multiple muscle groups. EMG abnormalities may be patchy in their distribution within a muscle or within muscle groups.

Normal muscle is electrically silent, but electrical activity may be detected in normal skeletal muscles. These are as follows:

- Insertional activity is caused by mechanical stimulation and disruption of both muscle fibers and membranes by the EMG needle; it should subside in a few hundred milliseconds.
- Miniature endplate potentials (MEPPs) are caused by spontaneous release of single quanta of acetylcholine causing partial depolarization of the postsynaptic membrane.
- Endplate spikes are associated with MEPPs when enough acetylcholine is released to completely depolarize a single muscle fiber. They should not be confused with fibrillation potentials.

- Motor unit action potentials (MUAPs) are large action potentials caused by summation of action potentials of one or several motor units. They are present during contraction. They are not routinely evaluated in veterinary electrophysiology.

The spontaneous activity of abnormal skeletal muscles are as follows:

- Increased and prolonged insertional activity is due to mechanical irritation of firing muscle fibers.
- Fibrillation potentials and positive sharp waves arise from depolarization of the T-tubular system or depolarization of the surface sarcolemma. They result from the same type of pathologic process but have a different morphology due to their orientation with respect to the EMG electrode.
- Giant MUAPs are large polyphasic potentials that suggest reinnervation of muscle fibers.
- Myotonic discharges result from delayed relaxation of single muscle fibers due to ion channel defects; the discharges have a distinct waxing and waning firing rate and produce the classic “dive bomber” sound.
- Complex repetitive discharges are the spontaneous firing of groups of muscle fibers; they do not wax and wane like myotonic discharges. They have previously been termed *pseudomyotonia* and *bizarre high-frequency discharges*.

91.2 MOTOR AND SENSORY NERVE CONDUCTION

Nerve conduction and nerve conduction velocities are affected by various neuropathies, and methods have been developed for testing nerve conduction of both motor and sensory nerves. Nerves commonly tested are the peroneal, tibial, radial, and ulnar. Clinicians can evaluate motor nerves by stimulating a peripheral nerve and recording the stimulated compound muscle action potential (CMAP). They can evaluate sensory nerves by stimulating cutaneous nerves (which have no motor axons) and recording the sensory nerve action potentials (SNAP) while the electrical potential conducts along the nerve.

Regardless of which nerves are stimulated, certain aspects of neurophysiology must be considered. Insulated stainless steel needle electrodes (except for the tip) are commonly used for stimulating and recording. Stimulating electrodes should be placed such that the negative pole (cathode) is more proximal to the recording site than the positive pole (anode) to avoid conduction block. The negative charges at the cathode depolarize the nerve, whereas the positive charge at the anode hyperpolarizes the nerve. Supramaximal stimulus strength is necessary to ensure that all axons are activated. A ground electrode is imperative, usually placed between stimulating and recording electrodes. Motor nerve conduction velocities are calculated by measuring the latency difference between the CMAP responses from two sites along the nerve and by measuring the distance between these sites, using the following formula:

328 329

$$\text{MNCV (m/s)} = \text{Distance (mm)}/\text{Latency}_{\text{proximal}} - \text{Latency}_{\text{distal}}\text{(ms)}$$

Using only one stimulation site results in inaccuracies of MNCV because it takes into account neither the neuromuscular transmission time nor the muscle fiber depolarization time. Sensory nerve action potentials are recorded directly from the nerve itself, so only one stimulation site is necessary to calculate the conduction velocity. SNAPs are quite small compared with CMAPs (μV versus mV), so signal averaging is necessary to obtain recordings, thereby avoiding background noise and muscle artifact.

Abnormalities of both motor and sensory nerve conduction studies include the following:

- Slowing of conduction velocity without a significant decrease in CMAP amplitude is caused by demyelination with the axons remaining intact.
- Temporal dispersion and polyphasia of action potentials occur normally due to axons with different conduction velocities but may be prolonged with demyelination.
- The number of muscle fibers activated determines the amplitude of the CMAP. Decreased amplitude of CMAPs without temporal dispersion is caused by axonal degeneration, myopathies, or disorders of neuromuscular transmission.
- Many neuropathies cause both segmental demyelination and axonal degeneration; therefore all of the previously mentioned abnormalities may be seen together.

92 CHAPTER • 92 Nasoesophageal, Esophagostomy, and Gastrostomy Tube Placement Techniques

Stanley L. Marks

The enteral route is the preferred method of nutritional support in animals with a functional gastrointestinal (GI) tract. Many techniques for obtaining enteral access are available, and the approach used depends on several issues, including anticipated duration of enteral support, aspiration risk, condition of the GI tract, the animal's temperament, and the level of local expertise. The reader is advised to review Chapter 161 in the Dietary Considerations of Systemic Problems section for a comprehensive overview of diet selection and feeding implementation for the anorectic or sick animal.

92.1 ENTERAL FEEDING ACCESS DEVICES

Most feeding tubes today are made of polyurethane or silicone. These materials have tended to replace the older polyvinyl chloride feeding tubes that stiffened when exposed to digestive juices and are more irritating, necessitating frequent tube replacement. Silicone is softer and more flexible than other tube materials with a greater tendency to stretch and collapse. Polyurethane is stronger than silicone, allowing for a tube of the same French size to have thinner walls and a larger internal diameter. The flexibility and decreased internal diameter of silicone tubes may lead to clogging or kinking of the tube. Both polyurethane and silicone do not rapidly disintegrate or embrittle in situ, providing a longer “wear.” The French (F) unit measures the outer lumen diameter of a tube (each F unit is equal to 0.33 mm).

92.1.1 Nasoesophageal Tube Placement

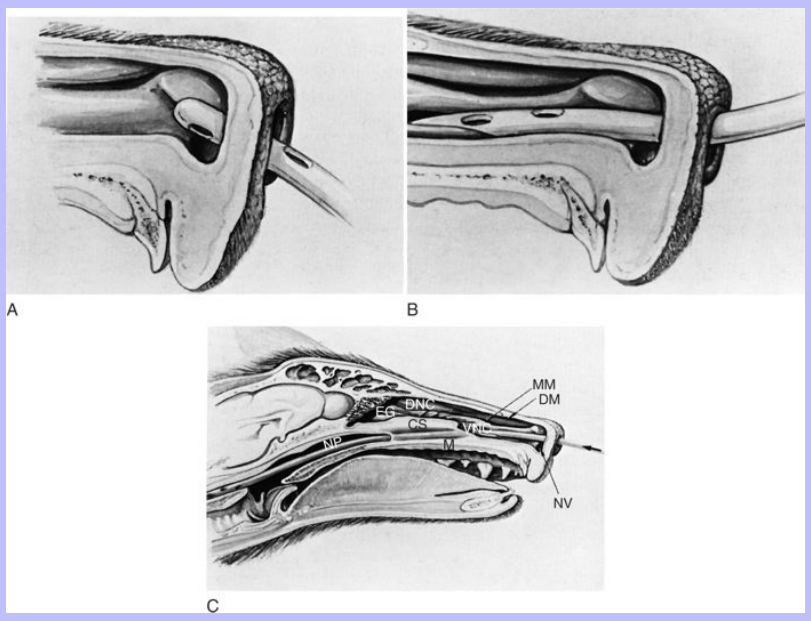
Nasoesophageal tubes are a simple and efficient choice for the short-term (less than 10 days) nutritional support of most anorectic hospitalized animals that have a normal nasal cavity, pharynx, esophagus, and stomach. Nasoesophageal tube feeding is contraindicated in animals that are vomiting, comatose, or lack a gag reflex. Polyvinyl chloride (Infant Feeding Tube, Argyle Division of Sherwood Medical, St. Louis, Mo.) or red rubber tubes (Sovereign Feeding Tube, Monoject Division of Sherwood Medical) are the least expensive tubes for dogs and cats, although the polyvinyl chloride tubes may harden within 2 weeks of insertion and cause irritation or ulceration of the pharynx or esophagus. Tubes made of polyurethane (MILA International, Inc., Florence, Ky.) or silicone (Global Veterinary Products, Inc., New Buffalo, Mich.) are more expensive; however, they are less irritating and more resistant to gastric acid, allowing prolonged usage. An 8 to 10 F × 43-inch tube (preferably with a guide wire) is suitable for dogs weighing more than 15 kg. A 5 to 8 F × 22-to 43-inch tube is recommended for dogs weighing less than 15 kg and for cats.

The length of tube to be inserted into the distal esophagus is determined by measuring the distance from the tip of the pet's nose to the eighth or ninth rib. This will help verify the correct placement of the tube in the distal esophagus rather than the stomach and decrease the likelihood of reflux esophagitis. Desensitization of the nasal cavity with four or five drops of 0.5% proparacaine hydrochloride is recommended. The tube tip should be lubricated with a water-soluble lubricant or 5% lidocaine ointment to facilitate passage. The tube is passed by maintaining the animal's head in the normal angle of articulation and gently directing the tip of the tube in a ventromedial direction. The tube should move with minimal resistance through the ventral meatus and nasopharynx and into the esophagus. In dogs, the presence of a small ventral ridge at the proximal end of the nasal passage necessitates directing the tip of the tube dorsally initially to allow passage over the ventral ridge and into the nasal vestibule (Figure 92-1). Nasoesophageal intubation is more difficult to perform in dogs

because of their long, narrow nasal passages and extensive turbinate structures. In the dog, the tube is directed in a ventromedial direction while pushing the external nares dorsally. This maneuver opens the ventral meatus and guides the tube into the oropharynx.

If the tube is unable to be passed with minimal resistance into the oropharynx, it should be withdrawn and redirected because it could be positioned in the middle meatus with its tip encountering the ethmoid turbinate. Once the tube has been passed to the level of the attached "butterfly" tape, it should be secured as close to the nostril as possible, with either suture material or glue (Superglue, Loctite Corp., Cleveland, Ohio). A second tape tab should be secured to the skin on the dorsal midline between the eyes (Figure 92-2). An Elizabethan collar is usually required for dogs to prevent inadvertent tube removal; however, most cats do not require such a device. The clinician can remove the tube by clipping the hair that is attached to the glue.

Figure 92-1 Parasagittal section showing step-wise insertion of a nasoesophageal tube through the ventral meatus of a dog. **A,** The presence of a small ventral ridge at the rostral end of the nasal passage necessitates directing the tip of the tube dorsally to clear the protuberance. **B,** Once past the protuberance, the tube is aimed medially and ventrally and advanced into the ventral meatus. **C,** Tube through ventral meatus and nasal pharynx *(NP)*. Structures identified: nasal vestibule *(NV)*, cartilaginous septum *(CS)*, maxilla *(M)*, dorsal meatus *(DM)*, middle meatus *(MM)*, ethmoidal conchae *(EC)*, ventral nasal conchae *(VNC)*, dorsal nasal conchae *(DNC)*, and alar fold *(AF)*. (Reprinted with permission from Crowe DT: Clinical use of an indwelling nasogastric tube for enteral nutrition and fluid therapy in the dog and cat, *J Am Anim Hosp Assoc* 22:675, 1986.)



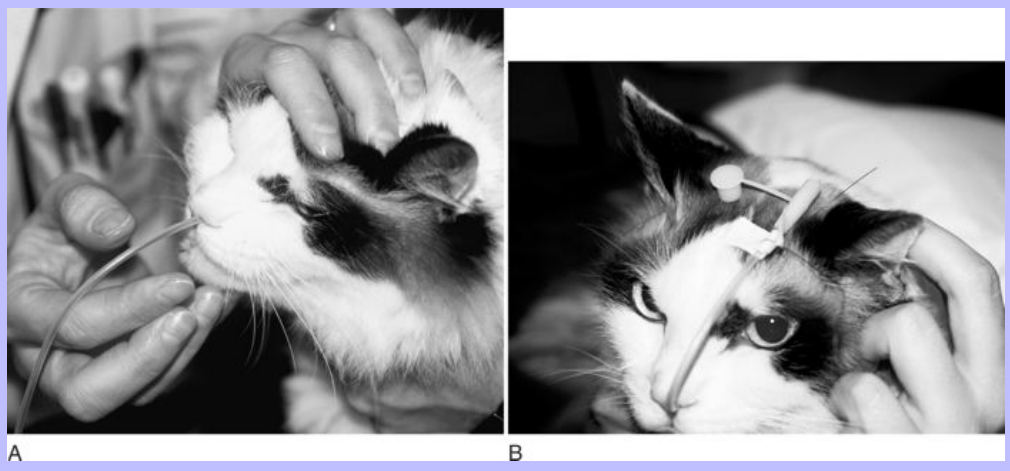
After placement the tube position is checked by injecting 5 to 10 mL of air while auscultating the cranial abdomen for borborygmus, or it is done by infusing 3 to 5 mL of sterile saline or water through the tube and observing for a cough response. Correct tube placement can also be confirmed with a lateral survey thoracic radiograph and observing the position of the radiopaque tube in the esophagus. The most common complications associated with the use of nasoesophageal tubes include epistaxis, dacryocystitis, rhinitis, tracheal intubation and secondary pneumonia, and vomiting.

92.1.2 Pharyngostomy Tube Placement

The increasing availability of endoscopic equipment and the superior benefits of esophagostomy and percutaneous gastrostomy tube placement have resulted in pharyngostomy tubes becoming virtually obsolete. Nevertheless, the introduction of placement modifications has resulted in a dramatic reduction in complications associated with the interference of epiglottic movement and partial laryngeal obstruction. The indications for pharyngostomy tube placement are similar to those for nasoesophageal tube placement; however, the procedure requires general anesthesia. Pharyngostomy tubes are specifically indicated for pets requiring long-term nutritional support with bypass of the oral cavity or oropharynx.

330
331

Figure 92-2 **A,** The tip of the nasoesophageal tube has been lubricated and passed into the ventral meatus by positioning the animal's head in a normal angle of articulation. **B,** The nasoesophageal tube can be secured to the skin on the dorsal midline between the eyes with tape “butterflies.” A second tape tab should be secured as close to the nostril as possible, using either suture material or glue.



For tube placement, the animal is anesthetized with either a short-acting injectable or inhalant anesthetic, intubated, and placed in lateral recumbency. The tube can be placed on either the right or left side of the oral pharynx. An area of skin caudal to the mandible over the hyoid apparatus is aseptically prepared. A 14 to 20 F red rubber, latex, silicone, or polyurethane tube can be used and is premeasured as described for nasoesophageal intubation, to avoid entering the stomach. A mouth gag is placed and an index finger is used to palpate the hyoid apparatus from inside the patient's mouth. Caution should be exercised to palpate dorsally and

caudal to the stylohyoid and epihyoid bones, as close to the cervical esophagus as possible. This will help avoid creating the stoma site rostral to the hyoid apparatus and causing obstruction or interference with epiglottic function. The pulsating carotid artery is palpated and avoided while a 1 cm skin incision is made over the finger that is pushing the pharyngeal wall outwards. The landmarks for the incision include the hyoid apparatus and the bifurcation of the external jugular vein into the maxillary and linguofacial veins. The incision is made caudal to the hyoid in a direction that bisects the angle created by the bifurcation of the external jugular vein. Curved Kelly forceps are used to bluntly dissect soft tissue to create a stoma from the skin incision to the inside of the pharynx in a caudal direction. Blunt dissection will help prevent damage to the external carotid artery, vagosympathetic trunk, and hypoglossal nerve in the dissection field. The flared end of the tube should be cut and grasped with the curved hemostats before inserting the tube into the esophagus by way of the oral cavity and tunneling the cut end of the tube out through the stoma. Alternatively, the tube can be advanced through the tunnel created by blunt dissection and passed down the esophagus. The tube should run straight into the esophagus without kinking to avoid interference with the epiglottis or glottis. The clinician secures the tube by placing adhesive tape in a butterfly configuration around it and suturing the tape to the skin or by placing friction (Chinese finger-tie) sutures. Antibiotic ointment should be applied to a cut gauze sponge that is placed around the tube at the stoma-skin edge. A protective circumferential bandage is used to keep the tube against the patient's neck.

Complications of pharyngostomy tube placement include airway obstruction, aspiration of food, vomiting or reflux, epiglottic entrapment, laryngeal obstruction, recurrent laryngeal nerve injury, tube displacement, chewing of the tube, esophagitis, and infection of the wound site. Large diameter tubes (larger than 24 F) are not recommended due to the increased risk of interference with epiglottic movement or obstruction of the glottis. Displacement of the tube secondary to vomiting or regurgitation necessitates replacement of the tube by opening the animal's mouth and redirecting the tube down the esophagus. If the tube is damaged due to chewing, a new tube may be passed through the old stoma, provided it has had at least 5 days to form.

92.1.3 Esophagostomy Tube Placement

Esophagostomy feeding tubes are easily inserted, and insertion only requires light general anesthesia with isoflurane, or heavy sedation and intubation with a cuffed endotracheal tube. The technique is minimally invasive, and no specialized endoscopic equipment is needed. The dog or cat should be placed in right lateral recumbency, and the left lateral cervical region clipped and aseptically prepared for tube placement. A 14 to 20 F red rubber catheter, (Sovereign Feeding Tube, Sherwood Medical) silicone catheter (Global Veterinary Products) or polyurethane catheter (MILA International) should be premeasured from the midcervical esophagus to the eighth rib and marked with a permanent marker to ensure the distal end of the catheter terminates in the distal esophagus.

Three basic techniques for placement of a midcervical esophagostomy tube have been described:

1. Technique using right-angled forceps (Carmalt, Mixter, Schnidt or Kantrowitz) forceps: The clinician should advance the right-angle forceps into the midcervical esophagus from the oral cavity and use the angle of the jaw and the point of the shoulder for landmarks to help ensure that the tip of the forceps can be palpated externally in the midcervical region. Then the curved tips of the Carmalt forceps should be pushed laterally at the midcervical esophagus, so they can be palpated below the skin. A No. 11 scalpel blade should be used to make a stab incision through the skin only, exposing the subcutaneous tissue and muscle layers of the esophagus. The clinician should be careful to avoid the jugular and maxillofacial veins when selecting the stoma site. The tip of the forceps should be exteriorized from the esophageal lumen through the skin incision, and the advancing forceps should be guided through the esophageal muscle layers; then the clinician should carefully dissect the esophageal mucosa off the tip of the forceps

with a scalpel blade. The tip of the forceps should be used to grasp the distal end of the feeding tube, and the tube should be drawn out of the oral cavity. Next, the clinician should secure the distal end of the feeding tube using the forceps to ensure that the tube remains exteriorized while the proximal end of the tube is pulled out of the animal's mouth. The proximal tip of the feeding tube should be retroflexed and advanced in an aboral direction across the pharynx and down the esophagus, while the external end of the tube is slowly retracted 2 to 4 cm. A wire guide can be used to facilitate pushing the proximal tip of the feeding tube into the esophagus. The exteriorized portion of the tube will be observed to rotate in a cranial direction while the tube moves down the esophagus, indicating correct placement of the tube in the esophagus. Retention sutures (Chinese finger-knot suture) using 3-0 polypropylene are used to secure the distal end of the tube to the skin. An additional method of securing the tube involves passing a heavy suture on a taper needle through the skin next to the tube and into the periosteum of the wing of the atlas.

Antibiotic ointment and gauze dressing is placed at the incision site, and the tube and entrance site is loosely bandaged with conforming gauze wrap. The correct placement of the tube in the mid-to distal esophagus should be confirmed radiographically. It is important to ensure that the tube does not traverse the lower esophageal sphincter, because the tube can cause irritation and predispose the pet to vomiting and gastroesophageal reflux. Feeding can be instituted once the animal has recovered from anesthesia. The tube esophagostomy and skin interphase should be examined at least daily during the first week for evidence of infection or leakage of food or saliva. The stoma site can be kept clean with a topical antiseptic solution (1:100 Betadine solution in 0.9% saline). Once nutritional support is no longer needed, the tube can be easily removed by cutting the Chinese finger-trap anchoring suture and pulling the tube. The wound should be allowed to heal by second intension.

2. Percutaneous feeding tube applicator technique: An alternative tube esophagostomy technique using an (ELD) percutaneous feeding tube applicator or similar device can be used. The applicator is inserted into the midcervical esophagus via the oral cavity. The distal tip is palpated, and an incision is made through the skin and subcutaneous tissue over the tip of the ELD. The trocar is advanced through the esophageal wall and directed through the incision. The distal end of the feeding tube is secured to the eyelet of the trocar with suture material. The ELD device and attached feeding tube are retracted into the esophagus and exteriorized out of the oral cavity. The feeding tube is redirected into the midcervical esophagus after inserting a wire stylet into the distal tip of the feeding tube. The tube is secured to the skin as previously mentioned.

3. Percutaneous needle catheter technique: This method incorporates the use of an esophagostomy introduction tube (Van Noort oesophagostomy tube set, Global Veterinary Products) (Figure 92-3) that is introduced into the midcervical esophageal area. The slot in the distal portion of the tube is palpated, and a peel-away® sheath needle (Global Veterinary Products) is introduced into the distal portion of the tube. The needle is removed from the sheath, and a 10 F catheter is introduced through the sheath to the distal third of the esophagus. The sheath is peeled away and the esophagostomy tube is carefully removed. The feeding tube is secured as described previously. This technique has limitations because the small diameter of the feeding tube (10 F) only allows for the administration of fluids and liquid enteral formulas.

Despite the potential for esophageal scarring and stricture formation, esophageal stricture or a persistent esophagocutaneous fistula has not developed. The most common minor complication is peristomal inflammation, with peristomal abscessation occurring infrequently. Most of the inflammatory reactions are mild and respond to thorough cleansing with topical antibiotics. Other less common complications include vomiting of the tube into the oral cavity.

92.1.4 Gastrostomy Tube Placement

Gastrostomy tube feeding is indicated for long-term (weeks to months) nutritional support of anorectic or dysphagic animals. Gastrostomy feeding tubes are relatively large in diameter (20 to 24 F), allowing administration of blended pet foods and medications. Gastrostomy tube feeding is contraindicated in animals with persistent vomiting, decreased consciousness, or GI obstruction. Caution should be exercised in conditions under which the stomach cannot be apposed to the body wall (severe ascites, adhesions, space-occupying lesions).

Gastrostomy tubes can be placed percutaneously or during laparotomy. Placement is usually accomplished with a percutaneous endoscopic gastrostomy (PEG) technique or a blind percutaneous gastrostomy (BPG) technique. There are a variety of feeding tubes that can be used for gastrostomy feeding including latex, polyurethane, and silicon tubes with French-Pezzer mushroom, balloon, bumper, or silicone dome tips (Figure 92-4). The silicone catheters can be purchased from Global Veterinary, Inc. (New Buffalo, KY) and US Endoscopy (Mentor, OH); polyurethane from MILA International, Inc. (Florence, KY); and latex catheters from BARD Urological Division (Murray Hill, NJ). One can modify the catheters by cutting off and discarding the flared, open end of the catheter and cutting off two 2 cm pieces of tubing (to be used as internal and external flanges) from the same end of the catheter. The end of the catheter opposite the mushroom tip is trimmed to facilitate its introduction into the larger opening of a disposable plastic micropipette. The clinician should make a small stab incision through the center of each flange, and fit one flange over the cut end of the catheter—sliding it down until it rests against the mushroom tip. The other 2 cm piece of tubing will be used as an external flange that lies against the abdominal wall. Cutting the small nipple on the mushroom tip to enhance the flow of food through the tube is *not* recommended. Removing the tip of the mushroom compromises the integrity of the mushroom and hinders percutaneous removal of the tube.

92.1.4.1

Percutaneous Endoscopic Gastrostomy Technique

Endoscopic and blind placement of gastrostomy tubes necessitates brief anesthesia. The animal should be placed in right lateral recumbency so that the stomach tube can be placed through the greater curvature of the stomach and the left body wall. Preparation for both percutaneous procedures is identical and involves a surgical prep of the skin caudal to the left costal arch. The endoscope is introduced into the stomach, and the stomach is carefully inflated until the abdomen is distended but not drum tight. The left body wall is transilluminated with the endoscope to ensure that the spleen is not positioned between the stomach and body wall. An appropriate site for insertion of the tube is determined by endoscopically monitoring digital palpation of the gastric wall. A small incision is made in the skin with a scalpel blade, and an intravenous catheter (16 to 18 G, 1.5 to 2 inches) is stabbed through the body wall into the lumen of the stomach (Figure 92-5, *A*). The stylet is removed and nylon or polyester suture is threaded through the catheter into the lumen of the stomach. The suture material is grasped with the endoscopic biopsy forceps (Figure 92-5, *B*), and the endoscope and forceps are carefully withdrawn through the esophagus and out of the mouth. The suture material is secured to the feeding tube, and gentle traction is applied to the suture material at its point of exit from the abdominal wall (Figure 92-5, *C*). The feeding tube is pulled out through the body wall, allowing the mushroom end to draw the stomach wall against the body wall (Figure 92-5, *D*). The feeding tube is anchored in this position by the external flange placed over the catheter at the skin surface (Figure 92-5, *E*). The endoscope is then reinserted into the stomach to verify the correct placement of the mushroom against the gastric mucosa. If blanching of the mucosa is observed, less tension should be applied to the tube, otherwise ischemic necrosis of the gastric wall may ensue. A plastic clamp is placed over the tube, and the tube is capped with a Y-port connector. A jacket made from stockinette (San Jose Surgical Supply, Inc., San Jose, CA) is fitted to protect the tube (Figure 92-5, *F*).

Complications related to PEG tubes include those associated with placement of the tube (splenic laceration, gastric hemorrhage, and pneumoperitoneum), and delayed complications such as vomiting, aspiration pneumonia, tube extraction, tube migration, and stoma infection. Clinicians can minimize splenic laceration by insufflating and transilluminating the stomach prior to placement of the needle or catheter into the abdominal wall. The authors have recognized a discordant number of large breed dogs that have had major

complications secondary to the stomach "falling off" the silicone dome at the end of the gastrostomy tube. The stoma appeared normal in all dogs, with the unfortunate consequence that several dogs were fed through the gastrostomy tube. This complication occurred despite the placement of an internal flange between the dome and the gastric mucosa. For this reason, it is recommended that all dogs heavier than 30 kg do not have a PEG procedure and instead have a gastrostomy tube placed surgically. Minor complications include pressure necrosis at the stoma site and cellulitis.

92.1.4.2 Blind Percutaneous Gastrostomy Technique

An alternative technique for nonendoscopic and nonsurgical gastrostomy tube placement has been described. The gastrostomy tube placement device can be prepared with a length of vinyl or stainless steel tubing (diameter 1.2 to 2.5 cm) purchased from a hardware store, or an ELD gastrostomy tube applicator (Jorgensen Laboratories, Loveland, Colo.) or gastrostomy tube introduction set (Global Veterinary) can be used. The ELD gastrostomy tube applicator is the only device that uses an internal trocar, whereas the Cook gastrostomy tube introduction set contains a wire that is threaded through an introduction needle. The distal tip of a stainless steel tube can be flared and deflected 45 degrees to the long axis of the tube to help displace the lateral body wall. The lubricated tube is passed through the mouth and into the stomach. The tube is then advanced until the end of the tube displaces the stomach and lateral abdominal wall. Positioning the animal with its head over the edge of the table and lowering the proximal end of the tube will facilitate identifying the tube tip through the body wall. For the Cook gastrostomy introduction set or similarly prepared device, a percutaneous needle is introduced into the lumen of the tube while the assistant firmly holds the distal tip of the tube between two fingers. A skin nick is made over the end of the tube and a 14-gauge over-the-needle catheter advanced into the lumen of the tube. Proper positioning of the catheter is confirmed by moving the hub from side to side and feeling the catheter tip strike the inside of the tube. A guide wire prepared from a banjo string is attached to suture material that is 60 cm longer than the stomach tube. The guide wire is threaded through the catheter, into the tube, and out the mouth of the patient. The attached suture is pulled through the tube and cut from the wire at the mouth. The tube and catheter are removed, and the suture is attached to a gastrostomy tube that is secured in an identical fashion to the PEG tube procedure.

The reported complication rate for BPG is similar to that of PEG; however, the risk of penetrating the spleen, stomach, or omentum is greater when the stomach is not insufflated with air prior to positioning the tube against the lateral abdominal wall. Contraindications to using the "blind" technique include pets with esophageal disease and those that are severely obese (which would preclude accurate palpation of the tube against the abdominal wall). Such animals should have gastrostomy tubes placed surgically.

333

334

92.1.5 Gastrostomy Tube Removal

For percutaneously placed tubes, it is recommended that the tube be left in place for a minimum of 14 days. Animal's receiving immune-suppressive therapy or those that are severely debilitated may require longer for a peritoneal seal to form. The tube should only be removed when oral food intake is sufficient to meet the pet's caloric requirement. One of two methods of Pezzer tube removal can be applied: The tube can be cut at the body wall and the mushroom tip pushed into the stomach to be passed in the feces. This method is safe in medium to large size dogs, because the mushroom and internal bumper should be easily passed in the stool. Alternatively, a stylet can be inserted into the tube to flatten the mushroom tip, while exerting firm traction on the tube. This method is recommended for cats and small dogs, because the mushroom can cause intestinal obstruction. Removal of the MILA catheter is accomplished by deflating the bumper, which occurs once the Y-port adapter is removed. Catheters with a dome (US Endoscopy) are removed by gentle, but firm traction on the tube. The gastrocutaneous tract should seal with minimal or no leakage within 24 hours.

Figure 92-5 Percutaneous endoscopic gastrostomy (PEG) technique. **A,** With the dog in right lateral recumbency, the endoscope is introduced into the stomach, and the stomach is insufflated with air. The left body wall is transilluminated with the endoscope to ensure that the spleen is not between the stomach and the body wall. A 16 to 18 G sheathed catheter is pierced transabdominally into the insufflated stomach lumen. **B,** The catheter stylet is removed, and nylon suture is advanced through the catheter until it can be grasped with endoscopic retrieval forceps. The nylon suture is pulled out through the mouth while the endoscope is withdrawn. **C,** The suture material is secured to the feeding tube and water-soluble jelly is applied liberally to the catheter sheath and the mushroom tip catheter. **D,** The lubricated catheter is drawn down the esophagus and into the stomach while the assistant applies traction on the suture exiting the abdominal wall. **E,** The catheter is advanced until the mushroom tip rests gently against the gastric mucosa. Endoscopy should be repeated to confirm the correct position of the mushroom tip. An external flange is fitted down the tube against the skin to prevent the tube from slipping into the stomach. **F,** Gastrostomy feeding tube in place with the clamp in the open position. The stockinette jacket is pulled over the gastrostomy tube once feeding is completed.

92.1.6 Gastrostomy Tube Replacement

The PEG tube may malfunction or be prematurely removed by the dog or cat, requiring replacement. If the gastrostomy tube is removed within 14 days of placement (before establishment of the gastrocutaneous tract), a PEG procedure should be performed to evaluate the gastric mucosa and verify correct positioning of the replacement gastrostomy tube. If the tube is inadvertently removed once the gastrocutaneous tract is well healed, one can replace the original catheter with a balloon-type catheter (Flexiflo Gastrostomy tube, Ross Laboratories, Columbus, OH) or a low-profile gastrostomy device (LPGD, Bard Interventional Products Division) (Figure 92-6, *A*). Neither of these catheter types require an endoscopic procedure or anesthesia for placement. The gastrostomy "button" is a small, flexible silicone device that has a mushroomlike dome at one end and two small wings at the other end that lie flush with the outer abdominal wall (Figure 92-6, *B*). A one-way antireflux valve prevents reflux of gastric contents through the top of the tube. There are two types of LPGDs: (1) obturated and (2) nonobturated. The obturated device has an enlarged mushroom tip that must be stretched for placement in the stomach by using a special introducer (Figure 92-6, *C*). The nonobturated tube works like a Foley catheter and does not require forceful entry into the gastrostomy stoma. The length of the gastrocutaneous fistula must be precisely determined to guide correct selection of the appropriate "button" shaft length. This is accomplished with a special stoma-measuring device provided with the kit. The main advantages of the LPGD include their durability due to their silicon material, decreased likelihood of inadvertent removal by the pet, and their aesthetically pleasing appearance to the owners.

334
335

92.2 COMPLICATIONS OF ENTERAL FEEDING

92.2.1 Gastric Pressure Necrosis

Gastric pressure necrosis can occur from either the mushroom of the PEG tube or flange eroding the mucus layer of the stomach due to excessive tension being exerted on the PEG tube during placement. In addition, overzealous traction of the PEG tube followed by placement of the external flange flush against the skin of the patient can also cause pressure necrosis characterized by redness, swelling, and moistness of the skin. To reduce the chance that this problem will occur, the clinician should ensure that the PEG tube can be rotated after its placement and leave a 5 mm space between the external flange and the skin.

92.2.2 Feeding Tube Displacement

This is a relatively common problem, particularly with nasoesophageal tubes. Displacement of the tube can lead to aspiration, diarrhea, or in the case of gastrostomy tubes, peritonitis. Gastrostomy tubes should be marked with tape or a marking pen at the level of the skin to help verify the position of the tube. Detachment of the stomach from the abdominal wall with consequent intraperitoneal leakage of gastric contents can occur in large breed dogs, and an internal flange should be placed in these animals to minimize chances of tube dislodgement.

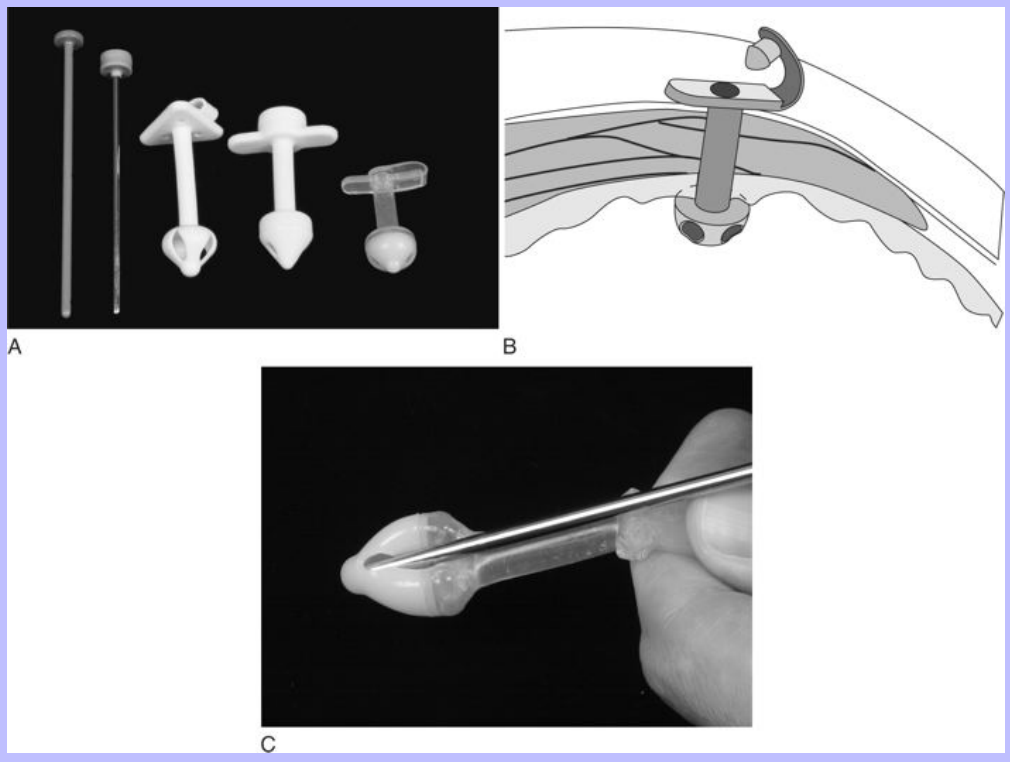
92.2.3 Tube Obstruction

Obstruction of the feeding tube is one of the most common complications of enteral feeding. Most obstructions are secondary to coagulation of formula, although obstruction by tablet fragments, tube kinking, and precipitation of incompatible medications can also result in tube obstruction. Nasoesophageal tubes are prone to obstruction because of their small diameters, and obstruction also occurs up to three times more frequently in patients fed by continuous versus bolus feedings. Sucralfate and antacids have been reported to precipitate with enteral formulas and cause tube obstruction. Several “remedies” have been advocated to relieve tube obstruction. Warm water injected with gentle pressure and suction will relieve most obstructions. For more unyielding obstructions, carbonated water is instilled into the tube and allowed to sit for one hour before applying gentle pressure and suction. Pancreatic enzyme infusions and meat tenderizer have also been advocated to dissolve tube obstructions. On rare occasions, the passage of an angiographic wire down the lumen is needed to unclog the tube. Clinicians can minimize obstructions by flushing the feeding tube with warm water before and after administering medications or enteral feedings. The tube should also be flushed after checking for gastric residuals, because the acid pH will cause the formula to coagulate in the tube. Elixir forms of medication should be used rather than crushed tablet forms whenever possible. Tablets should be crushed and dissolved in water prior to administration through the feeding tube, if no alternative form of medication is available.

92.2.4 Leakage Through Ostomy Sites

Mild leakage at the stoma site can occur for the first few days after placement of the feeding tube. Persistent leakage may indicate tube dysfunction, peristomal infection, or a stoma site greater than necessary for the tube. Signs of inflammation with or without discharge or fever may indicate infection of the stoma site. This must be differentiated from fasciitis. A simple wound infection can usually be treated locally with dilute Betadine solution, topical Betadine antibacterial ointments, and more frequent dressing changes. Systemically administered antibiotics are usually reserved for animals with systemic signs of infection.

Figure 92-6 **A,** Low-profile gastrostomy devices and obturators used for stretching the dome-shaped tip of the device. *Left to right:* The Ross Laboratories Stomate low-profile device, the Cook low-profile device, and the Bard "Button"® low-profile device. **B,** Low-profile gastrostomy device with small outer wings of the device lying flush against the skin of the abdominal wall. For feedings, the small plastic plug is removed and a feeding adapter is connected to a syringe. **C,** Correct technique for stretching the dome-shaped tip of the low profile gastrostomy device with an obturator. The dome should not be stretched by passing the obturator through the lumen of the device as it will compromise the integrity of the anti-reflux valve located adjacent to the dome.



92.2.5 Aspiration

Pulmonary aspiration is a common complication of enteral feeding, although the actual incidence of this complication is difficult to determine due to the lack of consistency in how aspiration is defined. Risk factors for aspiration include impaired mental status, neurologic injury, absence of a cough or gag reflex, mechanical ventilation, and previous aspiration pneumonia. The source of the aspirated material should be identified

because withholding gastrostomy feedings or placing a jejunostomy feeding tube will have no benefit if the pet aspirated oropharyngeal secretions. Although controversial, most authors agree that postpyloric feeding reduces the risk of aspiration. In addition, the use of continuous feedings has been shown to induce less gastroesophageal reflux than bolus feedings.

92.2.6 Diarrhea

Diarrhea is the most common complication associated with tube feeding in humans and animals. The incidence range is from 2.3% to 63%. The clinical implications of enteral feeding-related diarrhea are significant. Severe diarrhea leads to fluid, electrolyte, and nutrient loss, and it can cause considerable distress. Diarrhea in tube-fed individuals occurs due to multiple factors, including hypoalbuminemia, hyperosmolar or high-fat diets, infected diets, and concomitant antibiotic therapy. The incidence of diarrhea in enterally fed patients taking antibiotics far exceeds the incidence in those normally fed taking the same antibiotics. Antibiotic-associated diarrhea may arise from overgrowth of enterobacteria *(Klebsiella, Proteus, Pseudomonas)* or from proliferation of *Clostridium difficile*. Antibiotic administration is also associated with decreased concentrations of fecal short-chain fatty acids, occurring as a result of decreased colonic carbohydrate fermentation.

93 CHAPTER • 93 Gastric Lavage

Roger Gfeller

Gastric lavage is widely used as a gastrointestinal (GI) decontamination technique in small animals poisoned by ingestion of toxins. Removal of the stomach contents by gastric intubation and irrigation can be performed rapidly by trained staff members and does not require a cooperative patient. However, experts are beginning to question the value of gastric lavage; studies fail to confirm its value as a practical clinical procedure. Even when gastric lavage can be performed within minutes of ingestion, recovery of the toxin is limited. If the procedure is not completed before 1 hour has passed, recovery of many toxins is less than 15%. In small animal veterinary medicine, it is rare that gastric lavage would be completed within this period.

The volume of lavage fluid has also become a focus of attention. Using previously recommended volumes often results in gastric distention and complications (including fluid and electrolyte imbalances). Hypernatremia has been reported when large volumes of saline were used, whereas hyponatremia has been reported when water was the lavage solution. Further, one study found that when the volume administered resulted in gastric distention, as much as 25% of the lavage fluid passed into the small intestine carrying the ingested toxin with it. This knowledge has led experts to recommend two changes in gastric lavage protocols.

First, because a possibility exists that lavage solution may carry toxin into the duodenum, experts have begun to advise administration of activated charcoal before initiating the lavage procedure. In at least one study, administration of activated charcoal before (and after) gastric lavage resulted in reduced plasma levels of the toxin. Second, experts now agree that more attention should be paid to the degree of gastric distension allowed during lavage. It is advisable to have one staff member responsible for monitoring the amount of distension. Although visual observation of the abdomen is acceptable, it is better if one repeatedly palpates the stomach during lavage.

Additional complications of gastric lavage include aspiration pneumonia; traumatic injury of the oropharynx, esophagus, or stomach; hypoxemia; hypercapnia; and hypothermia. Gastric lavage is contraindicated in patients with an unprotected airway. Ingestion of caustic or corrosive toxins (e.g., acids, alkalis) or toxins with a high risk of aspiration (e.g., hydrocarbons) is also a contraindication to gastric lavage. A relative contraindication to gastric lavage is ingestion of a foreign body that could cause physical damage to the alimentary tract.

Gastric lavage has risks, it is messy, and it may not decontaminate the GI tract as efficiently as once thought. Before the veterinary team commits to this procedure, a scout radiograph of the stomach can be obtained. If the radiograph reveals an empty stomach, little evidence suggests that gastric lavage will decontaminate the patient more than administration of activated charcoal alone.

93.1 PROCEDURE

The patient must be anesthetized and intubated with a cuffed endotracheal tube (See Box 93-1). The cuff should be inflated just enough to create a seal between the tube and the trachea. The pop-off valve should be closed, and the rebreathing bag squeezed while filling the cuff. The clinician should listen for air escaping around the cuff and stop filling the cuff immediately when no further leakage of air occurs. The anesthetist should be able to inflate the lungs to a pressure of 15 to 20 cm of water without air leaking between the trachea and the endotracheal tube. The patient is maintained on an appropriate gas or injectable anesthetic. If injectable anesthesia is used instead of gaseous agents, the patient should be maintained on oxygen. If the patient is at risk for hypoventilation, the staff should consider ventilating the patient.

The clinician should prepare two tubes for use. The first tube is the *egress* tube. The egress tube should be as large as possible to allow rapid and complete removal of stomach contents. It should have additional side fenestrations in the end that will be inserted into the stomach. The tube should be marked with a piece of tape at a distance equal to the distance from the incisors to the xiphoid. The second tube is the *ingress* tube, through which activated charcoal and lavage solution will be instilled into the stomach. This tube should be smaller in diameter to allow the egress tube to be as large as possible. The distance from the incisors to the last rib should be measured and marked on the ingress tube with a piece of tape.

The patient is secured in right lateral recumbency. The patient's head should be positioned lower than the chest. The clinician should apply an appropriate lubricant (e.g., KY Lubricating Jelly, Johnson & Johnson, Arlington, Tex.) and insert the egress tube into the esophagus. The tube should be advanced into the stomach but not farther than the mark established previously. As much of the stomach contents as possible should be allowed to drain from the tube. If nothing drains from the stomach, the clinician should confirm that the tube is in the stomach. This can be done by several methods. In small animals, direct observation of the tube entering the esophagus and advancement of the tube to the measured distance is usually sufficient. Alternatively, one can push air through the tube while listening over the stomach. A gurgling sound can be heard in the stomach if the tube is properly positioned. A radiograph may be rarely required for confirmation.

If nothing comes from the egress tube after it has been confirmed to be in the stomach, the clinician should lubricate and insert the ingress tube. After confirming the ingress is in the stomach, the manufacturer's recommended dose of activated charcoal should be instilled. The egress tube should be clamped while the activated charcoal is infused so that the charcoal will be retained in the stomach long enough to mix with the contents. Gentle external agitation of the stomach will help the charcoal to mix with stomach contents. The egress tube should be opened to begin evacuation of the stomach contents.

Whether water or saline is to be used as the lavage solution, it should be warmed. Warming the lavage solution will slow gastric emptying and help prevent patient hypothermia. The clinician should attach the stomach pump to the ingress tube, begin to infuse the lavage solution slowly, and monitor gastric distension. Gentle external agitation of the stomach will help mix and remove stomach contents. If the egress tube does not allow free flow of fluid from the stomach, the tube should be withdrawn slowly. If flow begins, the lavage should continue. If no flow can be established, a small amount of water or air should be infused through the large bore tube to dislodge material. If flow is still not established, the clinician should remove the tube and check for a plug, then gently reinsert the tube to establish flow.

337 338

93.1.1

Box • 93-1 Materials Needed for Gastric Lavage

1. Large-bore stomach tube with additional fenestrations in one end (egress tube)
2. Small-bore stomach tube (ingress tube)
3. Lubricant
4. Stomach pump or funnel
5. Activated charcoal
6. Lavage solution (water or saline)
7. Container appropriate for laboratory submission of gastric contents, if desired

8. Disposal area for large quantities of lavage solution

The procedure should be continued until the effluent is clear. In some cases, this may take large volumes of lavage solution and a great deal of time. *At no time should the patient's stomach be distended.* The patient should be lavaged in both left and right lateral recumbency. In some cases it is helpful to move the egress tube gently back and forth to help mix and dislodge stomach contents. If this is necessary, it must be done gently to avoid trauma to the pharynx, esophagus, and stomach.

When the stomach is emptied, the clinician should crimp or clamp the egress tube and remove it. He or she should ensure that the endotracheal tube is still properly placed and sealed and instill activated charcoal through the remaining tube. Then the ingress tube should be crimped or clamped and removed.

To minimize the chances of aspiration, the patient should be recovered with the endotracheal tube in place and the cuff inflated until the swallowing reflex returns. The oropharynx should be carefully checked for fluid, activated charcoal, or stomach contents and suctioned clean before the endotracheal tube is removed.

94 CHAPTER • 94 Transcervical Catheterization in the Bitch

Autumn P. Davidson

Bruce E. Eilts

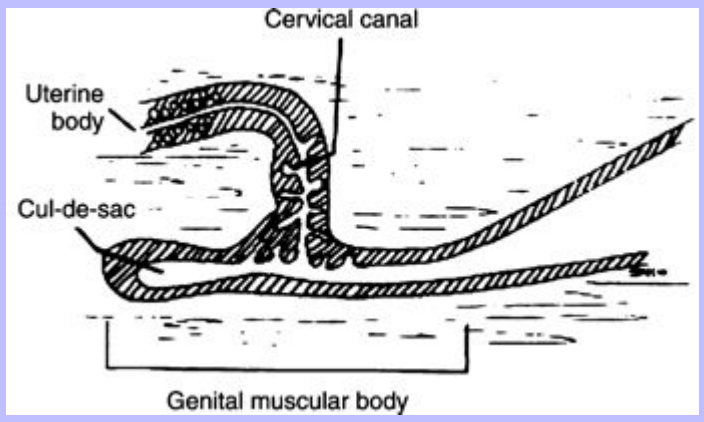
The anatomy of the vaginal vault and cervix in the bitch has hampered access to the canine uterus. Historically, both intrauterine diagnostic sampling (for endometrial biopsy, cytology, and culture) and intrauterine insemination have required an invasive procedure (laparotomy or laparoscopy) in the bitch. In addition to an invasive approach, laparotomy requires general anesthesia, factors some clinicians and breeder clients find objectionable for an elective procedure such as artificial insemination (Figure 94-1). A laparoscopic approach to the canine uterus has been used infrequently, especially in the practice setting, because of its invasive nature and because it requires special equipment, expertise, and anesthesia. Cryopreservation and subsequent thawing diminish semen quality, necessitating special insemination technology. The process and resultant quality of canine cryopreservation have improved with time; however, insemination techniques remained suboptimal until transcervical intrauterine access was developed.

94.1 ANATOMY

The vagina of the bitch is relatively long compared with other domestic animals; the total length from the cervix to the vulva (including the vestibule) has been reported to be 10 to 14 cm in an 11 kg bitch. The canine cervix is not accessible by digital palpation per vaginum, nor can it be visualized with an ordinary vaginal speculum or otoscope. Consequently, equipment for visualizing and approaching the canine cervix must be long (e.g., up to 29 cm for larger breeds). In addition, the presence of vaginal mucosal folds and the position of the cervix in the bitch require the use of rigid equipment to access the cervix.

Figure 94-1 Injection of thawed semen into the lumen of the uterine horn in a bitch during laparotomy.

Figure 94-2 Graphic representation of the canine vagina, cervix, and paracervix.



The *paracervix,* the most cranial portion of the vagina, surrounds the cervix and is dominated dorsally by a well-defined mucosal ridge, the *dorsal median fold (DMF)*. Cranially, the paracervical region ends in the *fornix,* a dead-end space cranio-ventral to the vaginal portion of the cervix that appears as a blind pocket when viewed endoscopically. The DMF extends from just distal to the vaginal portion of the cervix to the mid-vaginal region. It narrows the paracervix, necessitating the use of smaller diameter equipment to access the cervical area.

The DMF forms a distinct caudal tubercle where it ends in the mid-vagina. The cervix is approximately 2.5 cm cranial to the caudal tubercle of the DMF. The canine cervix is difficult to access blindly. It lies diagonally across the uterovaginal junction, with the canal of the cervix directed craniodorsally from the vagina to the uterus (Figure 94-2). The vaginal portion of the cervix appears as a large tubercle when viewed endoscopically. The internal (uterine) os of the cervical canal faces almost directly dorsally, whereas the external (vaginal) os is directed toward the ventral vaginal floor. The vaginal os is often located ventrally or laterally in the cervical tubercle, in the center of a rosette of distinct mucosal furrows. The cervical canal varies in diameter with the stage of the estrous cycle and parity; nonestrual and maiden bitches are expected to have a narrower cervical lumen. The actual appearance and general orientation of the vaginal cervix can vary from day to day during the estrous cycle.

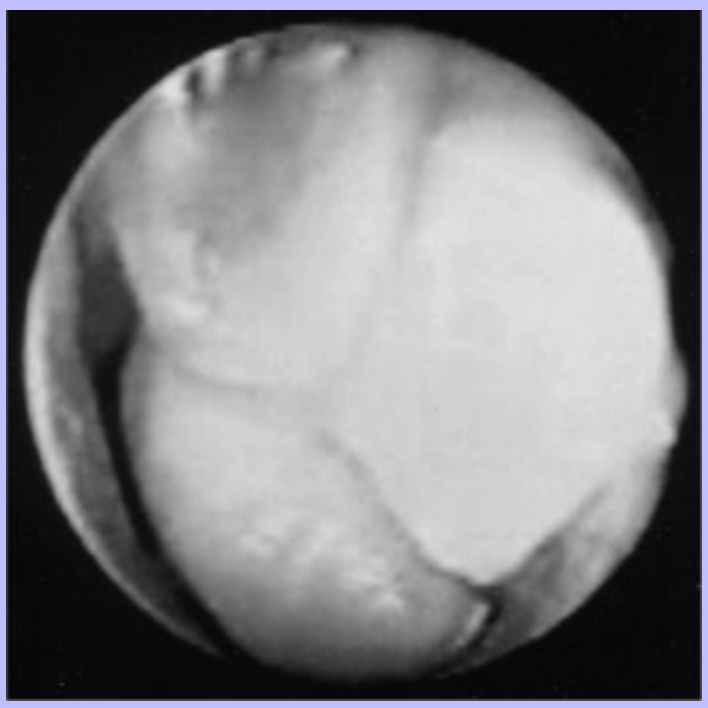
The mid-vaginal region is characterized by a somewhat narrowed, crescentlike lumen. When viewed through a speculum, the caudal tubercle and narrowed middle vaginal lumen give the misleading appearance of tissue with an opening; this is the *false cervix* (Figure 94-3). When rigid insemination pipettes are introduced blindly into this area, often some resistance is felt, followed by advancement; this may lead some clinicians to believe they have accomplished an intrauterine insemination. In reality, insemination into the cranial vagina is more likely, often into the paracervical area.

94.2 EQUIPMENT AND METHODOLOGY

Endoscopically guided transcervical catheterization requires the use of a rigid cystourethroscope,* the components of which are a 3.5 mm forward oblique telescope with 30-degree viewing angle; a 22 French (22 F) protective sheath with two Luer-Lok adapters and an obterator; a telescope bridge with one 10F instrument channel; and a cold light source (Figure 94-4). The working length of the scope is 29 cm. The 30-degree angle is essential for visualization of the dorsally oriented cervix. A video camera can be attached to the endoscope, permitting enlarged imaging of the procedure. Video-endoscopy is preferred because it also allows the audience (e.g., the client) to

watch the entire insemination procedure. Unlike with gastrointestinal endoscopy, electronic air pumps for insufflation and suction are not generally necessary. Adequate air insufflation or suction can be achieved, if needed, by connecting intravenous tubing and a syringe with a three-way stopcock to one of the working channels; this arrangement is sometimes useful for insufflation for routine vaginoscopy in a nonestrous bitch and occasionally for suctioning of copious estrual fluid to improve visualization of the vaginal lumen.

Figure 94-3 Endoscopic appearance of the false cervix.



Transcervical catheterization is best accomplished with the bitch standing under light restraint and with gentle sling support of the abdomen to inhibit sitting (Figure 94-5). The operator should work from a sitting position, with the arms raised to the level of the vulva. An adjustable chair can facilitate operator comfort. Bitches tend to tolerate transcervical catheterization well, especially during estrus. With proper restraint and table setup, the procedure can be accomplished by one operator. However, the participation of the breeder client for restraint and observation generally is rewarding.

339
340

Figure 94-4 Rigid cystourethroscope: *From left,* bridge, sheath, telescope, and light source/cable.

Figure 94-5 Bitch restrained lightly for transcervical endoscopy.

An 8 F urinary catheter is an appropriate size for most bitches for cervical catheterization, although a 6 F catheter sometimes is required for small or maiden bitches. The largest catheter accommodated offers the best rigidity for manipulation through the cervix. A smaller catheter can be placed inside a catheter if increased rigidity is required. Routine endoscopic biopsy and (guarded) culture instruments can be used for intrauterine sample acquisition.

Lubrication of the endoscope is seldom necessary. If a lubricant is used, it should be nonspermicidal and should be applied to the midportion of the sheath. Care must be taken to avoid contact with the lens, which would obscure visibility.

The endoscope is introduced through the vulva along the dorsal commissure, through the vestibule, over the brim of the pelvis, and into the vagina in a dorsal direction. To avoid the clitoral fossa and urethral orifice (Figure 94-6), the end of the endoscope must be directed dorsally. It is surprisingly easy to enter the urethra, which can be differentiated from the vagina by the characteristic smoother, more vascular appearance of the mucosa. The scope is then advanced between the vaginal folds by observing and following the direction of the vaginal lumen. During estrus, the vaginal lumen is cavernous in appearance until the false cervix is approached. Here the caudal tubercle of the DMF is commonly seen as a prominent landmark. Following the DMF facilitates passage into the cranial vagina. The vaginal portion of the cervix appears as a distinct tubercle with a cobblestone appearance due to a rosette of mucosal furrows converging at the os (Figure 94-7). The false cervix, by comparison, is smooth and has a single horizontal fissure. The actual cervical os sometimes can be identified by serosanguineous to hemorrhagic fluid of uterine origin flowing from the cervical canal.

Figure 94-6 Directing the scope dorsally when entering the vestibule avoids entry into the urethra, facilitating passage into the vaginal lumen.

The vaginal cervical os can be difficult to visualize, because it tends to be located ventrally or laterally on the cervical tubercle. The scope can be used to manipulate the somewhat moveable cervix into a position that permits better visualization of the os. If a large amount of estrual fluid impedes visualization of the cranial vagina, removal of the scope and having the bitch sit for a few moments can be helpful. The tip of the polypropylene catheter or

endoscopic instrument is advanced into the cervical os by simultaneous manipulation of the cervix using the endoscope and catheter (Figure 94-8). The rigidity of the endoscope permits manipulation of the cervical tubercle to access the os and start insertion of the catheter. If access to the cervical os is difficult because of its position, bending the tip of the polypropylene catheter beforehand may be helpful.

Figure 94-7 Catheterization of the vaginal cervical os, showing the rosette appearance of the cervix.

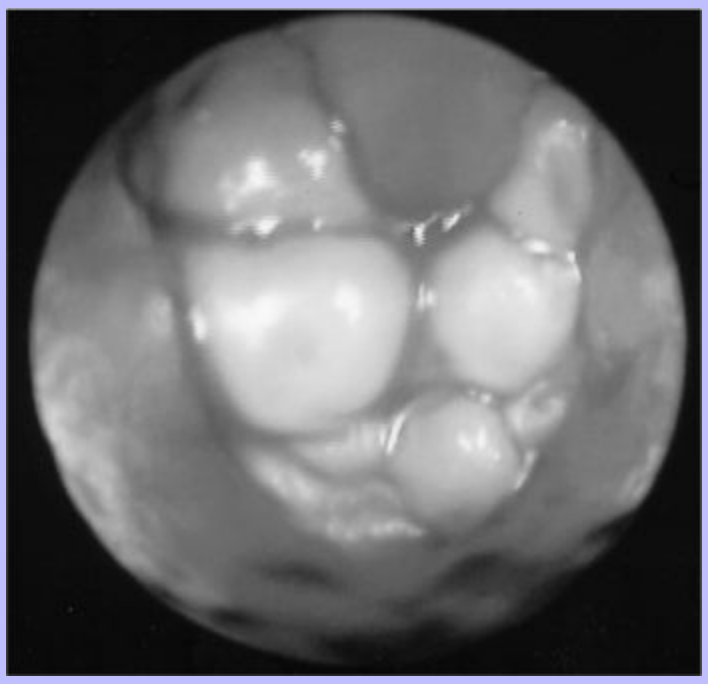


Figure 94-8 Passage of the catheter into the uterine lumen is accomplished by having one hand on the cystourethroscope and the other on the catheter.

After insertion of the tip of the catheter, the viewing end of the scope should be dropped significantly to align the catheter parallel to the direction of the cervical canal. Once the scope position is parallel to the cervical canal, the catheter can be steadily advanced through the cervix with a twirling motion. For intrauterine insemination, the catheter is passed in as far as possible without meeting resistance. The uterine lumen of the average-sized bitch in estrus can accommodate approximately 2 mL of semen, and semen has been shown to distribute throughout both horns even when inseminated into only one. Minimal backflow of semen occurs with proper catheter placement. In the event of semen backflow, the insemination should be stopped and the catheter repositioned cranially or caudally. Minimizing the amount of air introduced into the uterine lumen before semen reduces backflow. A small amount of air (1 to 2 mL) is used to flush all the semen from the catheter into the uterus (Figure 94-9). For intrauterine diagnostics, culture and biopsy instruments are similarly advanced until contact is made with the uterine mucosa. Saline can be infused in and out of the uterine lumen through a polypropylene catheter for cytologic specimen acquisition.

The ease of transcervical catheterization can be recorded for each bitch (1 = very easy, less than 5 minutes; 5 = not achievable). Rarely, access to the cervical canal cannot be achieved. A repeat attempt should be made in 24 hours, because the morphology of the cervix changes under hormonal influence. For this reason, frozen semen should not be thawed until successful catheterization of the cervix has been accomplished. The practitioner and client should

agree on a plan for vaginal or alternate intrauterine insemination beforehand, in the rare event that catheterization cannot be accomplished by the end of the bitch's fertile window. Repeat inseminations may provide better semen availability during the fertile period of the estrous cycle and may improve conception and litter size. The minimal inseminant dose in the dog has not been established.

Figure 94-9 Injection of semen through the catheter; afterward, a small amount of air is injected to clear all fluid from the catheter lumen.

Concerns about the introduction of vaginal flora into the uterine lumen through transcervical catheterization have not been realized. Normal vaginal flora can be found transiently in the uterus during proestrus and estrus, and vaginal flora is known to be introduced into the uterine lumen with natural breeding with no impact on fertility.

Unless rigid endoscopy is already a part of their practice, clinicians must make a substantial investment in equipment for video-endoscopic transcervical catheterization. However, the investment is soon returned, because the transcervical approach is popular with breeder clients who prefer to avoid surgery and anesthesia for intrauterine inseminations. Additional use of the equipment for diagnostic procedures, such as endometrial biopsy and intrauterine culture and cytology, may enhance its value.

Maintenance of the equipment is minimal; a 10-minute soaking of the immersible parts in 0.2% chlorhexiderm in solution, and through rinsing with distilled water followed by air drying, is optional. Techniques for sterilization are described by the manufacturer. The use of stronger disinfectants raises concern because of their spermicidal potential. Sterility does not appear to be necessary, because the vagina harbors normal flora.

Published pregnancy results for endoscopic insemination are not abundant, but some reported conception rates have been 100% when breeding twice with 200×10^6 sperm/breeding; 85% using as few as 50×10^6 sperm/breeding; and 57% using a total of 452×10^6 sperm in 2.4 breedings/cycle. The wide acceptance of frozen insemination by practitioners implies acceptable conception rates in field situations. As with all reproductive procedures, success is greatly influenced by the dogs' inherent fertility, by the timing of ovulation in the bitch, and by the quality of the semen. Collaborative multicenter studies to determine the minimal inseminant dose for

conception in the bitch, as well as the utility of intrauterine diagnostic and therapeutic efforts, will be facilitated by the endoscopic transcervical technique.

95 CHAPTER • 95 Laparoscopy

Keith Richter

95.1 INTRODUCTION

The use of laparoscopy for diagnostic and therapeutic purposes has increased tremendously in human medicine during the last 10 years. This acceptance of laparoscopy stems from technologic advances in equipment and impressive results achieved with this noninvasive modality. Though many procedures performed in human beings will have little appli-cability in veterinary medicine, many of the procedures will gain acceptance due to their ease, effectiveness, and lack of morbidity.

95.2 EQUIPMENT

Light is transmitted from a remote light source via a fiber-optic light cable to the rigid fiber-optic laparoscope (telescope). Size and viewing angles of laparoscopes vary. A forward-viewing (0 degrees), 5.0 to 10 mm outer diameter, 35 cm long scope is preferred. Smaller scopes have a smaller image with less field of view. In addition, a greater light intensity is needed for smaller scopes. A 6.5 mm scope is suitable for examining any dog or cat. Scopes are available in various degrees of angulation of view, including zero degree (direct forward viewing) up to 70 degree. The zero-degree angle is easier to use and generally preferred for most procedures. A 30-degree angle scope can be used to view structures to the side of the tip, and through rotation, to expand the field of view. Angled scopes are more difficult for inexperienced operators. Most scopes have no biopsy channel. Operating scopes have a 5 or 6 mm channel, with an eyepiece extending from the proximal end. These scopes allow introduction of instruments through the same puncture as the scope. The disadvantage of operating scopes is the limited ability to manipulate instruments passing through the channel. Usually the accessory or secondary puncture technique is preferred.

Video capabilities can be achieved with a handheld charged coupling device (CCD) video camera mounted on the eyepiece. These cameras have high resolution, magnify images 5 to 15 times, and provide a clear image. Three-chip cameras are superior to one-chip cameras in terms of clarity, light sensitivity, and color. The use of video is essential for operative laparoscopy. A bright light source (usually 150 to 300 watts) is required to adequately illuminate the abdomen.

To visualize abdominal structures, a pneumoperitoneum must be created to lift the abdominal wall away from the viscera. This is accomplished by insufflating gas through tubing attached to a Veress needle. The latter has a spring-loaded blunt inner portion and an outer cannula with a sharp point. The sharp point is used to penetrate the abdominal wall; then the inner blunt portion is protruded past the sharp point and left in that position to avoid traumatizing abdominal viscera. Gas can then be continually insufflated as needed throughout the procedure.

Three gasses can be used: carbon dioxide (CO_2), nitrous oxide (N_2O), or room air. Carbon dioxide is recommended because it has the advantage of being rapidly absorbed, and thus the risk for air embolism is minimized. The latter is a reported complication of laparoscopy using room air (the gas absorbed most slowly). The disadvantage of CO_2 is that it is slightly more irritating to the peritoneal surface and therefore requires a slightly higher plane of anesthesia. Nitrous oxide is intermediate in its rate of absorption. Gas is infused with an automatic insufflator. These devices regulate flow rate and intra-abdominal pressure. Ideally, intra-abdominal pressure should not exceed 15 mm Hg. Excessive pressure decreases venous return to the heart and causes decreased ability to ventilate.

The laparoscope is introduced into the abdomen with the use of a trocar/cannula assembly. The cannula is a metal or hard plastic sleeve with a one-way valve that permits passage of instruments (such as the trocar and laparoscope) and prevents the escape of gas. The trocar is a sharp-pointed stylet that is used to penetrate the abdominal wall. It is then removed leaving the cannula in place so that the laparoscope can then be introduced. Accessory puncture sites are made for introduction of additional trocar/cannula assemblies. This allows the introduction of blunt metal probes, suction tips, cautery instruments, grasping forceps, "spoon," or "clamshell" style biopsy forceps, and a wide variety of surgical instruments. These instruments are elongated, narrower versions of standard surgical instruments. The use of stapling equipment has enabled surgeons to perform procedures such as vessel ligation and bowel resection.

95.3 TECHNIQUE

It is preferred to perform laparoscopy with the animal under general anesthesia. The position of the dog or cat and location of the various puncture sites will depend on the procedure and organ being examined. Because the liver is the most common organ examined and biopsied, this procedure will be described in detail.

95.4 LAPAROSCOPY-GUIDED LIVER BIOPSY

The main advantage of laparoscopy-guided biopsy is the ability to obtain large biopsy samples and to visualize the liver, biliary tree, and other abdominal organs. With experience, the gallbladder can be examined, palpated with a blunt probe, and the bile duct traced to its entry into the duodenum. In this manner it can be determined whether a common bile duct or cystic duct obstruction exists. In addition, because focal lesions of the liver can be directly visualized, an appropriate biopsy site can be selected while avoiding other intrahepatic structures (gallbladder and portal vessels). Hemorrhage can be observed and, when excessive, controlled with direct compression with a blunt probe over the biopsy site. Alternatively, electrocautery or application of a hemostatic material (Gel-Foam®) can be used to control hemorrhage. Compared with laparotomy, much less anesthetic time exists. A complete laparoscopic examination can be completed and multiple hepatic biopsies obtained in 10 to 15 minutes. Because only a 1.0 cm incision is made, less risk exists for wound dehiscence.

342

343

The animal is placed in left dorsal oblique recumbency at a 45-degree angle. This position allows visualization of both sides of the liver, gallbladder, bile duct, pancreas, duodenum, and much of the abdominal viscera, and avoids the falciform ligament (which may be encountered with a midline approach). The puncture sites should be surgically prepared and draped. The Veress needle (for insufflation) is inserted through a small incision (using a No. 11 blade) on the midline near the umbilicus. Prior to insufflation, the Veress needle is aspirated to confirm that no viscus has been entered. Saline (6 to 8 cc) is then infused to ensure free flow into the abdominal cavity. The abdomen is then insufflated with gas to an appropriate pressure. This amount can be determined by a pressure gauge on an automatic insufflator (usually 10 to 15 mm Hg) or when the abdominal wall is tympanic to the touch. Overdistension should be avoided so as not to decrease venous return or cause impairment in ventilation. Once the desired degree of pneumoperitoneum is reached, a 1.0 cm skin incision is made on the right side between the last rib and the flank. The incision is adjusted in a cranial direction for larger animals, in a caudal direction for smaller animals, and should take into account the size of the liver. The trocar and cannula assembly is then "popped" into the abdominal cavity with a twisting motion. Grasping the cannula ~3 cm from the tip with the free hand will prevent inadvertent insertion of the assembly too far into the abdomen. The trocar is removed and laparoscope inserted into the abdominal cavity through the cannula. The remote light source is connected to the laparoscope with a fiber-optic cable and the liver examined. If a video camera is available, this should be placed on the eyepiece of the laparoscope. A secondary puncture site is made to the left of midline at the level of the umbilicus. Through this site, a second cannula can be introduced so that a blunt probe can be used to palpate the liver and

gallbladder. The probe should also be used to lift up each lobe of the liver to examine the dorsal surface and to get the omentum out of the way so the bile duct can be traced to its entry into the duodenum. The pancreas should also be examined.

Once the abdomen has been examined, a suitable place on the liver is selected for a biopsy site. The author prefers using a laparoscopic spoon or clamshell type of biopsy instrument. This can be placed through the same accessory cannula as the blunt probe, thus avoiding an additional puncture site. These types of instruments result in less hemorrhage than biopsy needles. Repeated twisting of the shaft or retracting the closed jaws into the cannula will prevent ripping of liver tissue and result in less bleeding. If a laparoscopic biopsy instrument is not available, an automated needle biopsy instrument can be used to obtain hepatic tissue. This is inserted into the abdominal cavity just caudal to the xiphoid cartilage and can be directly visualized to enter the liver. It is then operated in the standard manner under direct visualization to obtain hepatic tissue. The number of biopsies obtained depends on the risk of bleeding and the anticipated need of adequate tissue. Multiple samples from various areas of the liver are recommended (observing for hemorrhage after each sample). If excessive bleeding occurs, the blunt metal probe is used to put direct compression over the biopsy site. Suction can also be applied to clear the field if bleeding cannot be adequately assessed. If bleeding is not controlled, an electrocautery probe can be used to stop the bleeding. Alternatively, laparoscopic forceps can be used to place a piece of a hemostatic material (Gel-Foam®) on the bleeding biopsy site. Once the biopsy samples are obtained, the clinician completes the procedure by removing all instruments, evacuating all the gas through opened cannula valves, and suturing the puncture sites.

Potential complications of the procedure include those related to a general anesthetic, excessive bleeding, inadvertent organ damage during instrument introduction, overdistention of the abdomen with gas, air embolism, and a tension pneumothorax if the diaphragm is inadvertently punctured (as abdominal gas enters the thoracic cavity). Meticulous attention to details of technique together with experience will minimize the probability of these complications. Postoperative pain should be anticipated, and this should be addressed with appropriate analgesics.

95.5 OTHER USES OF DIAGNOSTIC LAPAROSCOPY

Laparoscopy can be used to diagnose and stage abdominal tumors through direct visual assessment and allowing directed biopsies. Laparoscopy can detect lesions less than 1 mm in diameter on the peritoneal surface. Laparoscopy can be also used to examine and biopsy the pancreas, an organ that can be difficult to image with radiographs and ultrasound. Other organs that can be biopsied via laparoscopy include the kidney, spleen, prostate, intestine, mesentery, omentum, and the parietal peritoneum. Laparoscopy can guide aspiration of the gallbladder, loculated ascites, and abdominal cysts or abscesses. Laparoscopy can guide transabdominal intrauterine artificial insemination. Laparoscopy can also be used in evaluation of abdominal trauma. Such injuries as hepatic and splenic laceration, diaphragmatic hernia, bladder rupture, renal rupture, and abdominal hernia can be assessed.

95.6 LAPAROSCOPIC SURGERY

Many laparoscopic surgical procedures are currently being performed on humans. These include cholecystectomy, ovariectomy and hysterectomy, adrenalectomy, appendectomy, bile duct exploration, hernia repair, bowel resection, gastropexy, pyloromyotomy, and others. Many of these are applicable to veterinary medicine. Limitations of laparoscopic surgery include the two-dimensional image, restricted freedom of movement of the instruments, restricted sense of touch, and the need for extensive training. Controlled studies are necessary to substantiate the role of all laparoscopic procedures in veterinary medicine. As clinicians and equipment

manufacturers address technical limitations, many surgical procedures performed within a body cavity should be amenable to laparoscopic surgery.

96 CHAPTER • 96 Fine Needle Aspiration and Lung Biopsy

Lynelle R. Johnson

Airway samples are often valuable in determining the underlying cause of respiratory signs in dogs and cats. They can be collected by means of tracheal aspiration, bronchoalveolar lavage, fine needle aspiration, or lung biopsy. The use of a particular technique depends on the results of the physical examination, the animal's stability for procedures that require anesthesia, the type and distribution of radiographic infiltrates, and the list of most likely differential diagnoses.

Fine needle aspiration (FNA) and lung biopsy are most useful for investigating the etiology of diffuse interstitial disease, mass lesions, or focal infiltrates. In general, fine needle aspiration or surgical lung biopsy should be performed when bronchoscopy or other noninvasive tests have failed to yield a diagnosis or to provide sufficient information to guide therapy.

Fine needle lung aspiration can be performed in a conscious animal, under light sedation, or during anesthesia. The technique may be done blindly or with ultrasound guidance. Lung biopsies are performed under general anesthesia and can be accomplished percutaneously with ultrasound guidance, via thoracoscopy, with a keyhole surgical approach, or during thoracotomy. Typically, thoracoscopic and keyhole biopsies provide evaluation of peripheral lung segments only. Focal histologic abnormalities or lesions in more central regions of the lung can be missed. Diagnostic yield can be improved by using preoperative computed tomography to identify and localize appropriate regions for aspiration or biopsy.

Contraindications for FNA include bleeding disorders, intractable tachypnea or hyperpnea, and mechanical ventilation. Standard contraindications for general anesthesia would preclude lung biopsy.

96.1 FINE NEEDLE LUNG ASPIRATION

In animals that are relatively eupneic, percutaneous FNA of the lung can be performed without sedation. Local anesthesia generally is not helpful, because infiltration with lidocaine often causes more discomfort than the single pass of the aspiration needle through the skin. The equipment for FNA includes a 23-to 27-gauge needle ¾ to 1½ inches long and a 6-to 10-cc syringe. Microscope slides should be readily accessible for preparation of the sample for cytologic evaluation, and aspirated material can be applied to culture swabs for microbiologic analysis if sufficient quantity is obtained.

For FNA, a small region of the chest is shaved and minor surgical preparation is completed. The needle is passed through the skin and subcutaneous tissue and into the thoracic cavity cranial to the border of the rib. With respiration halted, the needle is directed swiftly into the lung perpendicular to the lesion. It is inserted back and forth gently and quickly, and one or two gentle aspirations are applied to the syringe. The needle and syringe are removed together for preparation of cytologic specimens.

A second method uses an inverse aspiration technique. The needle (attached to syringe) is inserted through the rib muscles until it is close to the pleural cavity. To enter the lung, the barrel of the syringe is advanced toward the chest wall while the plunger is held stationary. Release of the plunger aspirates material into the hub of the needle. The syringe and needle are removed for preparation of the sample.

Generally, only a small aspiration sample is visible in the hub of the needle. The syringe is detached from the needle and filled with air, and the contents of the needle hub then are gently sprayed onto a slide or cover slip for

cytologic examination and Gram staining. Additional material can be applied to a culturette swab. If aspiration with an empty syringe fails to yield material, the syringe can be filled with 1 to 2 mL of sterile saline. The aspirated material in the hub of the needle is drawn back into the syringe to create a suspension of the aspirant. A cytospin preparation can be done; however, this technique may result in excess dilution of the sample.

For more central or focal lesions, ultrasound-guided percutaneous aspiration is performed with the animal under heavy sedation or anesthesia. Balanced anesthetic protocols that maintain cardiopulmonary support are preferred, and narcotic agents are often used. If a larger instrument (18 to 21 gauge) is used, the aspiration biopsy needle is preferred over a cutting biopsy needle because the former technique has a lower incidence of complications.

96.2 LUNG BIOPSY

Lung biopsy can be achieved through video-assisted thoracoscopic surgery (VATS), keyhole biopsy, or thoracotomy. Samples are submitted for histology and bacterial cultures (aerobic and anaerobic). Fungal cultures should be considered in some cases, and impression smears of biopsy samples may be helpful for early assessment of cytologic lesions.

Thoracoscopy is the least invasive surgical technique that provides an opportunity for visualized lung biopsy or lung lobectomy. General anesthesia with endotracheal intubation is used, and close anesthetic monitoring is required because a moderate pneumothorax is induced during the procedure. VATS is performed more commonly in dogs than cats because of their larger body size. This technique requires specialized rigid telescopes, trocars, and endoscopic instruments, a light source, and a video monitor. Formal training is required to develop expertise in this procedure. Peripheral biopsies of a distal lung segment can be obtained with a stapling instrument or an endoscopic loop ligature. Alternatively, a lung lobe can be resected. The most serious complication of thoracoscopic biopsy is hemorrhage.

Lung biopsy of a peripheral segment can also be obtained through a modified (keyhole) thoracotomy. The animal should be placed under general anesthesia and surgically prepared. An intercostal thoracotomy is performed, and a wedge of lung is exteriorized. A biopsy is obtained by applying loop ligatures around the segment or by using a stapling device.

In an animal with a solitary mass lesion, consolidated lung lobe, central pulmonary infiltrate, or focal abnormality, exploratory thoracotomy with lung biopsy, partial lobectomy, or lung lobectomy may be required to obtain a diagnosis. A lateral intercostal approach on the side of the lesion provides the best access to structures in the immediate area and usually has the advantage of an uncomplicated approach and closure. The technique is associated with less postoperative discomfort than a sternotomy; however, it does not allow access to the entire contents of the chest cavity. Median sternotomy is performed when a complete thoracic cavity exploratory is required, but it is difficult to perform lung lobectomy by this approach. In addition, access to hilar structures through a median sternotomy is limited in large, deep-chested dogs.

344 345

96.3 COMPLICATIONS

The most common complications of fine needle lung aspiration and percutaneous lung biopsy are pneumothorax and hemorrhage, although seeding of the pleural cavity with neoplastic cells is also of theoretical concern. Complications can occur when the technique is done either blindly or with ultrasound guidance, but the occurrence rate is substantially lower when small needles are used. Proper patient selection is also of critical importance, because animals with marked tachypnea and/or pronounced respiratory distress are more likely to develop pneumothorax. Highly agitated or fractious dogs or cats that are difficult to restrain are prone to hemorrhage, as

are animals with coagulopathies or pulmonary hypertension. Sedation or anesthesia of fractious animals might improve the safety of the procedure. After a lung aspiration procedure, the animal should be encouraged to lie on the side of the aspiration to promote the development of a seal at the site. Radiographs should be taken if an increase in respiratory rate or effort develops or if an absence of lung sounds is noted, which could suggest pneumothorax.

Complications of open lung biopsy are those associated with duration of anesthesia or respiratory depression. Chest tubes are placed after surgery, thus limiting the occurrence of pneumothorax. Hypotension, hypoxemia, and poor ventilatory recovery are potential postoperative problems.

97 CHAPTER • 97 Lymph Node Aspiration and Biopsy

David M. Vail

Lymph node aspirates, biopsies, or both are indicated when lymph nodes are clinically enlarged or are suspected of being involved in a disease process where their histologic assessment would be helpful in diagnosis or staging the extent of disease involvement. Whether a fine needle aspirate, incisional, or excisional biopsy is chosen depends on the disease process under consideration, the tissue volume requirements for assessment, and the condition of the dog or cat.

97.1 LYMPH NODE ASPIRATION

This simple, rapid, and low-morbidity assessment of lymph nodes can be performed several ways; the technique used will depend on operator preference and location of the node in question. For peripheral lymph nodes, sedation is rarely necessary; however, sedation or general anesthesia may be necessary if a dog or cat is fractious, or an intracavitary node is to be aspirated either by palpation or by ultrasound guidance.

For most accessible nodes, the author prefers the “needle without the syringe” approach to fine needle aspiration. This technique is well suited for lymph nodes because, in general, they readily exfoliate their cells. This allows the operator to experience a fingertip feel of the node texture; it also decreases blood admixture and cellular disruption secondary to vacuum aspiration (Figure 97-1). Alternative techniques for lymph node aspiration include aspiration with the needle attached to a 10-cc syringe. In this case, upon insertion of the needle (20 gauge) into the node, suction is created by rapid, repetitive aspiration of the syringe. Metal or plastic commercially available mechanical aspiration devices can also be used to create vacuum, but they are rarely necessary for lymph node samples.

No preparation is necessary for peripheral lymph nodes other than swabbing the site of penetration with alcohol. If the node is within a body cavity, then surgical preparation of the site of entry is recommended. Instrumentation includes a 20-gauge needle, a 10-mL syringe, and cytology slides. The process is as follows (see Figure 97-1, *A* and *B*).

While holding the node in an off hand, the operator holds the needle with one finger over the hub. The needle is passed once through the skin and into the node, followed by several quick thrusts in and out of the node without exiting the skin each time. The needle is then removed from the node, placed on an air-filled 10-cc syringe, and the contents are gently expressed onto several slides. The sample is smeared out and submitted for appropriate staining and analysis.

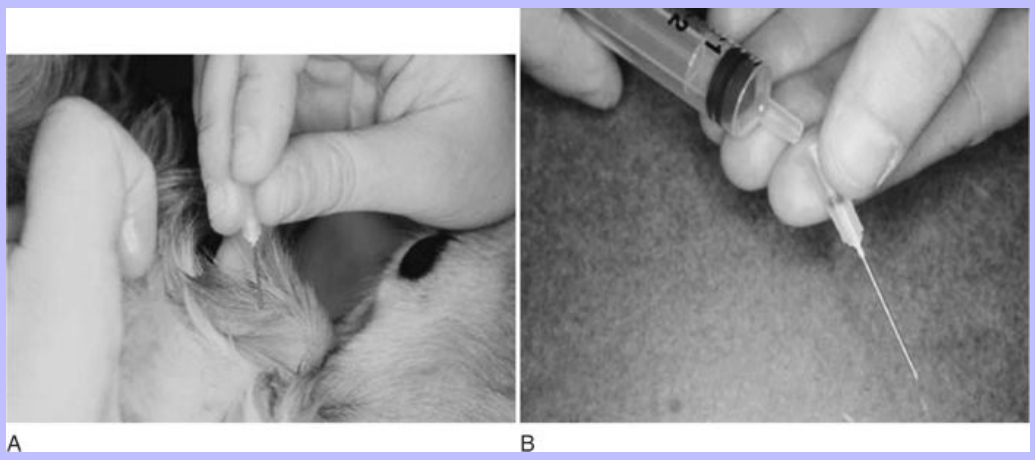
97.2 LYMPH NODE BIOPSY (INCISIONAL)

If a larger sample for histopathology is required, a needle core biopsy (e.g., Tru-Cut®) is recommended and outlined in Figure 97-2. Usually, only sedation and local anesthesia is required. Rarely, intravenous or gaseous anesthesia is necessary if a dog or cat is fractious or an intracavitary node is to be biopsied. Mechanical, spring-loaded needle biopsy instruments are also commercially available.

Instrumentation includes a No. 11 blade to make a stab incision for needle biopsy entry, a Tru-Cut® biopsy instrument, a specimen cassette, and suture material (only necessary if entry hole is large or if excessive hemorrhage occurs).

346

Figure 97-1 Fine needle aspiration—lymph node.



The Tru-Cut® core biopsy instrument can be set in one of two positions (see Figure 97-2, *A*): The first, the *closed* or sheathed position, has the inner canula within the outer sheath. This is the position used when placing the needle into the node. The second, or *open* position, occurs when the outer sheath is held in place and the inner cannula is thrust forward by pushing the handle plunger (indicated by the thick arrow in Figure 97-2, *A*) forward. This opens the specimen or sample trough (indicated by the narrow arrow in Figure 97-2, *A*).

After a No. 11 blade is used to make an entry hole in the surgically prepped area, the biopsy needle is passed through the skin just into the node while in the *closed* position (see Figure 97-2, *B*).

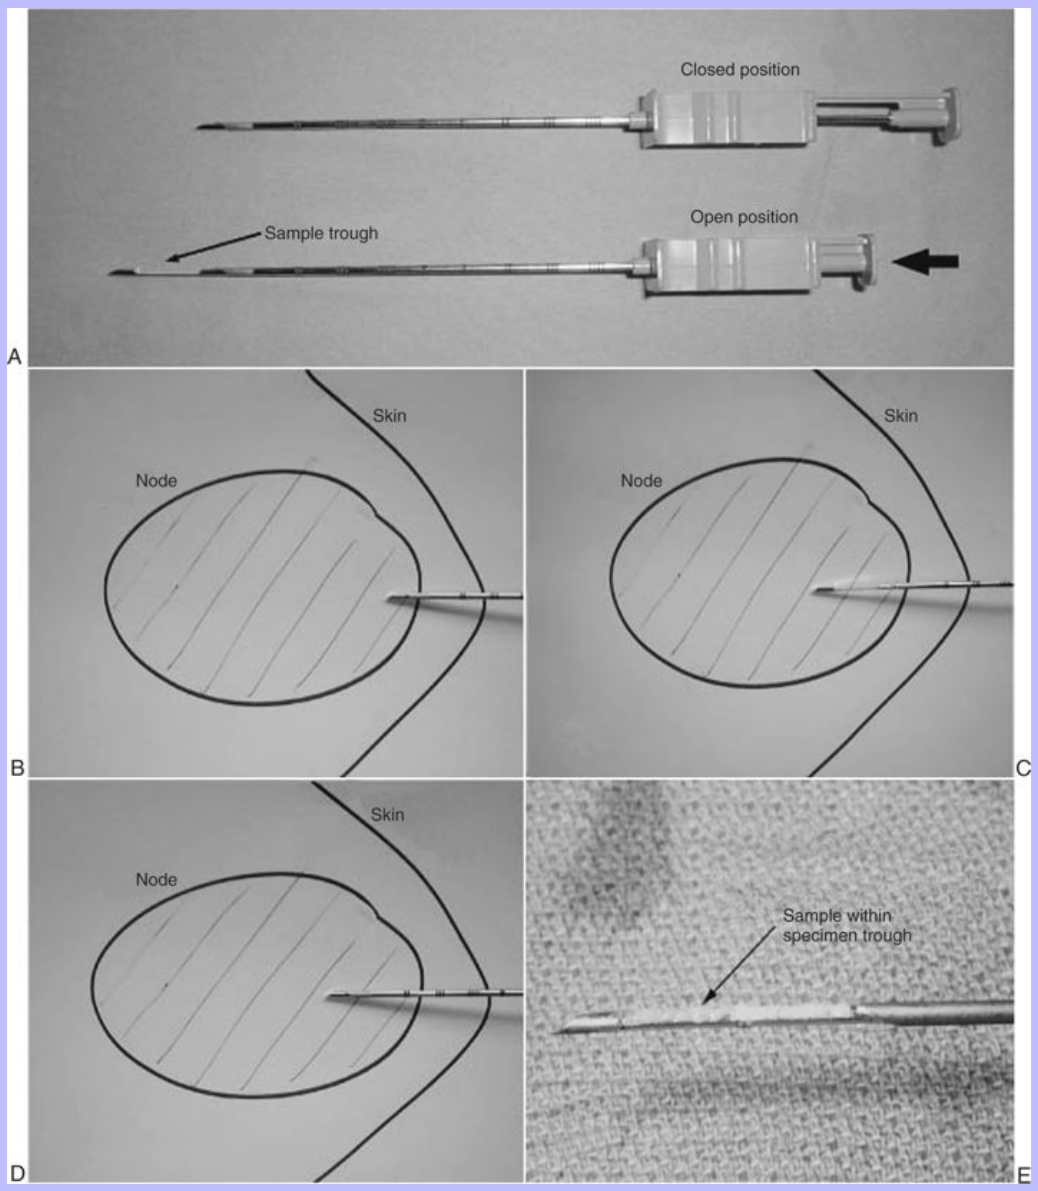
Next, the operator thrusts the plunger forward to place the instrument in the *open* position (see Figure 97-2, *C*), thereby allowing nodal tissue to fill the needle trough. While the biopsy plunger is held in a steady position, the operator slides the outer sheath forward over the inner cannula, thereby cutting the core sample off within the specimen trough (i.e., the biopsy instrument is again in the *closed* position); the entire instrument is then withdrawn from the node while in the *closed* position (see Figure 97-2, *D*). The biopsy needle is then *opened*, and the specimen (i.e., core sample) is placed in a biopsy cassette for processing (see Figure 97-2, *E*).

97.3 LYMPH NODE BIOPSY (EXCISIONAL)

In the case of low-grade lymphoma in dogs or when lymphoma is considered in cats where several well-documented benign lymphadenopathies may mimic lymphoma, the entire lymph node should be removed for histologic assessment. This is important for the pathologist to determine architectural changes and capsular invasion. The reader is referred to a general surgical textbook for techniques for whole-node extirpation.

346

Figure 97-2 Needle core biopsy—lymph node.



98 CHAPTER • 98 Pacemaker Implantation

Daniel F. Hogan

98.1 INTRODUCTION

Artificial pacing (AP) for the treatment of symptomatic bra-dyarrhythmias in veterinary medicine began over 30 years ago and is now considered the standard level of care for such patients. The most common conditions requiring AP include third-degree (complete) atrioventricular block (3AVB) and sinus node dysfunction (sick sinus syndrome [SSS]). Other less common conditions include high-grade second-degree atrioventricular block (2AVB), persistent atrial standstill, vasovagal syncope, reduction of obstruction gradient in hypertrophic obstructive cardiomyopathy (HOCM), and biventricular pacing in congestive heart failure patients. Pacing systems are varied and can range from simple to complex, depending on what the requirements are for the individual patient. The vast majority of pacing systems implanted today consist of single-chambered systems where one pacing lead is placed, usually into the right ventricle (RV), and programmed to deliver an electrical stimulus when intrinsic electrical activity is absent. A single-chambered system could also use a lead placed within the right atrium (RA), as sometimes used to treat SSS, but this requires a competent atrioventricular node (AVN). However, it is well recognized that maintenance of atrioventricular synchrony in pacemaker patients is preferable and results in increased cardiac output, improvement in neuroendocrine profile, and reduced incidence of the pacemaker syndrome. For these reasons, there has been increased use of dual-chambered systems in veterinary medicine over the past 5 years. These systems usually consist of two leads: one in the RA and one in the RV. Dual-chambered pacing can be established by use of a special single lead where free-floating electrodes reside within the RA that sense intrinsic atrial electrical activity. However, atrial pacing is precluded in this system.

98.2 PACING COMPONENTS

The pacing system consists of (1) a pulse generator that contains a lithium-iodide power source and magnetic switches that determine how and when the electrical stimulus is delivered and (2) lead or leads that deliver the electrical stimulus and sense intrinsic electrical activity. These components must be compatible; the clinician can determine this by consulting with a local pacemaker representative, by reading publications such as the *Pacemaker* and *Connector Encyclopedia*, or by obtaining the components from the Companion Animal Pacemaker Registry and Repository (CANPACERS).*

Pulse generators have two main categories: (1) single or dual chambered and (2) unipolar or bipolar. Dual-chambered generators have two channels or connectors for the leads. Unipolar generators serve as the anode to complete the electrical circuit and are only compatible with unipolar leads. The noninsulated surface of the unipolar generator must be in contact with body tissues to allow pacing. Bipolar generators can be programmed as unipolar, allowing compatibility with unipolar and bipolar leads that results in greater flexibility of such systems. Generators also differ with respect to their programmability, with the newer generators having more functions that can be modified by the user.

Leads are classified as (1) endocardial or (2) epicardial. Endocardial leads contact the endocardial surface of the RV or RA and are implanted by the transvenous route, whereas epicardial leads are implanted by thoracotomy or celiotomy and contact the epicardial surface of the left ventricle (LV). As already mentioned, leads are classified as unipolar (epicardial leads are always unipolar) or bipolar, and this will influence compatibility issues. The clinician can identify bipolar leads by the distal ring electrode on the lead that functions as the anode or by the two ring electrodes on the connector pin. In addition, the size of the connector pin on the lead can vary, but this must

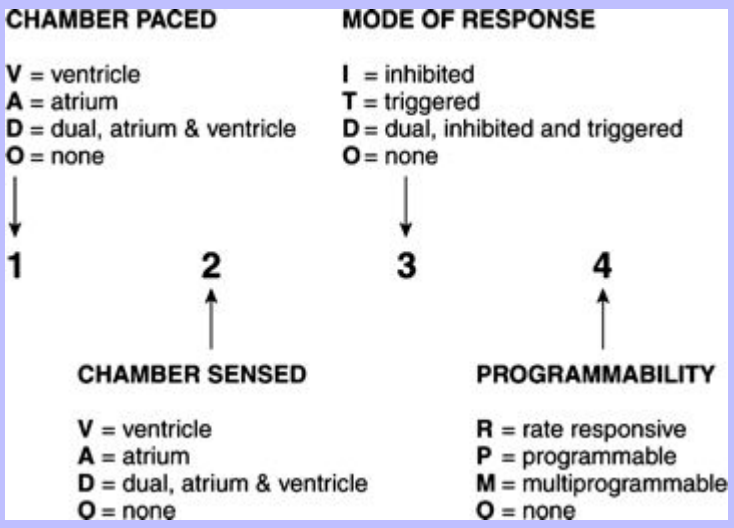
match the connector size of the generator. Older leads can have connector sizes of 5 or 6 mm, whereas newer components have been standardized (these leads are listed as IS-1 UNI or IS-1 BI for unipolar and bipolar, respectively). However, adapter sleeves can be used to allow a smaller-diameter lead connector to fit into a larger generator channel. Leads also have two different types of fixation to the myocardium. Active fixation leads penetrate the myocardial wall with a corkscrew mechanism, whereas passive fixation leads have silicone or polyurethane tines that become entangled within the trabeculae of the endocardial surface. Epicardial leads must have some form of active fixation either through a corkscrew mechanism, suture disc, or both. Either fixation technique can be used for endocardial leads, because the dislodgement rates from the ventricle are similar. However, the author prefers to use active fixation for atrial leads for more secure myocardial engagement. Most of the newer leads have steroid-eluting tips that reduce the risk of excessive fibrosis around the contact site that could result in exit block and loss of pacing.

It is important to have access to a pacing system analyzer (PSA) on site, through a pacemaker representative, or from a local hospital. However, most PSAs are only compatible with generators from the same manufacturer as the PSA, and compatibility needs to be confirmed prior to pacemaker implantation. The PSA allows programming of user-modified parameters through the application of a magnet over the generator. After implantation, the magnet can be applied on the skin surface overlying the generator, allowing noninvasive programming of the pacing system.

348

349

Figure 98-1 Pacemaker programming code.



Pacing systems in veterinary medicine are most commonly coded by a four-letter system (Figure 98-1). The first letter represents the chamber paced, the second letter the chamber sensed, the third letter is the mode of response to sensed intrinsic electrical activity, and the fourth letter indicates the programmability of the generator. In veterinary medicine, the most common pacing modality is VVI, with a fixed pacing rate ranging from 70 to 100 pulses per minute (ppm). However, over the last 5 years there has been increased use of dual-chambered pacing systems where DDD or VDD pacing modalities are used. A PSA is used prior to implantation to estimate battery life and to program nominal pacing parameters. During implantation the PSA allows evaluation of the surface ECG, atrial or ventricular electrograms (or both), determination of lead impedance, and optimal pacing parameters. Postimplantation, the PSA is used to interrogate the pacing system for changes that occur over time that could require the pacing parameters to be altered. In addition, the PSA can program in-stock generators to

nonpacing modes such as OAO or OVO to prolong the battery life of the generator prior to implantation. If a PSA is not routinely available, then a pulse generator can be programmed to the following parameters: pace amplitude 5 V, pacing pulse width 0.5 ms, sensitivity 2.5 mV, ventricular refractory period 250 ms, and pacing rate 70 to 100 ppm within a VVI pacing system. The author does not recommend implanting a dual chambered pacing system without having a PSA readily available because these systems are more complex and often require multiple adjustments during implantation.

98.3 PREIMPLANTATION DIAGNOSTIC EVALUATION

Preimplantation diagnostics should include a complete blood count, serum chemistries, and urinalysis to identify possible underlying causes of the rhythm disturbance and determine overall health of the animal. An electrocardiogram is necessary to accurately diagnose the arrhythmia. Thoracic radiographs and echocardiograpy should be performed to identify any possible underlying causes of the rhythm disturbance and any concurrent cardiac disease and to assess baseline cardiac function. It is important to determine baseline cardiac function because a small subset of animals with 3AVB develop myocardial failure after pacemaker implantation, either from an adverse effect of the pacemaker or extension of the disease process that resulted in the arrhythmia requiring pacemaker implantation (Figure 98-2). Additional diagnostics may be performed to identify diseases that have been associated with arrhythmias requiring pacemaker implantation such as Lyme disease and myasthenia gravis.

98.4 PACEMAKER IMPLANTATION

Perioperative antibiotics are routinely used on a prophylactic basis. First-generation cephalosporins such as cefazolin (22 mg/kg IV q 2 hours) are most commonly used. However, the use of antibiotics does not replace good aseptic techniques. Controversy exists as to whether a temporary pacing system should be placed prior to general anesthesia for permanent pacemaker implantation. The procedural time is increased, there is no significant decrease in adverse events and no clear consensus from cardiologists if temporary pacing systems should be placed on a routine basis. However, it is generally agreed that animals with unstable escape rhythms should be temporarily paced. The author routinely uses temporary pacing in all cases with propofol anesthesia, which allows a more controlled and relaxed environment for permanent pacemaker implantation.

The vast majority of pacing systems use endocardial leads placed via the transvenous approach. However, epicardial leads are routinely placed in cats due to complications with transvenous systems and in the rare instances of persistent single left cranial vena cava in dogs.

98.5 TEMPORARY PACEMAKER IMPLANTATION

When implanting a temporary pacemaker, the clinician can use the following as a guide:

- A large area over the left or right jugular vein is clipped and surgically prepared.
- Anesthesia is induced with propofol intravenously to effect (4 to 6 mg/kg), and the animal is intubated and given oxygen.
- A 5 or 6 F vascular introducer is placed in the jugular vein via percutaneous technique.

- A 4 to 6 F temporary pacing lead is advanced into the RV under fluoroscopic guidance.
- The lead is attached to the external generator and paced as VVI with 5 V amplitude, 0.5 ms pulse width duration, 2.5 mV sensitivity, and 60 to 90 ppm.

Note: Alternatively, the femoral vein can be used for venous access using the previously described procedure.

98.6 PERMANENT TRANSVENOUS PACEMAKER IMPLANTATION (JUGULAR VEIN)

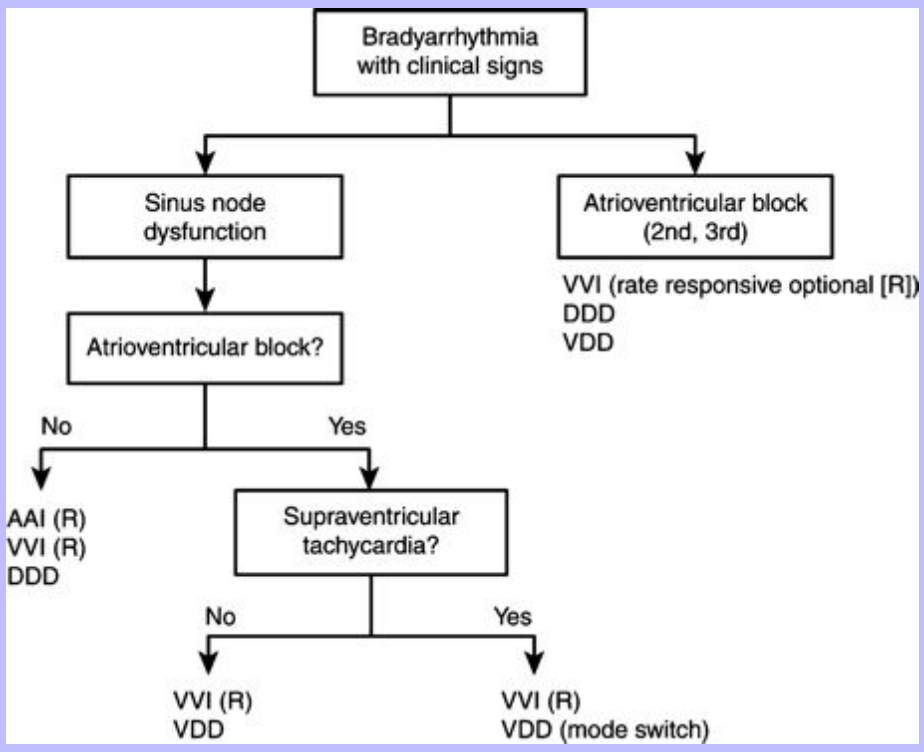
98.6.1 Ventricular Lead

When preparing a ventricular lead via the jugular vein, the clinician should do the following:

- Surgically prepare a large area over the right or left jugular vein, ipsilateral neck extending dorsally just to the contralateral side from the base of the skull to the midlevel of the scapula.
- Isolate a jugular vein segment via surgical cut-down and temporary encircling sutures or sterilized rubber bands.
- Perform a horizontal venotomy.
- Advance a straight or curved, appropriately sized stylet through the inner channel of the endocardial lead. 349
- Verify performance of extrusion-type active fixation leads by connecting the fixation tool to the connector pin and advance the corkscrew electrode by rotating the fixation tool clockwise. 350
- After extrusion, rotate the fixation tool counterclockwise to return the corkscrew into the lead. (The tool should not be overrotated counterclockwise or the mechanism may break.)
- Advance the endocardial lead through the venotomy site to the RA under fluoroscopic guidance. When using a curved stylet, the lead can often be directed into the apex of the RV. If using a straight stylet, withdraw some of the stylet to render the distal aspect of the lead more flexible and advance the distal tip to the apex of the RV.
- Advance a straight stylet to the end of the lead and gently advance the lead tip against the endocardial surface. With active fixation, connect the fixation tool to the connector pin and rotate clockwise to extrude the corkscrew under fluoroscopic guidance. Two radiopaque markers present at the lead tip touch when the corkscrew is fully extruded. With passive fixation, the lead is gently advanced to entangle the tines within the trabeculae of the RV.
- Ideally, at this time a PSA will be used to determine lead impedance and pacing thresholds. The lead can be placed at a different location within the ventricle if the pacing thresholds are determined to be inadequate for effective and safe pacing.
- Perform a “tug test” by gently pulling on the lead to verify that the endocardium is engaged.
- If a dual-chambered system is to be employed, insert the atrial lead prior to proceeding to the next step.

- Slide the suture sleeve on the lead distally and insert it into the distal aspect of the venotomy site. Place two to three circumferential nonabsorbable sutures around the jugular vein and the suture sleeve, taking care to advance enough lead to allow some slack for neck movement.
- Double ligate the proximal portion of the jugular vein.
- Make an incision over the dorsal neck. (Blunt dissection is used to create a pocket just large enough for the pulse generator.)
- Using a long, straight hemostat, tunnel to the venotomy site, grasp the proximal aspect of the lead, and pull until the lead enters the pulse generator pocket.
- Insert the connector pin into the ventricular lead channel of the pulse generator and tighten the screw or screws with a manufacturer-supplied wrench tool (overtightening should be avoided). If using a unipolar system, the pulse generator must be in contact with the tissues for pacing to occur. Temporary pacing should either be turned off or the rate dramatically slowed to not interfere with the permanent system.
- Place any excess lead underneath the generator, place a nonabsorbable suture through the suture sleeve on the generator, and anchor it to the deep fascia of the dorsal neck.
- Close incisions routinely, taking care to close as much dead space as possible to avoid possible seroma formation.

Figure 98-2 Bradyarrhythmia with clinical signs.



98.6.2 Atrial Lead

When placing an atrial lead via the jugular vein, the clinician should do the following:

- When used with a dual-chambered system, the ventricular lead is placed first. Care is taken when manipulating the atrial lead because dislodgement of the ventricular lead could result.
- If using a straight lead, insert a straight stylet into the lead and advance the lead tip under fluoroscopic guidance just until it enters the RA.
- Replace the straight stylet with a *J*-shaped stylet to direct the lead tip into the cranial-lateral aspect of the right auricle.
- If using a preformed *J*-shaped atrial lead, insert a straight stylet into the lead and advance the lead tip under fluoroscopic guidance just until it enters the RA.

350

351

- Slowly retract the stylet while advancing the lead; this should allow the tip of the lead to move into the cranial-lateral aspect of the right auricle.
- *Note:* Proper placement of the lead tip is verified by dorsoventral movement or “wagging” in concert with the beating heart.
- Regardless of the lead used, a *J*-shaped stylet should then be advanced to the lead tip and fixation performed as with the ventricular lead.
- When removing the stylet, the clinician should advance some of the atrial lead while the stylet is removed to reduce the risk of dislodgement.
- Place circumferential sutures around the jugular vein and suture sleeve as with the ventricular lead.

98.7 PERMANENT TRANSVENOUS PACEMAKER IMPLANTATION (COSTOCERVICAL VEIN)

When implanting a permanent transvenous pacemaker via the costocervical vein, the clinician should do the following:

- Perform a thoracotomy at the right second intercostal space.
- Isolate the costocervical vein (CCV) and ligate it 2 to 3 cm distal to the cranial vena cava.
- Perform a venotomy and advance the lead into the RV as with the jugular technique.
- Create the generator pocket deep to the external abdominal oblique muscle by a vertical incision over the seventh rib.
- Tunnel the lead deep to the subcutaneous tissues and over the lateral thorax to enter the generator pocket.
- Close all incisions in routine fashion.

98.8 PERMANENT EPICARDIAL PACEMAKER IMPLANTATION

When implanting a permanent epicardial pacemaker, the clinician should do the following:

- Perform a ventral midline celiotomy extending from just caudal to the umbilicus to the xiphoid.
- Make a vertical incision in the diaphragm, left of midline, to expose the cardiac apex.
- Incise the pericardium and retract with tissue forceps to expose the apex of the LV.
- Implant an active fixation epicardial lead into the apex of the LV by using the manufacturer-supplied lead tool.
- Create the generator pocket between the transverse abdominis and internal abdominal oblique muscles along the lateral abdominal wall.

Note: The clinician should not suture the pericardium; instead, the diaphragm and abdominal incisions should be closed in routine fashion.

98.9 POSTOPERATIVE CARE AND MONITORING

Thoracic radiographs and electrocardiography are performed postoperatively to verify lead placement and record QRS morphology, respectively. The animal is generally placed in an intensive care unit (ICU) overnight with continuous ECG monitoring for possible arrhythmias and loss of capture. With endocardial systems placed via the jugular route, a padded bandage is placed around the neck to cover both the jugular and generator incisions to protect the incision sites and prevent excessive fluid accumulation. The bandage is changed every 2 to 3 days until the sutures are removed in 10 days. Antibiotics such as cephalexin (22 mg/kg q 12-8 hrs) or amoxicilin with clavulanic acid (13.75 mg/kg q 12 hrs) are continued orally for 7-10 days. Strict exercise restriction is required for the first month to reduce the risk of lead dislodgement. After 1 month, the lead is usually anchored firmly in place and the animal can resume normal activity.

The author follows a monitoring protocol of 1 month, 3 months, and 1 year after implantation with annual or biannual rechecks scheduled thereafter. Thoracic radiographs, surface ECG, and programmer interrogation by a PSA are performed to evaluate lead placement and function. Appropriate adjustments are made to the generator via the PSA as needed; end of battery life for the generator can also be identified.

99 CHAPTER • 99 Peritoneal Dialysis

Cathy Langston

Peritoneal dialysis is used to treat acute renal failure, occasionally poisoning by a dialyzable toxin (i.e., ethylene glycol, phenobarbital, ethanol), or chronic renal failure. Some peritoneal dialysis techniques can also be applied for peritoneal drainage (i.e., uroabdomen) or peritoneal lavage (i.e., pancreatitis, hypothermia, hyperthermia).

99.1 PERITONEAL DIALYSIS CATHETERS

Access to the peritoneal cavity is accomplished via a peritoneal catheter. The general design of percutaneously placed catheters includes multiple fenestrations at the tip of the catheter to allow fluid ingress and egress. A variety of catheters are available that are made specifically for this purpose (i.e., Peritoneal Lavage Catheter, Cook Veterinary Products, Spenser, Ind.; Pediatric Peritoneal Dialysis Catheter, Baxter Healthcare Corp., Deerfield, Ill.), or fenestrated chest tubes may be used. For percutaneous placement, local anesthesia in conscious animals or a short-acting injectable anesthetic may be used. The patient is placed in dorsal recumbency, and the abdomen is sterilely prepped and draped. A stab incision through the skin lateral to the midline at the level of the umbilicus allows introduction of a trocar threaded through the dialysis catheter. The trocar is tunneled under the skin for 1 to 2 cm before puncturing the abdominal musculature. The trocar should be directed toward the opposite hip. Having the abdomen slightly distended with fluid facilitates percutaneous placement. After the trocar has been introduced, the catheter is advanced off the trocar. The tip of the catheter should rest near the urinary bladder to facilitate fluid drainage. If a trocar is not provided with the catheter, the tip of the catheter can be grasped with curved hemostats, which can be used to tunnel the catheter under the skin and then puncture the abdomen.

The coaxial catheter (Cook Veterinary Products, Spenser, Ind.) and the fluted-T catheter (Ash Advantage Peritoneal Dialysis Catheter, Medigroup, Inc., Aurora, Ill.) are less likely to occlude with omentum. The fluted-T catheter has two limbs, each with channels extending the length of the catheter, to minimize the chance for complete occlusion. These catheters are placed surgically or via laparoscopy. Both have a Dacron cuff that allows attachment of fibroblasts in the subcutaneous portion to enhance stability and diminish leaks and infection. With surgical placement, the catheter is placed in the abdomen via a small caudal abdominal incision. The catheter should exit the ventral body wall through a separate stab incision (not through the abdominal incision), and tunnel under the skin lateral to the midline. The tip of the catheter should rest near the urinary bladder. A partial omentectomy is performed to diminish catheter occlusion. If omentectomy is not desired due to recent intestinal surgery, an omentopexy should be performed.

With both percutaneous and surgical placement, the catheter is secured to the skin at the exit site via a purse string suture. A sterile dry bandage is placed over the catheter. Ideally, the catheter would not be used for 24 hours after placement to allow formation of a fibrin seal, but the animal's condition rarely allows this. When the catheter must be used immediately, a small volume of dialysate (half of the standard volume) should be used for each exchange for the first 24 hours.

99.2 DIALYSATE SOLUTIONS

Dialysate is the fluid that is introduced into the abdomen. Uremic toxins (e.g., blood urea nitrogen [BUN], creatinine, potassium) diffuse from the area of high concentration (the patient's bloodstream) across the peritoneal membrane into the area of low concentration (dialysate). The dialysate is then drained and discarded and the process is repeated. Dialysate should be similar in content to plasma and should contain physiologic

concentrations of readily diffusible substances like sodium, chloride, calcium, and magnesium. It should also contain dextrose, which may be varied in concentration to create an osmotic gradient to either promote or retard fluid removal, based on the animal's needs. If no fluid removal is desired, a dextrose concentration of 1.5% is typically used. If the dog or cat is overhydrated, dextrose concentrations of 2.5% or 4.25% can be used to promote movement of water into the hypertonic dialysate in the abdomen—a process called *ultrafiltration*. Commercially prepared dialysate is available, or dialysate can be improvised from intravenous fluids. Dextrose is added to lactated Ringer's solution or saline to create the desired dextrose concentration (30 mL of 50% dextrose per liter for 1.5% solution, 50 mL per liter for 2.5% solution, or 85 mL per liter for 4.25% solution). Heparin (250 to 1000 U/L) should be added to the dialysate for the first few days after catheter placement to minimize fibrin clot formation. Magnesium should be added after the first several days of dialysis to achieve a concentration of 1.5 mEq/L. If saline is used, sodium bicarbonate should be added to achieve a concentration of 30 to 45 mEq/L. Each additive to the dialysate increases the risk of contamination and formulation error.

99.3 EXCHANGE PROCEDURE

Frequent dialysate exchanges are necessary in dogs or cats with acute oliguric or anuric renal failure, with hyperkalemia, or those that are overhydrated. Initially, exchanges may be as frequent as every 45 to 60 minutes. As the uremia improves (typically after 24 to 48 hours), the frequency of exchanges can be gradually decreased to four times a day, with the goal of maintaining the BUN concentration between 60 to 100 mg/dL. The volume of dialysate to instill is 40 mL/kg per exchange. With small volumes of dialysate, weighing the dialysate bag or using a burette is recommended to increase the accuracy of measurement. Dialysate should be warmed to 38°C to maintain body temperature and to improve peritoneal permeability. Dogs and cats need to be closely observed for signs of abdominal discomfort or respiratory compromise.

352

353

Because peritonitis is a frequent complication of peritoneal dialysis, the catheter and all connections should be handled as aseptically as possible. The connection ports should be covered with antiseptic-soaked gauze and should be scrubbed prior to any connection or disconnection. Sterile gloves should be worn when handling the connections, and the frequency of connections and disconnections should be kept to a minimum. Most contamination occurs when connecting to the dialysate bags. A Y connector (or stopcock) can be placed on the catheter and connected to a multidose bag of fresh dialysate and to an empty bag to collect spent dialysate. A small amount of fresh dialysate is flushed into the drain bag with the catheter closed to the animal in an attempt to flush any contaminant that may have been introduced during the connection process into the drain bag and not into the abdomen. The dose of dialysate should then be instilled into the abdomen by gravity feed, usually taking less than 10 minutes. The fresh dialysate bag should then be clamped and the catheter closed to the dog or cat during the dwell time. After the appropriate dwell time, the catheter is opened to allow drainage of the abdominal fluid into the drain bag. It is important that the drain bag be positioned lower than the catheter to allow gravity drainage. Gentle ballottement of the abdomen and repositioning the animal can facilitate more complete drainage. After draining ceases (approximately 15 to 30 minutes), fresh dialysate is again instilled into the abdomen. If the entire volume of the fresh dialysate bag is infused per exchange, the empty bag should be clamped after infusion and left attached. After the dwell time, the clamp should be opened and the bag used as the drain bag.

The volume of dialysate instilled and the volume recovered should be monitored carefully, as should urine output and volume of administered fluids, medications, and feedings. When hypertonic dialysate is used (i.e., 4.25% dextrose), a larger volume of dialysate should be recovered than instilled, indicating net fluid removal from the animal. The dog or cat should be monitored for evidence of dehydration. If less dialysate is being recovered than is being instilled, the catheter tubing should be checked for kinks or occlusion and the animal repositioned. The catheter can be forcefully flushed with heparinized saline, or 15,000 U of urokinase can be instilled in the catheter for 2 to 3 hours to dislodge fibrin clots or omentum. If these measures do not restore flow, the catheter may need

to be repositioned or replaced. If the dog or cat is dehydrated, fluid may be reabsorbed from the peritoneal cavity, decreasing the volume of dialysate recovered.

In addition to meticulous attention to fluid balance, several other parameters should be monitored routinely. Blood glucose concentration should be monitored once or twice daily. If hyperglycemia is documented, low doses of insulin may need to be administered. Packed cell volume (PCV), total solids, and electrolytes should be monitored twice daily. Initially, BUN, creatinine, and albumin should be monitored once or twice daily. Cytology should be performed on the spent dialysate on a daily basis, and the dialysate should be cultured weekly or if it becomes cloudy.

99.4 COMPLICATIONS

Peritonitis is a major complication of peritoneal dialysis. Meticulous attention to aseptic technique is necessary to decrease this risk. Diagnosis is made by presence of clinical signs (e.g. abdominal pain, fever), cloudy dialysate, or greater than 100 inflammatory cells per mL of dialysate. Because *Staphylococcus* is the most common organism isolated, systemic cephalosporins are recommended pending culture results. Intraperitoneal administration of antibiotics may be helpful (i.e., 125 mg cephalothin per liter of dialysate). Although peritonitis may be successfully managed while continuing dialysis, removal of the peritoneal dialysis catheter may be required to allow resolution of unresponsive peritonitis.

Catheter occlusion is a common problem with peritoneal dialysis. The omentum has tremendous migratory capability and can rapidly encompass the catheter. Acute peritoneal dialysis catheters may occlude within 24 to 72 hours of placement. The fluted-T and coaxial catheters fare better, but occlusion can still occur with these. A partially occluded catheter drains more slowly and incompletely. Incomplete emptying of the dialysate decreases efficiency of toxin removal and risks overdistension of the abdomen, with concomitant problems (abdominal or respiratory distress). Flushing the catheter with saline in the first 24 hours after placement may help delay this problem. If the catheter occlusion cannot be dislodged with flushing or urokinase, the catheter may need to be replaced. Other catheter-related complications include dialysate leakage or exit site and subcutaneous tunnel infections.

Hypoalbuminemia is one of the most common complications of peritoneal dialysis and can be partially addressed by providing adequate nutrition either enterally or parenterally. Enteral feeding is frequently difficult, due to anorexia or vomiting. Gastrostomy or jejunostomy tubes are contraindicated in peritoneal dialysis due to exit site leaks and increased risk of infection. Dialysate containing amino acids may provide partial nutrition but should not be used unless adequate nonprotein calories are being provided.

99.5 DISCONTINUING DIALYSIS

Intermittent rest periods, in which no dialysate dwells in the abdomen, with close evaluation of the animal's clinical and biochemical status can be used to determine when dialysis can be discontinued. When the dog or cat can maintain homeo-stasis without dialysis, the catheter should be removed surgically. Unfortunately, survival with peritoneal dialysis has been low, with most reports around 30%.

100 CHAPTER • 100 Veterinary Nuclear Medicine

Brian A. Poteet

100.1 INTRODUCTION

Nuclear imaging (scintigraphy) has been used in veterinary medicine as a primary or secondary modality to aid in the diagnosis of disease processes and for therapy. The utility of nuclear medicine procedures lies in the fact that they enable the imaging of physiologic processes. Nuclear medicine is to physiology as radiographs are to anatomy. Table 100-1 lists six nuclear medicine studies and their primary indications for use. Although these studies and others have been used in animal patients, the thyroid scan, portal scan, bone scan, and glomerular filtration rate (GFR) scan are the most commonly performed scans in a clinical setting. The *Handbook of Veterinary Nuclear Medicine*[1] further describes these and other types of scans.

Nuclear imaging differs from radiographic imaging in that the instrumentation (a gamma camera) emits no radiation. Instead the patient emits gamma radiation after a dose of radiation has been intravenously administered. The most common radionuclide used for diagnostic purposes is ^{99m}Technetium (^{99m}Tc, Tc, Tech, or pertechnetate). ^{99m}Tc is eluted using sterile saline in liquid form from its parent isotope, ^{99}Molybdenum (^{99}Mo), in a lead-encased generator system (also known as the “cow”); the whole process commonly referred to as “milking the cow.” The eluate (^{99m}Tc suspended in saline) is then placed in a small lead-encased dosing bottle (known as the “pig”) and kept for use either alone (as a radionuclide) or it tagged to a pharmaceutical (to form a radiopharmaceutical). The amount of radioactivity obtained with each elution is variable and will depend on the size of the generator system, its age, and the timing of each elution. The most common unit of a dose of radioactivity is the Curie (Ci), with most fresh eluates being around 1 Ci in strength. Most patient doses are in the millicurie (MCi) range (1 Ci = 1000 MCi). An individual or institution must have a radioactive materials license (RML) from either the state in which they practice (an “agreement state”) or from the Nuclear Regulatory Commission (NRC). Qualifications and experience required to obtain an RML varies, but it generally requires proven experience and training in nuclear medicine procedures and radiation safety. The regulations concerning the use of radioactive materials in veterinary patients are often different from that of human patients. The major differences usually pertain to patient release criteria and safety requirements. For example, human patients are allowed to leave the hospital if they have been administered 30 MCi or less, as compared with animal patients that must typically be hospitalized for 24 hours until their exposure levels are below a specific level that the state has set (typically 0.5 mR/hour at 1 m. The overall dose of radiation that a patient is exposed to from a typical nuclear medicine procedure is minimal, and adverse side effects are rarely seen.

Table • 100-1 Commonly Performed Nuclear Medicine Studies in Veterinary Medicine

SCAN NAME	INDICATIONS FOR USE
Thyroid scan	Feline hyperthyroidism, occult hyperthyroidism
Portal scan	Macroscopic portosystemic shunt detection
Bone scan, three-phase bone scan	Occult lameness, differentiate septic arthritis or osteomyelitis vs. severe chronic degenerative joint disease (DJD), metastatic bone disease
Glomerular filtration rate (GFR) scan	Quantitative evaluation of differential renal function
Perfusion lung scan	Pulmonary thromboembolic disease
Multigated acquisition cardiac scan (MUGA)	Subjective and objective evaluation of cardiac performance

The site and method of tissue localization depends on several factors, the more important of which are blood flow, the type of radiopharmaceutical used, and individual species differences. When administered intravenously to a patient as a radionuclide (pertechnetate ion), localization will mimic that of halogenated compounds, such as iodine, and occurs in glandular tissues, such as the thyroid gland, choroid plexus, salivary glands, and mucosal glands that line the stomach. When administered as a radiopharmaceutical, the method and site of localization depend on the physical or chemical characteristics of the radiopharmaceutical itself. Table 100-2 lists commonly used radiopharmaceuticals, their various sites and methods of tissue localization, and their various uses.

Instrumentation required in a basic veterinary nuclear medicine lab will vary, but includes a gamma camera, an interfaced computer with acquisition and processing software, an exposure meter, safety equipment including a radioactive materials spill containment and clean-up kit, shielding material such as lead bricks, and a properly shielded and ventilated radiation isolation ward. New gamma cameras and computers are expensive, but good quality used and refurbished equipment is available.

Radiation safety is extremely important when performing nuclear medicine procedures. The word “nuclear” often conjures up thoughts of nuclear weapons, mushroom clouds, and genetic defects. In fact, many owners are surprised to find out that their animals will not “glow in the dark” after a scan. Four basic premises to radiation safety are considered universal: First, is the as low as reasonably achievable (ALARA) concept, which states that individuals should never allow themselves to be exposed to any more radiation than is absolutely required to do their jobs. The last three radiation safety guidelines that should be remembered are time, distance, and shielding. One should always minimize the time exposed to a radiation source, maximize the distance from it, and when possible place protective shielding (lead, cement walls) between him or herself and the radiation source when possible. For all nuclear medicine procedures performed in veterinary medicine, the users should always wear disposable exam gloves, a lab coat, and should always be monitored (properly wearing a radiation exposure detection device) with a film badge, thermoluminescent dosimeter (TLD) badge, or pocket dosimeter. For most institutions, employees working strictly with nuclear medicine patients will have about one tenth the dose of other employees who work in radiology sections.

354
355

Table • 100-2 Commonly Used Radiopharmaceuticals

RADIOPHARMACEUTICAL OR RADIONUCLIDE	SITE OF LOCALIZATION	METHOD OF LOCALIZATION	TYPICAL USE
^{99m}Tc-Methylene diphosphate	Hydroxyapatite	Chemiadsorption	Bone scan
^{99m}Tc-Diethylene triamine pentaacetic acid	Glomerular filtrate	Active transport	GFR scan
^{99m}Tc-Macroasgregated albumin	Pulmonary capillary bed	Capillary blockade	Perfusion lung scan
^{99m}Tc-HIDA xxx	Hepatocytes and bile	Active transport	Hepatobiliary scan
^{99m}TcO4 xxx	Glandular tissue		Thyroid scan
^{67} Gallium xxx	Sarcoma tissue, abscess	Transferring analog	Sarcoma imaging, FUO
$^{123 \text{ or } 131}$MIBG xxx	Neuroendocrine cells	Active transport	Pheochromocytoma

100.2 THYROID SCINTIGRAPHY

100.2.1 Introduction and Basic Techniques

The thyroid scan is the most commonly performed diagnostic scan in veterinary nuclear medicine and is used to confirm and diagnose feline hyperthyroidism. The diagnostic thyroid scan is considered to be the "gold standard" means of diagnosing feline hyperthyroidism. Because technetium behaves as a halogen (iodine) when administered, it is actively trapped by thyroid cells. However, unlike iodine, technetium is only trapped and does not progress through the remaining steps of thyroid hormone synthesis (organification, coupling, storage, and release).[2,3] The trapping of technetium is competitive with iodine (recent administration of iodinated contrast material may hinder the uptake by the thyroid) and is also influenced by thyroid-stimulating hormone (TSH) levels.[4] Adenomatous hyperplasia of the feline thyroid results in a hyperfunctional gland in two ways. First, the gland synthesizes and releases too much thyroxine, resulting in an elevated T4 value and (more fundamentally) the gland has increased ability to trap iodine (and therefore technetium). This is not always true in the canine species as will be discussed later.

Although the thyroid scan can be performed with either ^{123}I or ^{99m}Tc, technetium has the advantages of being more economical, readily available, and it has a shorter half-life. If disparate imaging between the two radionuclides occurs, they are typically insignificant.[5] The dose of ^{99m}Tc used for a feline patient is typically 4 MCi (+/− 2 MCi) and is administered intravenously into a cephalic or medial saphenous vein. It has been shown that the maximal uptake by thyroid cells is at 45 to 60 minutes after injection[6]; although approximately 90% of cats will demonstrate positive scans in just seconds after injection. Normal salivary gland to thyroid gland ratios are 1:1.2 or less[7] and can be obtained by calculating the count density within a region of interest (ROI) encircling the respective glands. For practical purposes, however, the zygomatic salivary glands and thyroid gland should have very similar degree of uptake in normal cats. In hyperthyroid cats, a portion or all of one or both of the thyroid lobes will have significantly more uptake than that seen by the salivary glands.

100.2.2 Indications for Performing a Thyroid Scan

A thyroid scan should be performed for several reasons. The scan can be used to confirm suspect hyperthyroidism in feline patients that have elevated circulating thyroxine levels prior to administration of radioiodine. The majority of centers routinely perform thyroid scans on all patients prior to administration of radioiodine (^{131}I), thus preventing wrongful treatment of normal patients that have a false-positive elevated T4 or fT4 assays. Negative results of a thyroid scan will prevent an unnecessary surgery or inappropriate administration of radioiodine. The amount of uptake and size of the glands may also aid the clinician in determining the dose of radioiodine to be used, thus allowing some degree of individual tailoring of the dose of radioiodine. Lastly, by routinely performing a diagnostic thyroid scan on all patients, one may be able to exclude a patient whose scan suggests an aggressive thyroid carcinoma, the presence of which may change the owner's decision-making process.

Thyroid scanning may also diagnose patients with "occult" hyperthyroidism. In these cases a diagnostic thyroid scan can quickly diagnose hyperthyroidism in a patient that may otherwise be missed.

A thyroid scan can also be used before or after attempts at surgical resection of both or one lobe of the thyroid in clinically persistent hyperthyroid cats. In these cases, foci of ectopic thyroid tissue can be easily localized

within the cervical region (incomplete resection) or within the cranial mediastinum. Once located, the persistent hyperfunctional thyroid tissue can be removed or ablated with radioiodine.

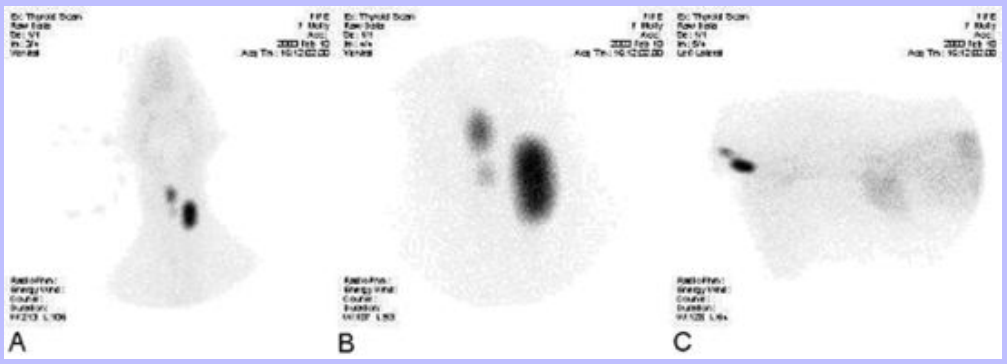
100.2.3 Image Acquisition

A minimum of three views should be taken during acquisition of a routine feline thyroid scan (Figure 100-1). The first image should be a ventral view, which includes both lobes of the thyroid gland and the mandibular and zygomatic salivary glands. This view is used to confirm the diagnosis of hyperthyroidism because the amount of uptake by the thyroid glands can be easily compared with that of the salivary glands, either by drawing ROIs around the individual glands and comparing count density or by subjective comparison. The second ventral view should be a close up view of just the thyroid gland itself, taking care to include any area of uptake. This view is important in evaluation of the morphology of the thyroid itself. The last view that should be acquired is a lateral view (right or left), including the entire thorax. To ensure that the entire thorax is included, the thyroid should be seen on one side of the image and stomach uptake on the opposite side. This view is important in evaluating for possible uptake within the cranial mediastinal region and lung fields. If uptake is seen in these regions, a ventral view of the thorax and opposite lateral should also be obtained. All images should be acquired on a count basis (as opposed to a time acquisition) for approximately 200,000 counts using pinhole collimation. Each image acquisition should take approximately 3 minutes, giving a total scan time of about 10 minutes (assuming a ^{99m}Tc dose of 4 MCi).

355

356

Figure 100-1 Thyroid Scan. Hyperfunctional thyroid adenoma, bilateral, in a fourteen-year-old domestic shorthair, male castrated technetium injected with 4 MCi of ^{99m}Tc. Images shown are 200,000-count static images with pinhole collimation. **A,** Ventral neck view. Focal intense activity is seen by both lobes of the thyroid glands, more so than that seen by the salivary glands. The right thyroid has a "hot" nodule in the cranial and caudal pole. **B,** Ventral thyroid view. Both glands exhibit benign scanning characteristics (intense center, homogeneous uptake, tapering margins, no evidence of regional tissue invasion). **C,** Left lateral thorax view. No abnormal areas of uptake in the thorax are seen.



100.2.4 Interpretation and Analysis

In normal cats (not hyperthyroid) the amount of uptake seen by the salivary glands and thyroid gland is very similar. Placement of ROIs around the salivary glands and thyroid tissue with comparison of the amount of uptake should yield a thyroid to salivary gland ratio of less than 1.2 in normal animals. In most cases the placement of ROIs is not needed to confirm the diagnosis of hyperthyroidism, and subjective evaluation of significantly more uptake within the thyroid tissue versus that of the salivary gland tissue is all that is needed (Figure 100-2).

False-positive ^{99m}Tc thyroid scans can be seen in hyperthyroid cats secondary to recent administration of methimazole because it may cause false increased uptake by the thyroid tissue due to stimulation by an elevated TSH concentration.[10] This same phenomenon has not been evaluated in normal euthyroid cats. False-negative thyroid scans are extremely rare but may be due to severe thyroiditis, recent intake of iodinated contrast material, or ingestion of excess dietary or administered iodine[11] overlying and attenuating soft tissues or malfunctioning nuclear medicine equipment.

Several classifications of feline hyperthyroidism exist based on the location of uptake. Unilateral uptake by one lobe with complete suppression of the contralateral lobe is reportedly seen in approximately one third of patients[3] (Figure 100-3, *A*). Bilateral uptake in both lobes is seen in the remaining two thirds[3] (Figure 100-3, *B*). Bilateral uptake is defined as uptake, regardless of the amount, seen in both thyroid lobes. It is common for one lobe to have more uptake, be larger than the contralateral lobe (incomplete suppression), or both; however, this is still considered to be bilateral because a normally functioning thyroid should demonstrate no evidence of autonomous function and be completely suppressed (thus not seen at all) (Figure 100-3, *C*).

Hyperfunctional ectopic tissue can occur anywhere from the base of the tongue to the base of the heart; the incidence is estimated to be as high as 10%[14] (Figure 100-4). The presence of ectopic hyperfunctional thyroid tissue does not imply malignancy. It is also very common to detect adenomas with intense focal uptake by very small (2 to 3 mm), nonpalpable, thyroid nodules (Figure 100-5).

A thyroid scan can also be used to help differentiate benign adenomatous hyperplasia versus a malignant thyroid carcinoma. Close examination of the morphologic scanning characteristics of each thyroid lobe may give clues that help distinguish nonaggressive disease versus an infiltrative carcinoma. Pinhole collimation is very helpful in evaluating the morphology of thyroid disease because it magnifies the appearance of the otherwise small lobes. Characteristics of a simple adenoma (benign) include round to oval shape, smooth or homogeneous uptake, margins that taper uniformly, and no evidence of regional tissue invasion. Malignant thyroid carcinomas often exhibit very abnormal shapes with poorly defined, irregular margins, heterogenic uptake, and evidence of invasion into surrounding tissue facial planes (Figure 100-6).

Figure 100-2 Normal feline thyroid scan. The amount of uptake by the thyroid gland is similar to that seen by the salivary glands.

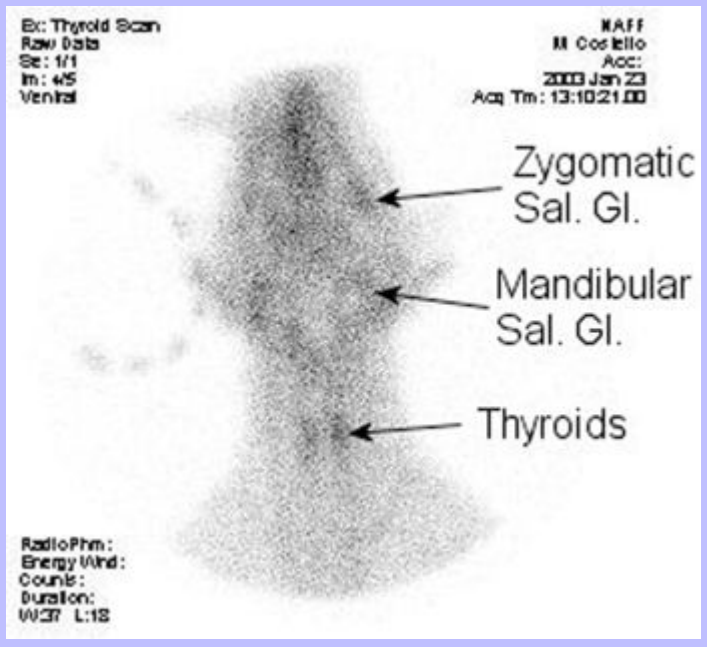


Figure 100-3 Variations of feline hyperthyroidism. Three commonly seen morphologic variations of feline hyperthyroidism exist. **A,** Unilateral with complete suppression of normal contralateral thyroid lobe. **B,** Bilateral hyperthyroidism. **C,** Bilateral hyperthyroidism with incomplete suppression of one thyroid lobe.

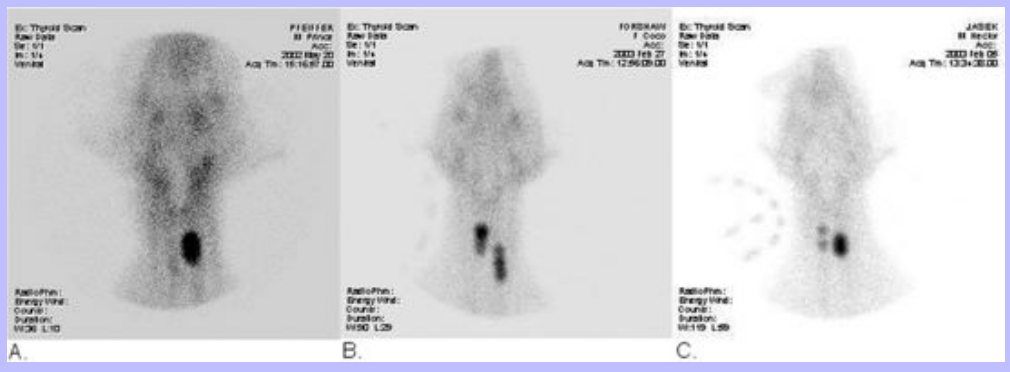
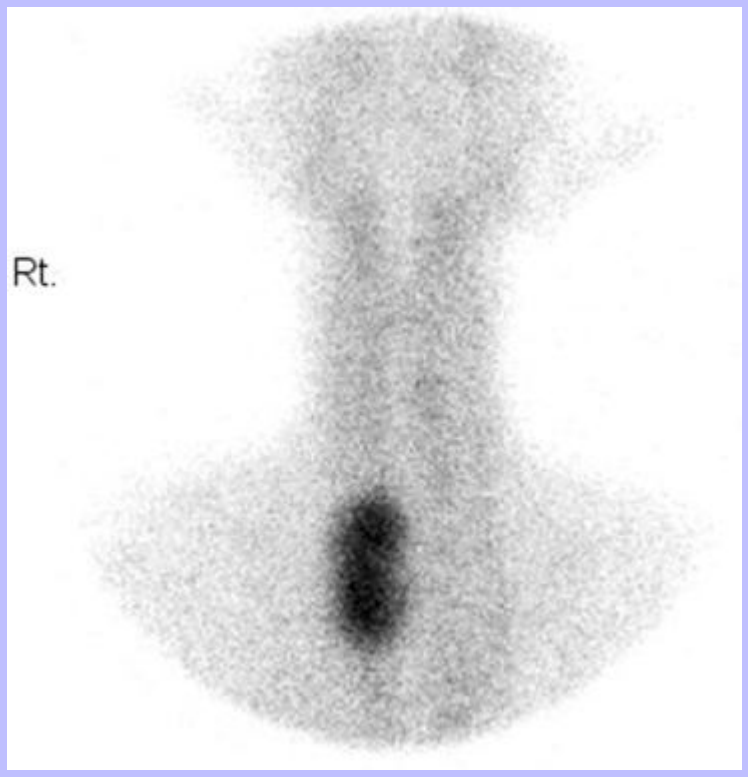


Common findings that occur in adenomas that can be confused with a carcinoma include nodular to multinodular uptake, photopenic areas caused by thyroiditis, follicular cyst or parathyroid adenoma, or ectopic

hyperfunctional tissue within the thoracic inlet or cranial mediastinum. In these cases it is important to examine each focal area of uptake individually for evidence of benignancy or malignancy. If the cat has undergone previous attempts at thyroidectomy, caution must be exercised because the surgical intervention can cause a very abnormal morphologic appearance of the persistent or recurrent thyroid tissue that can mimic a thyroid carcinoma (Figure 100-7).

In cats with suspected thyroid carcinoma, ultrasound is often the next step because it can often detect the reason for photopenic areas caused by follicular cysts or an enlarged parathyroid gland and evaluate if the thyroid appears to be well encapsulated. If none of the aforementioned are true, if the thyroid gland appears of mixed echogenicity, or if it appears invasive into surrounding tissues, surgical intervention usually follows.

Figure 100-4 Ectopic thyroid tissue. Ventral view shows focal intense uptake in functional thyroid tissue located within the cranial mediastinum on the right.



After a diagnostic thyroid scan using ^{99m}Tc, the feline patient must be housed in a radiation isolation ward until it clears the individual clinics release criteria, which is typically set by the issuer of the RML (the author's practice requires 0.5 mR/hour at 1 m). This is measured using an appropriate monitoring device such as a Geiger counter or “Cutie Pie” exposure meter. Once the animal returns home, the owner is instructed on how to care for the pet physically, told to minimize time holding the cat for the next week or so, and instructed how to handle the very small amount of radioiodine that will still be excreted in the cat's urine. (The specifics of these requests often vary from state to state.)

357
358

Figure 100-5 Extremely small, nonpalpable thyroid tissue. Focal intense uptake is evidenced by a very small foci of thyroid tissue on the left side. This nodule was not palpable even in retrospect after the scan localized it.

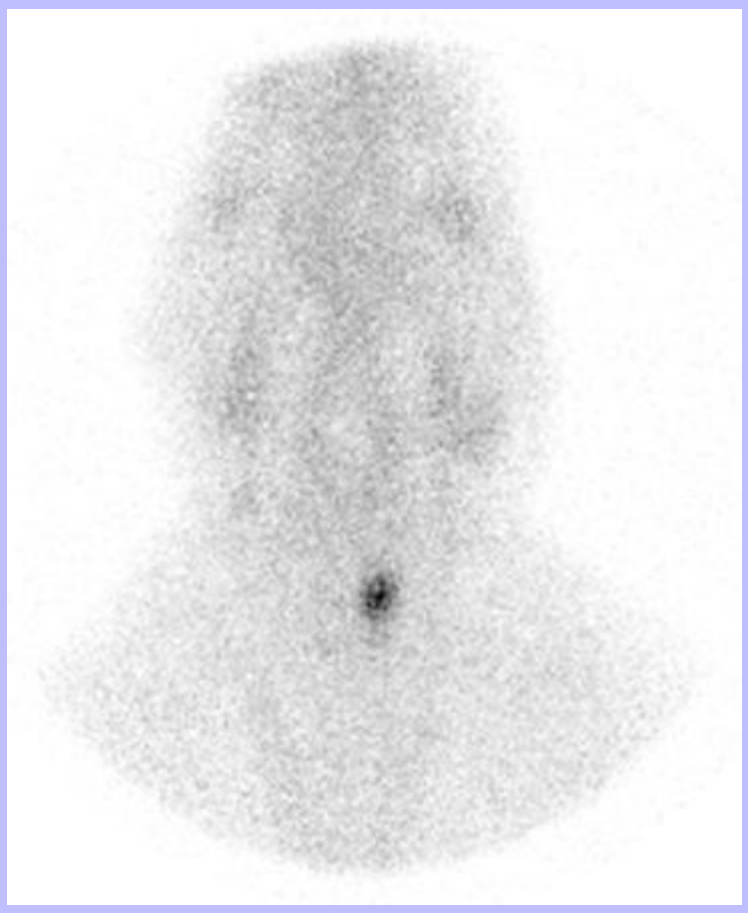


Figure 100-6 Feline thyroid adenocarcinoma. The right thyroid lobe shows very heterogeneous uptake with irregular margins. Extension of functional malignant tissue can be seen into fascial planes and into the cranial mediastinum. Numerous photopenic areas are present.

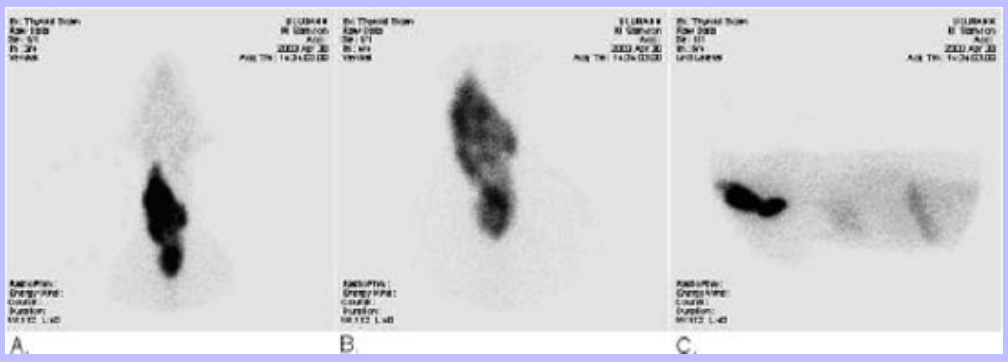


100.2.5 Radioiodine Therapy for Feline Hyperthyroidism

Three treatment options exist for feline hyperthyroidism: (1) medical therapy with methimazole, (2) surgical removal of the thyroid glands, and (3) radioiodine therapy. All methods have pros and cons, which will be discussed.

Radioiodine therapy using ^{131}I also has both advantages and disadvantages. Radioiodine therapy is extremely targeted in that once injected the iodine is preferentially trapped and organified by the hyperfunctional thyroid cells (little to know uptake is seen by normally suppressed thyroid cells) and once there, the high-energy beta particles that are emitted during the decay process cause irreparable damage to the cells. The distance of beta particle travel, and therefore the area of tissue damage, is confined to 1 to 2 mm; thus concurrent damage to adjacent parathyroid tissue is not seen. Administered radioiodine is taken up by all hyperfunctional thyroid tissue, regardless of its anatomic location. Because feline hyperthyroidism is not an autoimmune form of thyroid disease (human Grave's disease) and most closely resembles toxic nodular goiter (multinodular goiter), the great majority of cats that are diagnosed with hyperthyroidism retain some suppressed (but otherwise normal) thyroid cells. The advantage is that approximately 95% of cats treated with radioiodine will be euthyroid after treatment, requiring no supplementation. It is relatively common for cats to have subnormal total thyroid hormone levels immediately after radioiodine therapy, but it is extremely rare for any of these cats to demonstrate any signs of hypothyroidism. In these cats, a recheck of the thyroid hormone levels in 1 to 3 months after therapy will often demonstrate normal values.

Figure 100-7 Postsurgical thyroid. Fifteen-year-old domestic shorthair, female spayed. Patient is persistently hyperthyroid despite two attempts at bilateral subcapsular thyroidectomy. The left thyroid lobe is irregular in shape and bulbous in appearance secondary to previous surgical intervention (left-sided subcapsular thyroidectomy) and subsequent recurrence. The right thyroid lobe is incompletely suppressed.

Care must be taken regardless of the form of therapy chosen if the patient has concurrent renal compromise. Readers are encouraged to review the many studies that pertain to the correlation of the treatment of hyperthyroidism and renal disease.[15–17] In general, cats that have normal renal function based on normal serum blood urea nitrogen (BUN) and creatinine (CR) values should have few problems with any form of therapy for hyperthyroidism. In patients that are both hyperthyroid and show equivocal or definitive evidence of renal failure (azotemia and inability to concentrate urine), a 3-to 4-week trial period using methimazole is recommended. If at the end of this time the BUN and CR levels are not increased, the animal is not showing signs of renal failure, and the total T4 values have dropped to within the normal range, a more definitive form of therapy can be safely considered. In these patients a lower dose of radioiodine may be used in an effort to minimize any effects on the kidneys and, at the same time, control hyperthyroidism. Radioiodine itself is not toxic to the kidneys. The cause of the worsening of renal disease that can accompany any form of hyperthyroid therapy is unknown but may relate to changes in hemodynamics within the kidney and glomerular filtration. Supplementation of thyroid hormone in cats that experience manifestation of renal failure after definitive thyroid therapy may be of benefit; however, no such studies have been undertaken to prove this theory.

358

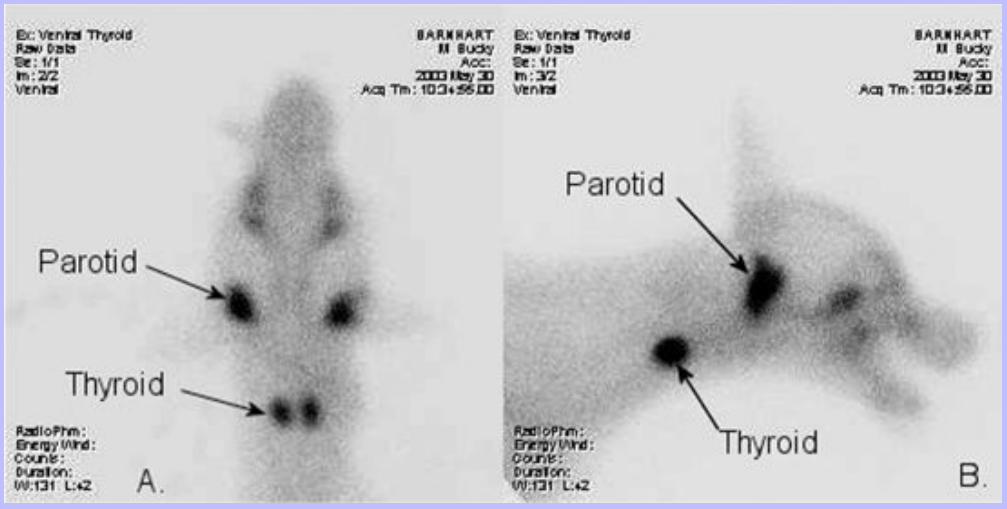
359

100.2.6 Thyroid Scan and Canine Thyroid Disease

The parotid salivary glands in dogs demonstrate much more uptake compared with those of cats; however, the amount of uptake by the salivary glands and thyroid should be very similar in individual animals of either species (Figure 100-8). The indications to perform thyroid scans in dogs are fewer than in cats but may include

presurgical evaluation of the degree of regional tissue invasion (which may aid the surgeon in evaluating the degree to which one rejects the cervical mass). A thyroid scan can also confirm that a cervical mass is indeed thyroid in origin and identify functional distant metastasis. Canine thyroid carcinoma is different from that seen in cats in that approximately one third of affected patients will demonstrate decreased or no uptake (inability to trap ^{99m}Tc), one third of patients will have relatively normal amounts of uptake (normal ability to trap ^{99m}Tc), with the last third demonstrating increased uptake (increased ability to trap ^{99m}Tc). Uptake by distant metastasis appears to have similar patterns. The same scanning characteristics of malignancy can be applied to the canine patient in that most carcinomas will demonstrate heterogeneous uptake, very irregular gland shapes, and often evidence of regional tissue invasion (Figure 100-9). Thoracic radiographs are more sensitive than a thyroid scan for the detection of pulmonary metastasis, and as such they should always be obtained whenever thyroid carcinoma is suspected.

Figure 100-8 Normal canine thyroid scan. Similar amounts of uptake of the radionuclide by the parotid salivary glands and the thyroid tissue occur. Both thyroid lobes are normal in size, shape, and location.



100.2.7 Radioiodine Therapy for Canine Thyroid Carcinoma

^{131}I has also been used as therapy for canine thyroid carcinoma.[18,19] Radioiodine therapy is best suited for therapy for micrometastatic disease in cases where the primary carcinoma is proven to retain the ability to trap iodine (technetium); as such a diagnostic thyroid scan using ^{99m}Tc or ^{123}I should be performed prior to surgical intervention. The thyroid-associated mass should be removed or debulked surgically followed by radioiodine therapy. Presurgical external beam radiation therapy may also be used in certain cases in an attempt to shrink the primary tumor prior to intervention. If the primary tumor exhibits no ability to concentrate iodine, then conventional chemotherapeutics may be preferential for potential or known micrometastatic disease in combination with external beam radiation therapy for any incompletely resected margins. The dose used for canine thyroid carcinoma varies widely but may range from 20 MCi to 100 MCi or more. The dose is usually administered intravenously through a preplaced catheter. After administration, the animal must be kept in a radiation isolation ward until it has cleared release criteria. Strict radiation safety practices must be instituted

during the entire stay, and it is not uncommon for these patients to contaminate their exterior surfaces with iodine. The typical hospital stay for these patients in the author's practice ranges from 10 to 21 days. Side effects seen with large-dose radioiodine therapy are rare but may include transient neutropenia that lasts only a few days.

100.3 PORTAL SCINTIGRAPHY

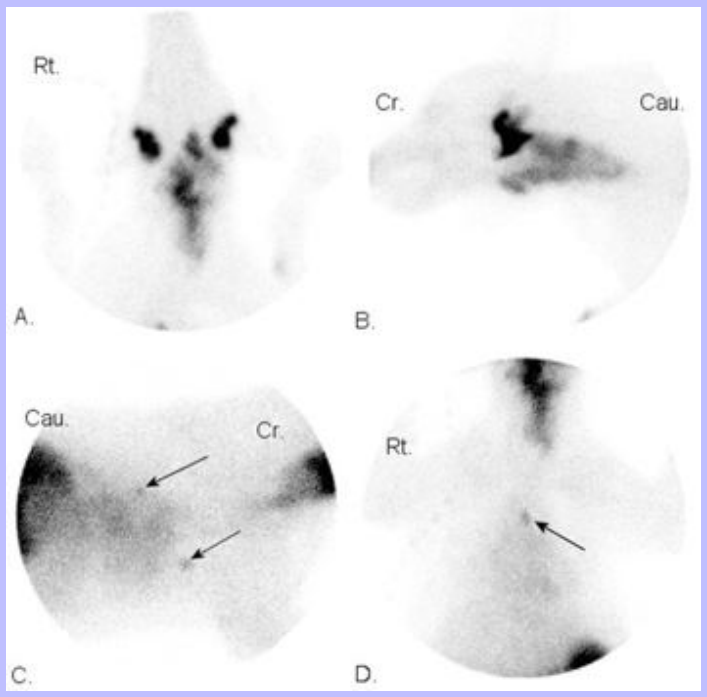
100.3.1 Background and Basic Techniques

Nuclear portography (portal scan) has been used as first introduced in the canine by Caride.[20] A portal scan greatly aids in the diagnosis of a macroscopic portosystemic shunt. The scan can rarely differentiate the types of portal shunts (it typically cannot differentiate if the shunt is intrahepatic versus extrahepatic or if a shunt is a single-vessel extrahepatic shunt or from a multivessel extrahepatic shunt). Hepatic microvascular dysplasia will result in a normal portal scan because the radioactive bolus is transported in normal fashion to the liver prior to the cardiac ROI.

359

360

Figure 100-9 Canine thyroid adenocarcinoma. **A,** Ventral neck view shows heterogeneous, ill-defined uptake associated with the left thyroid lobe. Invasion into the caudal and cranial neck region and into fascial planes is seen. **B,** Lateral view of neck. **C,** Right lateral view of the thorax. The arrows are demonstrating two functional pulmonary metastatic lesions. **D,** Dorsal view of the thorax. The arrow points to a visible functional metastatic pulmonary nodule.



100.3.2 Indications for Performing a Portal Scan

The usefulness of a portal scan appears to be in patients that are suspected of having a portosystemic shunt based on clinical signs and high bile acid levels. The portal scan is performed to confirm the existence of a macroscopic shunt prior to surgical exploratory and subsequent ligation or coil placement.

100.3.3 Image Acquisition

A portal scan is performed on a tranquilized or (preferably) anesthetized animal in right lateral recumbency with the diaphragm centered over a gamma camera. The field of view (FOV) should include the entire heart and liver region. Although the scan can be performed without the aid of an interfaced nuclear medicine acquisition computer system, one is highly recommended and is necessary for any type of quantitative analysis and subsequent storage. To help localize the position of the heart and liver, an external source of activity (μCi point sources or the ends of a flexible cobalt ruler) are placed ventral to the animal, directly below the point of maximum intensity (heart) and level of the xiphoid (liver).

A red rubber catheter is placed into the descending colon and inserted to the level of the cranial most aspect of the ilial wings. Careful placement of the tip of the catheter along the ventral aspect of the colon is helpful in preventing a "fecal-o-gram." It is preferable to perform a portal scan with an empty colon and administration of a cleansing enema 2 to 3 hours prior to the scan is recommended by some[21]; however, it is not routinely required. A dose of approximately 3 to 8 MCi of ^{99m}Tc is used in a volume of 0.5 to 1.0 ml of saline. The higher the dose used, the more accurate the results will be owing to better counting statistics. A three-way stopcock is attached to the preplaced catheter, the dose syringe, and a 12-cc syringe filled with room air. A ⅛-inch thick piece of lead is placed between the camera top (imaging table) and the patient, directly under the tip of the catheter and caudal abdomen. Care must be taken to avoid placement of the lead under the liver region or too caudally so that it allows a "bloom" artifact from the radioactive bolus within the colon. The bolus of radiation is injected first, followed by a small amount (3 to 10 ml) of room air at a slow to moderate rate. A dynamic acquisition should be obtained, starting just prior to injection of the bolus of radiation, and continued at 4 seconds per frame for a total of about 3 minutes. Once the pertechnetate is placed within the colon, a small percentage (10% to 20%) is absorbed across the colonic mucosa and is taken up within the portal venous system.

100.3.4 Interpretation and Analysis

In normal patients, activity should be seen within the liver ROI prior to activity seen within the cardiac ROI (Figure 100-10). In animals with macroscopic shunts, the cardiac ROI is seen at the same time or preceding the liver ROI (Figure 100-11). With the aid of a computer and appropriate software, percent shunt fractions can also be obtained using the following formula:

$$\frac{(\sum \text{total heart counts over time i})}{[\sum (\text{total heart counts} + \text{total liver counts}) \text{over time i}]} \times 100$$

Normal animals will have a shunt fraction of less than 20%. A positive scan is considered to be one with a shunt fraction of greater than 50%. Values obtained between 20% and 50% are considered to be abnormal and may be caused by a less severe shunt. In these cases the scan should be repeated or the animal should be explored. A shunt fraction of 0% is not physiologic, owing to the hepatic arterial blood supply. Calculation of a shunt fraction is not necessary for the diagnosis of the existence of a shunt. False-negative scans may be caused by improper placement of the radionuclide bolus in the colon cranial to the level of the shunt, incomplete

absorption of the bolus across the colonic mucosa due to infiltrative disease of the colonic wall itself, or if the bolus is lodged in a ball of feces. Incorrect results (falsely elevated shunt fraction) may be seen if the bolus is administered too far cranially within the colon where a bloom artifact may overlie the liver ROI. This is commonly seen if the colon is filled with liquid, such as just after administration of an enema. The majority of the technetium is excreted in the feces (that which remains in the colon) and in the urine (that which was absorbed systemically) within the first 12 hours after the scan.

Portal streaming, as reported by Daniel,[22] is the phenomenon seen in a small portion of animals that causes only one or two lobes of the liver to scintillate. Portal streaming is caused by abnormal patterns of blood flow within the extrahepatic or initial portion of the intrahepatic vasculature that results in a “steering” of the radioactive bolus into only a section of the liver.

In the author's facility, animals with a positive portal scan accompanied by high pre-and postprandial bile acids are subsequently ultrasounded to help rule out the possibility of an intrahepatic shunt or multivessel extrahepatic shunt. If the ultrasound is negative for an intrahepatic shunt and no evidence of a multivessel extrahepatic shunt is seen, the patient proceeds to surgery for definitive localization and repair. Only in rare cases, intraoperative mesenteric portograms are required for definitive identification of the shunt vessel.

100.4 BONE SCINTIGRAPHY

100.4.1 Background and Basic Techniques

Bone scans are highly sensitive and equally highly nonspecific. Evaluation of the extent, pattern, and anatomic origin of an area of abnormal uptake, coupled with other factors such as the animal's age, sex, breed, history, physical examination, and radiographic findings can increase the specificity; in many cases a diagnosis can be made. Most images are acquired with the gamma camera head placed underneath a Plexiglas scanning table. Care should always be taken to ensure that the camera face is placed as close as possible to the underside of the imaging table and that the camera face is exactly parallel to the tabletop. By imaging from under the animal, positioning is easier and the patient feels less threatened than if the camera were placed above it. Dorsal and ventral dynamic or static images can be easily obtained on most, if not all, small animals. Using a large FOV gamma camera, a whole-body bone scan can be obtained on a large breed canine in approximately 30 to 45 minutes.

Figure 100-10 Normal portal scan. Dynamic image acquisition shows uptake within the liver region of interest (ROI) preceding that seen within the cardiac ROI.

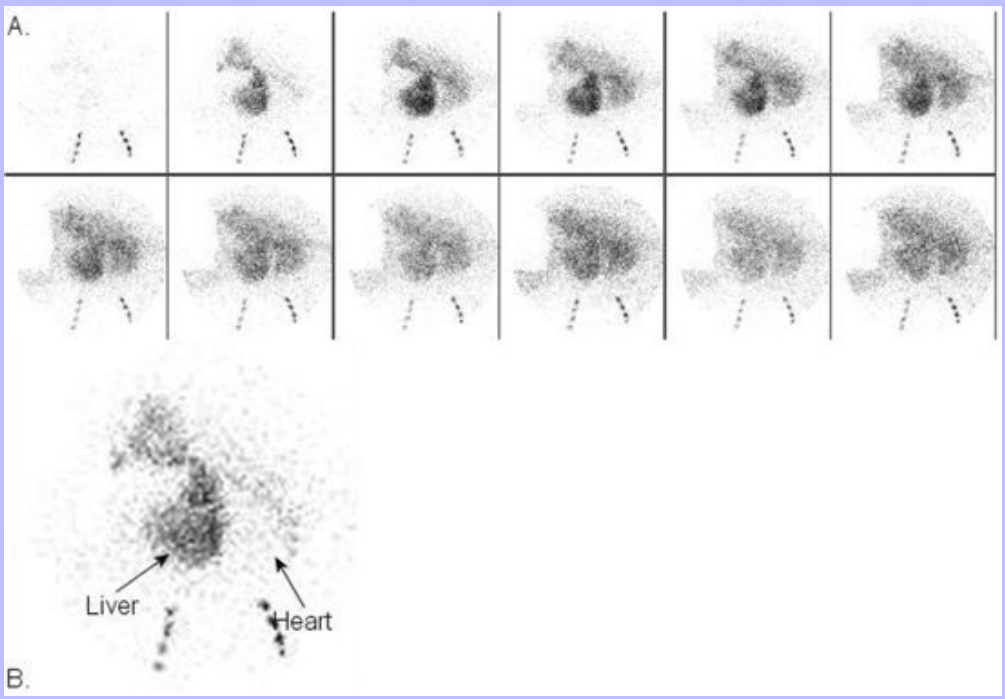


Figure 100-11 Abnormal portal scan. Dynamic image acquisition shows uptake within the cardiac region of interest (ROI) preceding that seen within the liver ROI.

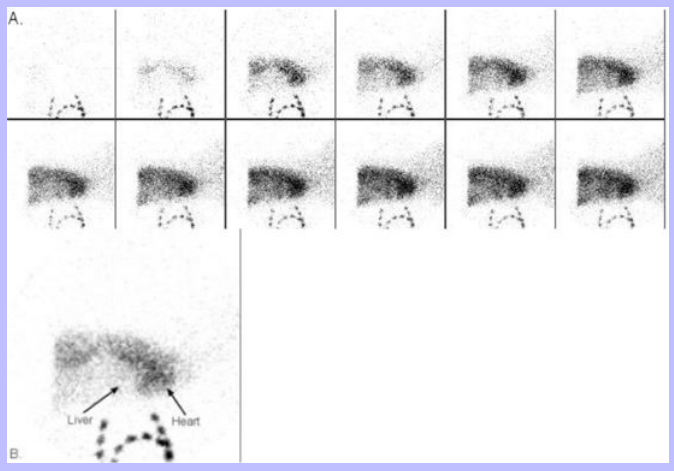


361

100.4.2 Indications for Performing a Bone Scan

Bone scintigraphy has multiple uses in small animals. These include evaluation for primary and metastatic disease, septic arthritis, osteomyelitis, prosthetic implant loosening or infection, soft tissue and bone viability, occult lameness, and fracture healing. Bone scanning can often times localize subtle lesions not seen radiographically until days or weeks later.

100.4.3 Image Acquisition

In small animals, all static images should be acquired on a count basis, as opposed to a timed acquisition. Timed acquisitions often result in images with low count densities and poor target-to-background ratios, which renders less than optimal image quality. The higher count density and high target-to-background ratio images that are obtained using count acquisition parameters are usually of much higher quality than those obtained on a time acquisition basis. The longer scan time needed per image (1 to 3 minutes) is only significant if the animal is not under general anesthesia and patient movement is likely.

Patient preparation prior to scanning is not needed. The radiopharmaceutical ^{99m}Tc-MDP is used commonly and results in high-quality images with good target-to-background ratios. Nonradioactive (“cold”) MDP is sold in a kit form and is easily made using a fresh eluate of reduced (Sn) $^{99m}TcO_4$, which allows the labeling (“tagging”) of the short chain polyphosphate. Because little binding of the radiopharmaceutical to plasma proteins takes place, urinary excretion is rapid, with 59% of the dose excreted within 24 hours.[23] Adequate blood flow is necessary for delivery of the radiopharmaceutical; however, once delivered, skeletal uptake is not a function of perfusion.[24] The exact mechanism of binding is not well understood, but it is known that the phosphate itself is merely the delivery vehicle for the ^{99m}Tc; once arriving at the hydroxyapatite surface, the ^{99m}Tc is released and then chemiadsorbs to the hydroxyapatite surface as ^{99m}Tc-oxide.[24,25] Uptake of the MDP is directly proportional to osteoblastic activity and can be affected by decreased perfusion and regional sympathetic tone.[26] Maximum bone uptake is at 65 minutes postinjection, with the maximum target-to-background ratio (highest activity in the bone and lowest activity in the soft tissues) occurring at 6 hours postinjection.[27]

Radiopharmaceutical dose ranges from approximately 5 MCi to 30 MCi, depending on the animal's size (Table 100-3).

Dosing of small animals for nuclear medicine procedures will vary; however, small breed canines (e.g., toy poodles) and cats are administered 5 MCi doses, medium-sized canines (e.g., Beagles) are given 10 to 15 MCi doses, large breed dogs (e.g., Labradors) are given 20 MCi doses, and giant breed dogs are given 30 MCi doses. As with all radiopharmaceuticals, intravenous routes of administration are used. If the dose is injected through a preplaced catheter, the catheter should be flushed well after the dose is given. Even a small amount of extravasated dose will result in an injection site hot spot on subsequent imaging. Because injection site hot spots occur, it is recommended to inject in a limb that is not in question for diagnosis or to inject into a rear limb if imaging a front limb, for example. For single-phase scans, bone phase images should be acquired no earlier than 3 hours after administration. During this incubation time, care should be taken to minimize external contamination of the animal by urine. When possible, the urinary bladder should be emptied just prior to scanning by passing a urinary catheter, manually evacuating the urine, and safely disposing of the radioactive waste when done. Emptying of the bladder should be done in a careful manner to minimize contamination in

the surrounding area. Clinicians should adhere to the ALARA concept in all cases; personnel that will handle the patient or urine should wear examination gloves to avoid exposure.

Table • 100-3 Small Animal Bone Scan Doses

ANIMAL SIZE	DOSE (MCi)
Toy breeds and cats	5
Medium breeds	10–15
Large breeds	20
Giant breeds	30

Routine bone scan images should be obtained using a general all-purpose (GAP), parallel hole collimator with a 20% window centered over the 140 keV gamma photo peak of ^{99m}Tc. Occasionally, a pinhole collimator is helpful in acquiring high-resolution images of small parts, such as the coxofemoral joints (Legg-Calve-Perthes Disease), elbows, carpi, and sesamoid bones associated with the extremities. If a pinhole collimator is used, the number of acquired counts will need to be decreased because the acquisition time becomes prohibitively long.

As with thyroid imaging, all static images should be acquired on a count basis. Generally speaking, the more counts that can be acquired, the higher quality the image will be. The following are suggestions regarding recommendations for static acquisitions for different body parts (Table 100-4).

During acquisition, the animal should not be allowed to move. Movement associated with respiration cannot be avoided; however, panting artifact can be minimized by manually holding the animal's muzzle closed.

Positioning of the animal for a particular body part to be imaged can be critical in obtaining a high-quality scan that is free of artifact. The following recommendations are an attempt to aid in positioning (Table 100-5).

Two methods for accurately comparing two similar ROIs (e.g., the elbows) are available. The easiest way is to place both limbs or ROIs in the middle of the camera in the same field of view. Care must be taken to ensure that both limbs are positioned exactly the same and not rotated. It is also very important to make sure that both limbs or ROIs are equally distant from the camera face, ideally in contact with the camera face. If one limb is further from the camera than the other, it will appear artifactually more intense. The second method for comparison of similar ROIs is to image the areas separately. This is accomplished by imaging one ROI for a preset number of counts and recording the time of acquisition. The contralateral ROI should then be imaged for the amount of time it took to acquire the first ROI image, then recording the total number of counts. For this method to be accurate it is very important to make sure that the two images used for comparison appear exactly the same on the field of view.

362

363

Table • 100-4 Recommendations for Bone Scan Count Acquisitions

ANATOMIC SECTION	COUNTS TO ACQUIRE
Thorax	750,000 (750 k)
Pelvis*	500,000 (500 k)
Skull or C-spine	350,000 (350 k)
Lumbar spine*	350,000 (350 k)
Elbow or stifle	200,000 (200 k)
Distal extremity	100,000 (100 k)

* Assumes the urinary bladder is empty.

Table • 100-5 Positioning Recommendations

ANATOMIC SECTION	RECOMMENDATIONS
Dorsal or ventral skull, spine or pelvis	Animal is placed in radiolucent V trough, legs are extended out, and symmetrical placement is ensured
Lateral skull	Neck is extended, head is rotated axially so that eyes are perpendicular to tabletop, and forelimbs are pulled caudally
Lateral C-spine	Traction is applied to neck, head is rotated axially to straighten skull, and front limbs are pulled caudally
Lateral shoulder	Neck is extended, shoulder to be imaged is placed down with the ipsilateral front limb extended and pulled cranially, and contralateral limb is pulled caudally
Lateral thorax Lateral lumbar spine	Front limbs are pulled cranially
Lateral pelvis	Urinary bladder is evacuated (or shielded), rear limbs are pulled caudally, pelvis is rotated axially until ilia are superimposed
Lateral stifle	Urinary bladder is evacuated (or shielded), stifle to be imaged is placed down, rear limb is pulled caudally (placing stifle in center of the camera), and contralateral stifle is abducted out of field of view (FOV)
Distal limbs	Palmar/plantar view—both paws are placed side-by-side in same field of view, centered, and rotated until symmetrical Lateral view—limbs are extend, one limb is done for counts (note time of acquisition), contralateral limb is done for time of first acquisition (clinician should note total counts acquired and compare to contralateral limb)

100.4.4 Interpretation and Analysis

Without experience the normal bone scan in small animals can be difficult to interpret. Skeletally immature animals have very focal intense uptake in metaphyseal regions of long bones and at costochondral junctions (Figure 100-12). Normal areas of increased skeletal uptake in all (immature and mature) small animals include areas of thick bone (ends of long bones), temporomandibular joints (TMJs), occiput, the first cervical vertebrae (on the lateral image), sinuses, and costochondral junctions (Figure 100-13). Normal areas of soft tissue accumulation include kidney and urinary bladder. Activity in the kidneys can be minimal to marked. Activity in the bladder is marked, requiring evacuation prior to imaging or lead shielding.

Nonskeletal distribution of bone-seeking radiopharmaceuticals include calcinosis cutis, pulmonary mineralization, renal infarcts, acute rhabdomyolysis, lymph node uptake (after extravasation of the dose),[28] thyroid uptake of free pertechnetate, or dystrophic mineralization of soft tissues.[29] Tracer uptake has also been reported in lactating breast tissue of women[30–32] and the pregnant uterus.[33]

Several reasons exist for generalized poor skeletal uptake that results in poor image quality. These include decreased cardiac output, an increased overlying mass of soft tissue (edema formation), renal failure, or simple old age.

100.4.5 Neoplastic Disease

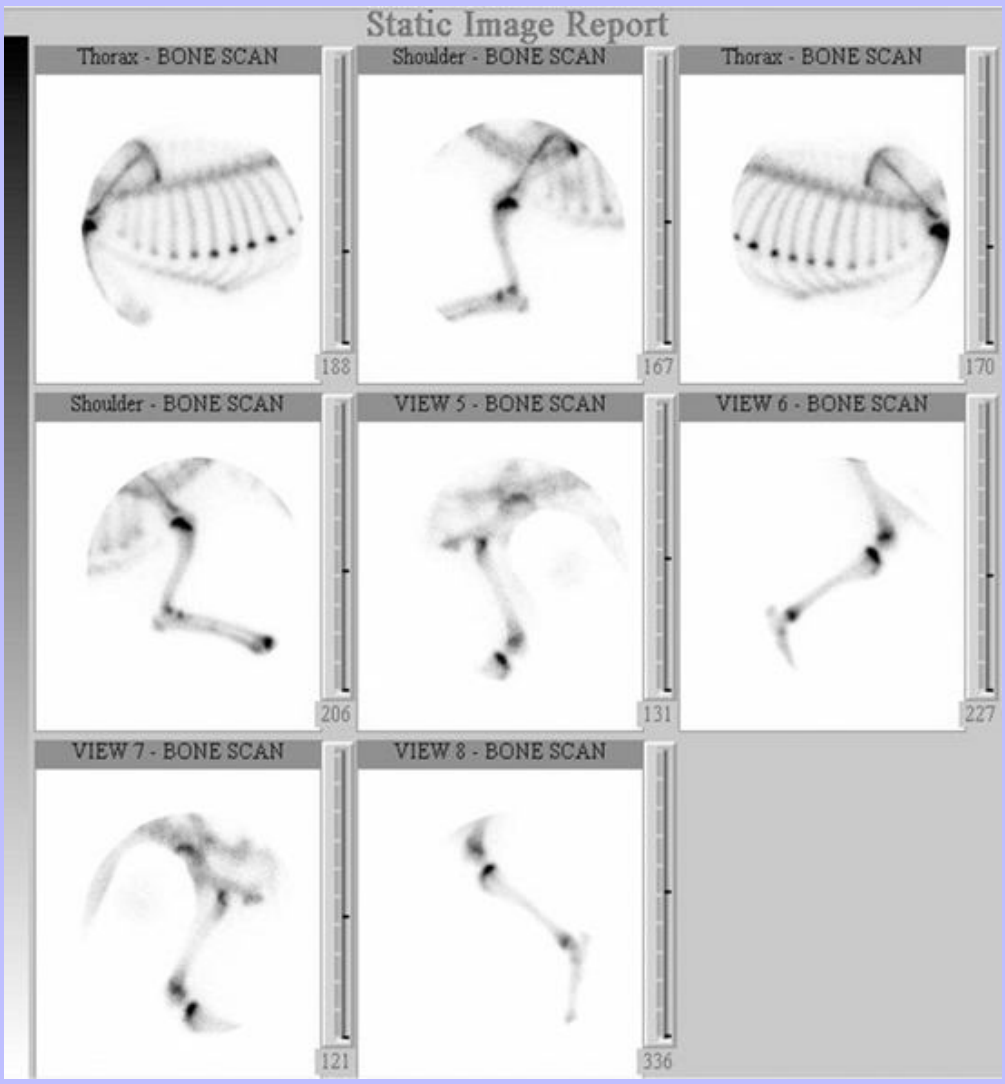
Bone scanning is the most common nuclear medicine procedure performed at many human hospitals, making up over nearly half of the nuclear medicine caseload. By far, the most common indication to order a bone scan

is for evaluation of possible or known metastatic bone disease.[34] Bone scanning has been shown to be a sensitive indicator for the detection of skeletal metastasis.[35,36] The majority of these patients have primary prostatic or breast cancer. In these patients, a whole-body bone scan is obtained using a moving gamma camera (or moving patient gantry) that acquires a static image of the entire human body in less than 30 minutes. If an abnormal area of uptake is seen, additional "spot" images can be obtained. In veterinary medicine, overall rate of occurrence of skeletal metastasis is not known but is considered low (<10%).[37] Tumors that have shown a propensity for bone metastasis include prostatic adenocarcinoma, transitional cell carcinomas, primary bone osteosarcoma, thyroid adenocarcinoma, and mammary carcinomas (Figure 100-14).[37,38] Bone scans have been shown to be 30% to 50% more sensitive for the detection of metastatic bone disease than radiographs.[39] Because of this, the bone scan may pick up metastatic disease before the animal shows skeletal pain.[38] In many cases, bone scans allow for earlier detection of metastatic bone disease, which can significantly alter the owner's decision to proceed with further therapy or change treatment options. Several patterns of metastatic bone disease have been described, the most common of which is variably sized, multiple, focal, intense hot spots, randomly distributed throughout skeleton.[40] The axial skeleton is most commonly affected (skull, vertebral bodies, ribs, and pelvis), followed by the femur and humerus.[41] In the skull the metastatic lesions are usually associated with suture lines. Rib uptake should be randomly distributed—uptake at the same level on adjacent ribs is most often due to previous trauma, not metastatic disease. If this is seen, a careful history should be obtained from the owner and radiographs of the ROI should be obtained. In the ribs the normal increased uptake of costochondral junctions should also be differentiated from metastatic bone disease. If the appendicular skeleton is involved, metastatic bone disease will typically spread to the diaphyseal portions of long bones, especially at the sites of nutrient foramen. False-negative bone scans are uncommon but can be due to the fact that up to 5% of bone metastasis are "cold," showing little to no uptake.[42] In most cases multiple myeloma or other purely lytic tumors are generally negative (although ^{99m}Tc-Sestamibi or ^{201}Tl may be positive), owing the fact that little osteoblastic activity takes place. Other benign lesions that may have similar focal intense uptake include sepsis, osteophytes, enthesiophytes, spondylosis deformans, and chronic healed fractures. These lesions can usually be differentiated based on the location of uptake (metaphyseal, diaphyseal, or within a joint space) and the history, signalment, and physical examination findings.

363

364

Figure 100-12 Normal bone phase images from skeletally immature canine. The reader should note the marked areas of normal uptake in the metaphyseal regions of long bones and the costochondral junctions.



A persistent problem in both human and veterinary medicine is that of a solitary focus of increased uptake in a patient known to have a primary tumor elsewhere. Although a similar study does not exist in veterinary medicine, Tumah and colleagues[43] reported only 10% of solitary rib lesions were due to metastatic disease in a group of patients with known breast cancer. In these cases radiographic correlation is essential, and demonstration of benign radiographic features can sometimes answer the question definitively. In some cases histological confirmation may be required.

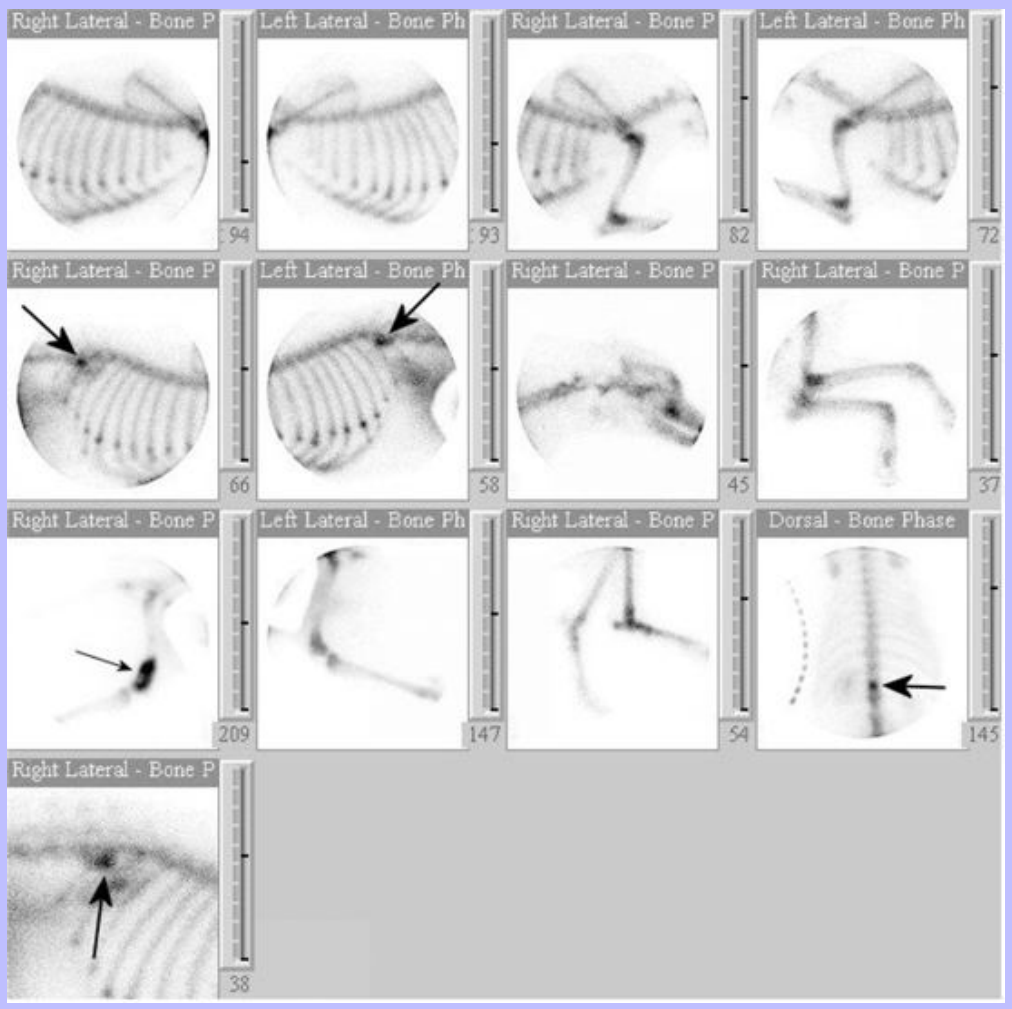
Primary bone neoplasia such as osteosarcoma, chondrosarcoma, fibrosarcoma, or synovial cell sarcoma most commonly is seen first on radiographs. Scanning characteristics associated with primary bone tumors include metaphyseal location, extremely intense uptake, and extension toward the diaphyseal portion of the involved bone; many may have photopenic centers or heterogeneous uptake (Figure 100-15).[44,45] The usefulness of a bone scan in these patients is to rule out the presence of metastatic bone disease prior to costly amputation, chemotherapy, radiation therapy, or limb-sparring techniques. Magnetic resonance imaging (MRI) has proven to be superior to radiography, computed tomography (CT), and scintigraphy in evaluating the extent and degree of invasiveness of neoplastic bone tumors.[46–48] Bone scans tend to overestimate the extent of primary bone tumors due to the "bloom" effect (Figure 100-16).[44] Pulmonary metastasis may demonstrate a faint blush on bone scans, and areas of mineralized soft tissue (metastatic or dystrophic mineralization) will also be positive (Figure 100-17).

In rare cases a "super scan" is seen (Figure 100-18).[49,50] Although the exact mechanism is not clear, these scans are felt to be related to paraneoplastic hypercalcemia. Such scans will have marked, diffuse, symmetrical skeletal uptake; the kidneys are not seen; little-to-no soft tissue uptake occurs; and obvious bone activity is seen on soft tissue phase images. The significance of the "super scan" is not known, and it does not appear to be correlated to one particular tumor type.

364

365

Figure 100-13 Normal bone scan in an adult canine. The reader should note the location of normal "hot spots" including C1 (end-on spinous processes), occiput, temporomandibular joints (TMJs), metaphyseal regions, and costochondral junctions. A primary bone tumor (osteosarcoma) is seen in the distal right humerus *(small-headed arrow)*. The hot spot on the ventral aspect of T13-L1 is spondylosis deformans *(large-headed arrow)* and should not be confused with a metastatic lesion.



100.4.6 Non-Neoplastic Disease

In small animals, acute hematogeneous osteomyelitis is relatively rare; however, septic arthritis, physitis, and discospondylitis are more common. Hematogeneous osteomyelitis will typically demonstrate intense linear cortical uptake within 24 to 48 hours[51] (radiographs are positive at 10 to 21 days).[52] The bone scan will often remain positive for weeks to months after the infection has resolved.[53] Because of this, bone scanning cannot confirm presence of *active* disease, but a negative scan excludes it. Septic arthritis (Figure 100-19), septic physitis, and discospondylitis will all demonstrate extremely focal intense uptake on bone phase images and in some cases may be positive prior to radiographs.[54,55]

Occult lameness can be defined as a persistent, often subtle, undiagnosed lameness that cannot be localized on physical or orthopedic examination. If anatomic localization is possible, radiographs are often normal or inconclusive. Causes for an occult lameness often include mild panosteitis, fragmented medial coronoid processes, partial tear of the cranial cruciate ligament, meniscal injury, stress fractures, fractures of the sesamoid bones, and small avulsion fractures (Figure 100-20). Both single-phase and three-phase bone scanning may be useful in definitively localizing these conditions.

Panosteitis appears on bone scans as intense linear uptake within the medullary cavity of the diaphysis on bone phase images, as well as having minimal-to-marked uptake on the soft tissue phase images (Figure 100-21). Bone scans can often diagnose panosteitis on animals with subtle, nonlocalizable lameness or may be helpful when radiographic findings are equivocal.

Although radiography is typically the primary imaging modality to assess abnormalities associated with the medial coronoid process, radiographs can often be inconclusive in the early stages of this developmental disease because many of the Roentgen signs include degenerative changes associated with the anconeal process and ulnar trochlear notch.[56–58] CT has also been shown to have excellent sensitivity in diagnosis of fragmented medial coronoid processes; however, the availability of CT may be limited.[57] Bone scan findings that suggest a fragmented medial coronoid process are dependent on the animal's age. In puppies the medial coronoid process overlies the proximal radial physis on the lateral view. Because this physis demonstrates typical physeal uptake, a focal intense “hot spot” in this region may be due to either a fragmented medial coronoid process or the proximal radial physis. In these dogs, however, comparison of the amount and pattern of uptake bilaterally can be helpful in diagnosing a unilateral fragmented medial coronoid process. Focal intense uptake associated with the proximal radial physis should be symmetrical. Asymmetrical uptake suggests a diagnosis of fragmented medial coronoid process. Because the diagnosis is dependent on asymmetrical activity in these young dogs, the scintigraphic diagnosis of bilateral fragmented medial coronoid processes may be insensitive using bone scan findings alone. Although rare, fragmented medial coronoid processes can occur in middle-aged to older dogs (Shetland Sheepdogs). In these animals the scintigraphic diagnosis is often easier because no focal increased uptake of the proximal radial physis occurs. In skeletally mature animals, the amount of uptake by the radial head and medial coronoid process region should be similar to that of the distal humeral condyles (in the lateral projection). Focal increased uptake by the region of the medial coronoid process that is significantly more than that seen by the distal humeral condyles is highly suggestive of a fragmented medial coronoid process (Figure 100-22).[59] In both young and older animals, anterior-posterior (AP) views or pinhole collimation (or both) may also be helpful in differentiating uptake by the radial head and the medial coronoid process.

365
366
366
367

Figure 100-14 Metastatic bone disease. Focal intense uptake is seen that is associated with multiple ribs and proximal aspect of right scapula in an animal with a transitional cell carcinoma of the urinary bladder.

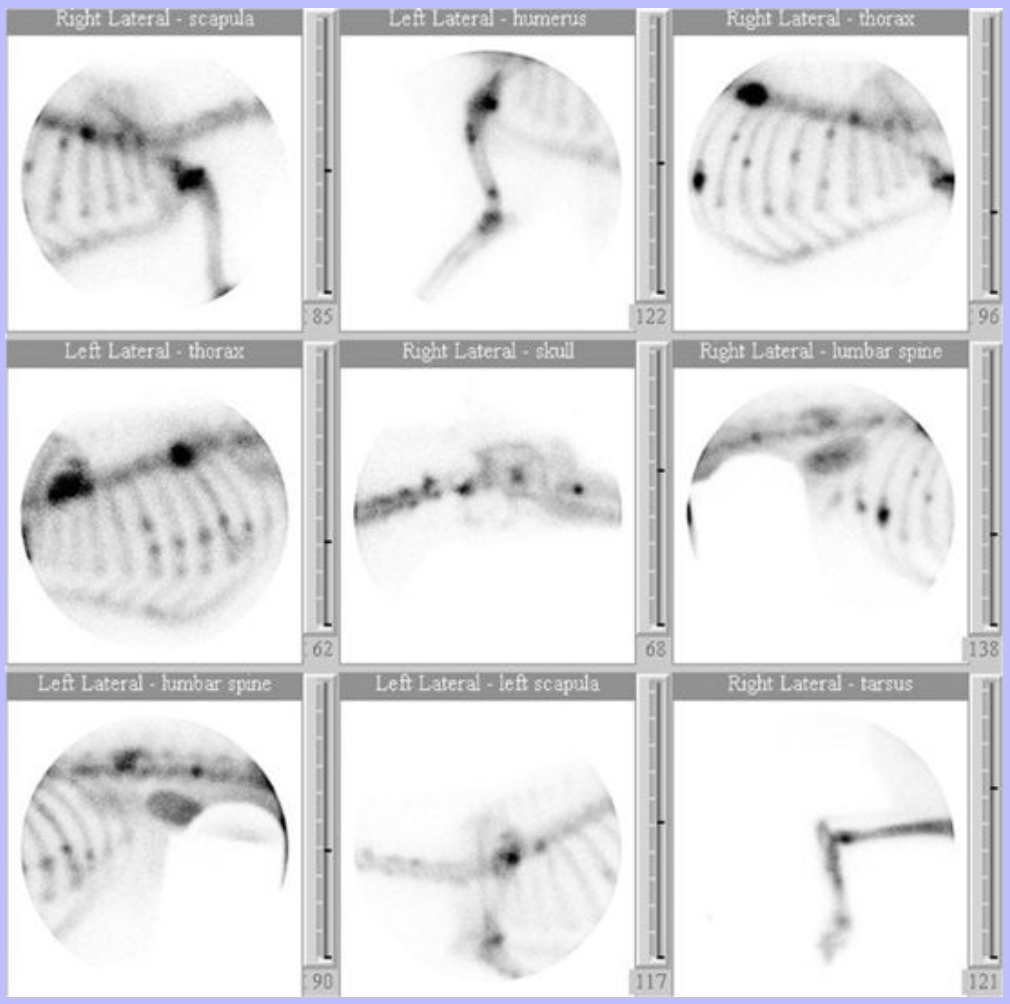


Figure 100-15 Primary osteosarcoma distal left tibia. An irregular area of focal intense heterogeneous uptake is seen in the distal metaphyseal region of the left tibia **(A).** With the intensity turned down, a photopenic center is visible, suggestive of a central area of necrosis **(B)**.

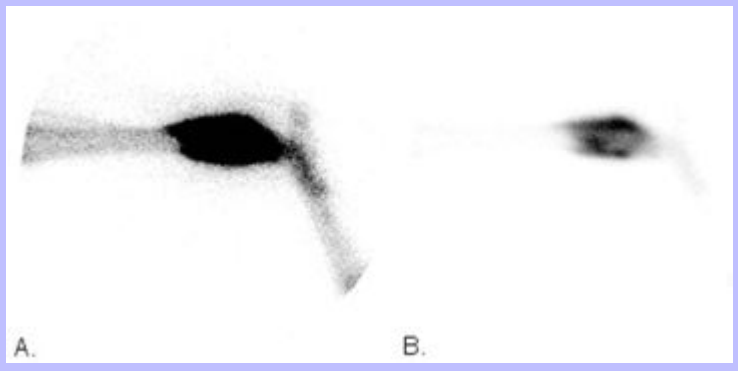

Figure 100-16 Primary osteosarcoma of the left humerus. A large, poorly defined area of intense uptake is seen in the proximal metaphyseal region of the left humerus. The reader should note that the lesion has marked heterogeneous uptake, does not appear to cross the scapulohumeral joint space, and appears to extend to the mid-diaphyseal region ("bloom" effect).

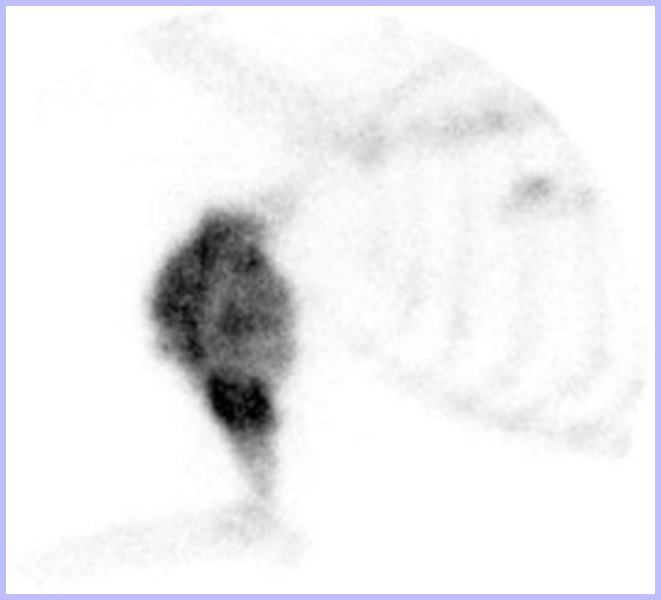

Figure 100-17 Pulmonary metastatic nodules seen on a bone scan. Areas of radiopharmaceutical uptake are seen between the ribs. The amount of uptake ranges from faint to marked. “Shine through” from rib lesions on the opposite side of the thorax should be differentiated from areas of uptake in the lung.

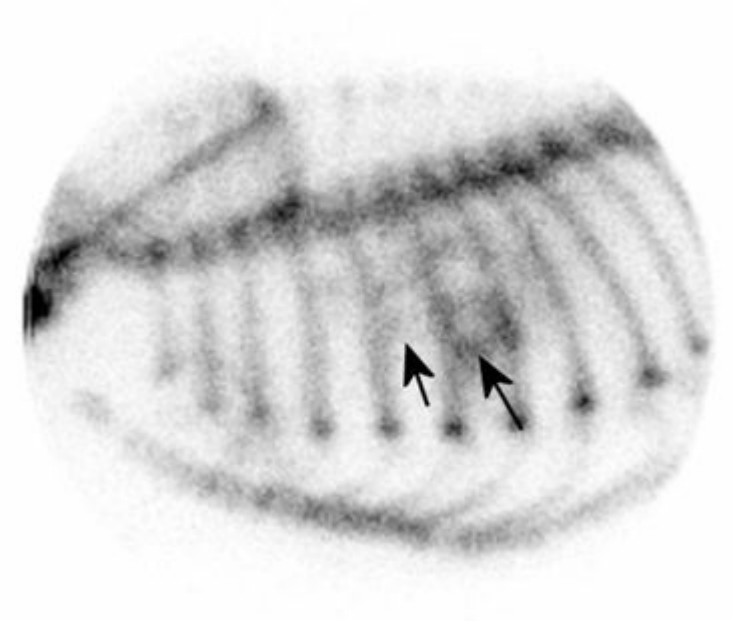

Figure 100-18 Super scan. The reader should note the “pretty bone scan” appearance with marked skeletal uptake within all portions of the skeleton and prominent kidney uptake.

Three-phase bone scans may also be helpful in diagnosing partial (incomplete) tears of the cranial cruciate ligament (Figure 100-23).[60] In these cases the soft tissue phases may be helpful in differentiating acute (active) synovitis from chronic (inactive) intracapsular soft tissue swelling. In the normal canine stifle, a distinct photopenic area is seen within the cranial aspect of the stifle joint that corresponds with the shape and location of the infrapatellar fat pad. In animals with active synovitis, this area demonstrates a faint uptake (blush). Comparison to the contralateral stifle is usually helpful. This same “blush” is not seen in animals with chronic effusion or joint capsule thickening. Bone phase images are not typically helpful in evaluating potential acute cruciate disease.

Stress fractures result from repetitive, prolonged muscular action on bone that is unaccustomed to such stress. Typical symptoms include mild to marked lameness, bone pain, minimal soft tissue swelling, and bone pain that are relieved by discontinuing the exercise. In dogs, stress fractures are seen in athletic and working species and most commonly occur within the diaphyseal portions of long bones, particularly the tibia (Figure 100-24). Bone scintigraphy has proven to be highly sensitive in the early detection of stress-related bone disease[61–63] and is often positive prior to radiographic abnormalities.

In human beings the incidence of bipartite sesamoid bones is approximately 10% to 33%. Although the incidence in small animals is unknown, breeds such as Rottweilers, Greyhounds, Dobermans, and Labradors may have higher incidence of sesamoid disease.[64,65] A bone scan can also differentiate bipartite sesamoid bones from fractured sesamoid bones. Bipartite sesamoids will have no abnormal uptake, whereas recently fractured sesamoid bones will have marked focal uptake (Figure 100-25).

Evaluation of fracture and fracture healing can also be performed using bone scanning. Bone phase images are very sensitive to fracture, and it can be difficult to differentiate acute pathologic conditions from healed previous fracture. It has been reported that bone scans (bone phase images) are 80% positive by 24 hours, 95% positive by 72 hours, 98% positive by 7 days.[66] It has also been shown that 90% of patients with previous fracture are negative on bone phase images at 2 years.[26] Bone scans may also be helpful in the evaluation of the nonunion fracture (lack of progressive healing at 6 months postfracture). Focal intense uptake at fracture ends indicates viable tissue and shorter time to union, whereas little uptake at fracture ends indicates nonunion is likely.[67]

Avascular necrosis of the femoral head (Legg-Calve-Perthes disease) has a unique appearance, depending on the maturation of the disease. Within 12 to 48 hours after injury, a focal photopenic area within femoral head is seen, which is then followed by a rim of moderately focal intense activity around a central photopenic core at 1 to 3 weeks. As the condition becomes chronic, the photopenic central core will fill in and have similar activity to the remainder of the femoral head.[68]

Figure 100-19 Osteomyelitis. Soft tissue phase and bone phase images of the right and left stifle joints obtained 3 months after bilateral cruciate surgery. On the soft tissue phase images, marked uptake is seen in the proximal metaphyseal and diaphyseal regions of the right tibia and within the cranial aspect of the stifle joint. The bone phase images show very intense uptake of the distal metaphyseal regions of the femurs and proximal metaphyseal regions of the tibias. *Staphylococcus aurous* was isolated from a joint fluid.

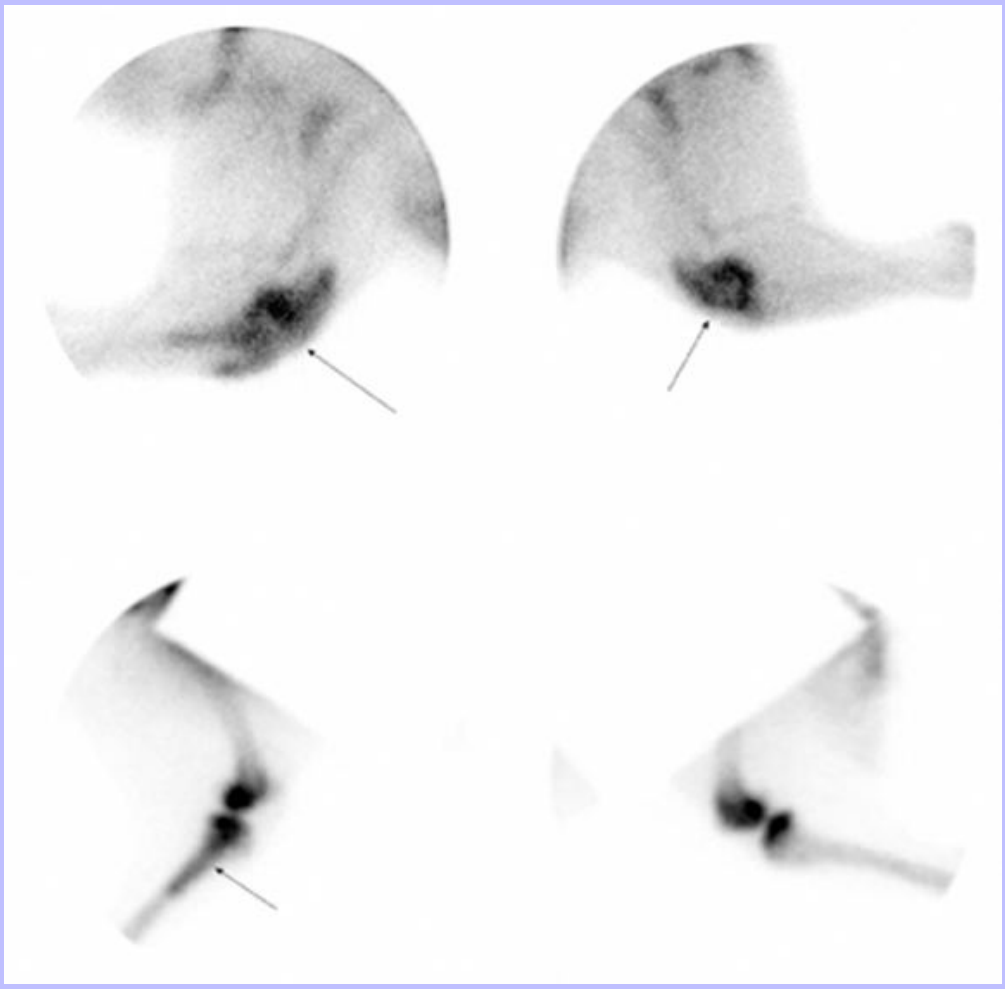

Figure 100-20 Enthesiopathy and syndesmitis of the insertion of the tendon of the gastrocnemius on the right tuber calcaneus. Bone phase images show marked focal uptake in the region of the right tuber calcaneus. The comparison view of the left tibial tarsal region is normal.

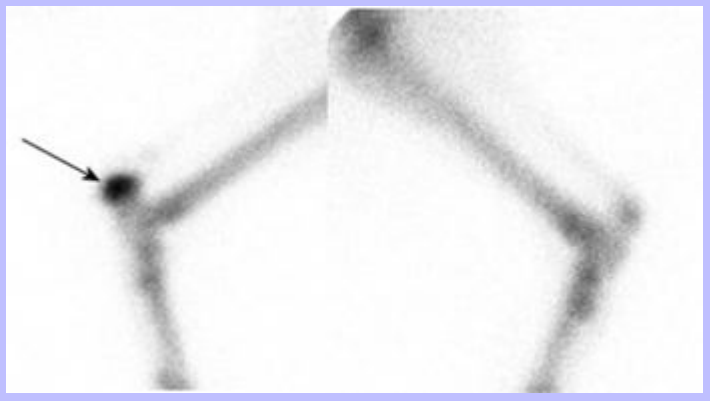


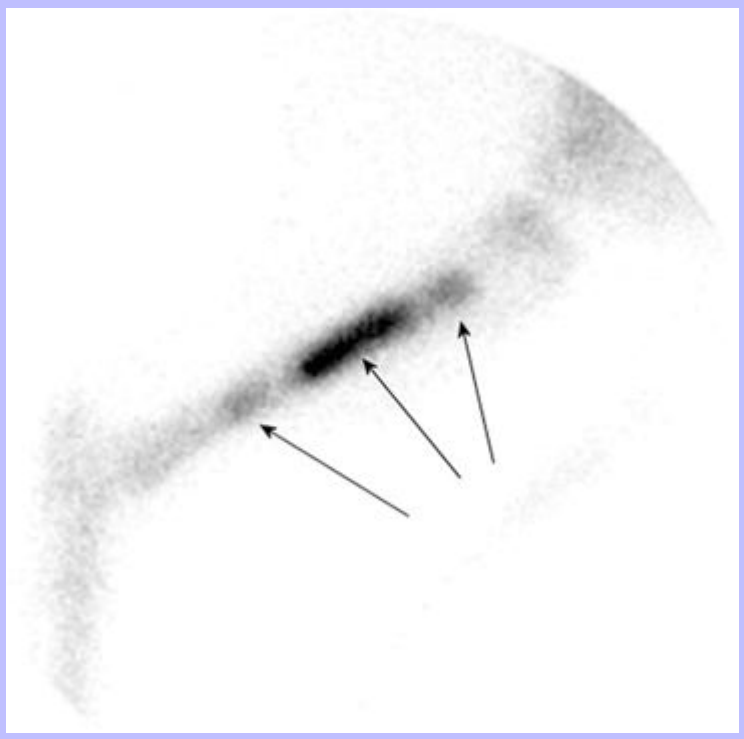
100.4.7 Three-Phase Bone Scanning

Multiphase bone scanning is extremely helpful in differentiating active septic from nonseptic conditions.[69] The three-phase bone scan (Table 100-6) consists of an initial "arterial phase" dynamic study (2 seconds/frame for 30 frames) of blood flow (Figure 100-26). The imaging sequence is started immediately upon injection of the radiopharmaceutical into a peripheral vein. The injection should be made as far away from the area of interest as possible to minimize any injection site hot spots that would interfere with interpretation. It is recommended that the dose be injected in bolus fashion (within 2 seconds) into a preplaced intravenous catheter followed by 12 ml of saline flush. The use of an extension set and three-way stopcock is preferred. Because of the dynamic acquisition, the arterial phase is limited to one ROI. Because of the number of images that are acquired over a short period of time, matrix sizes (in pixels) of 64 × 64 or 128 × 128 are used. Postprocessing of these images include viewing a cine loop and summing pertinent images together to render a high total count static image.

368

369

Figure 100-21 Canine panosteitis. Soft tissue and bone phase images of the right tibia demonstrate marked focal intense uptake in a linear pattern in the mid-diaphyseal region.



Phase two is termed the *blood pool phase* and is obtained by acquiring static images over the ROI at minutes postinjection (Figure 100-27). Blood pool (sometimes called *venous phase*) images include 1 to 2 static, 500 K images over the ROI and contralateral area for comparison.

Phase three represents the “bone phase” images. Static spot bone phase images of the ROI, comparison views of the contralateral side and remaining skeleton are obtained at 3 to 4 hours postadministration. A matrix size (in pixels) of 256 × 256 is recommended for both the blood pool phase and bone phase images.

The three-phase bone scan helps to differentiate noninflammatory versus inflammatory conditions. The technique can be helpful in differentiating a loosened versus a septic total hip prosthesis. The typical appearance of a loosened femoral component includes a normal vascular and blood pool phase with focal increased activity of moderate intensity seen at the level of the distal tip of the metallic stem, usually in the mid-diaphyseal region on the bone phase images (Figure 100-28). Loosening of the acetabular component is seen as curvilinear area of focal, moderately intense uptake in the acetabulum on bone phase images and normal soft tissue phase images. A septic prosthesis is suspect when moderate to marked uptake occurs on all three phases in and around the acetabular component or diffusely surrounding the femoral component (Figure 100-29).[70] When comparing with the contralateral limb on the same dorsal image, close attention to

symmetrical positioning should be made to ensure both acetabuli and femoral shafts are equidistant to the camera face and that no foreshortening of the limb occurs.

Figure 100-22 Fragmented medial coronoid process. Focal intense uptake is seen in the region of the right medial coronoid process *(long arrow)* greater than that seen by the adjacent humeral condyles. Comparison normal left elbow shows normal amount of uptake associated with the distal humeral condyles and less uptake seen by the normal medial coronoid process.

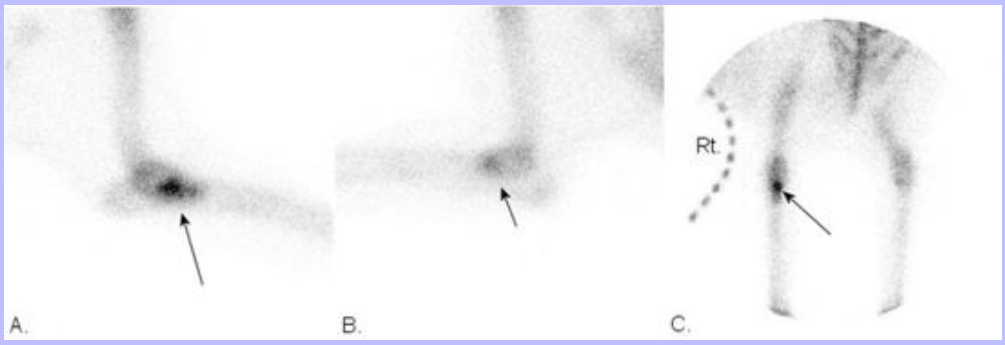


Table • 100-6 Three-Phase Bone Scan

	PHASE 1 (ARTERIAL)	PHASE 2 (POOL)	PHASE 3 (BONE)
Cellulitis	+	+/–	–
Septic arthritis	+	+	+
Osteomyelitis	+	+	+
Fracture	+/–	+/–	+
Chronic DJD	–	–	+

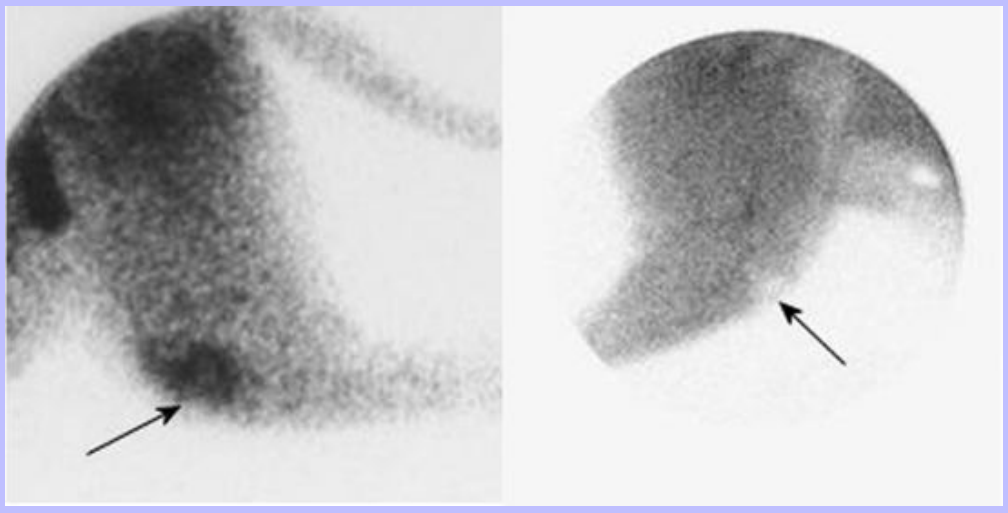
Three-phase bone scanning is also helpful in assessing tissue viability secondary to injury such as gunshot[71] and frostbite.[72] Decreased perfusion (soft tissue phase images) and uptake (bone phase images) indicate nonviable tissue, which usually necessitates amputation. Decreased perfusion but normal to slightly decreased uptake on bone phase images can often be successfully treated with débridement surgery and medical therapy.

100.5 QUANTITATIVE RENAL IMAGING (GFR SCANS)

100.5.1 Background and Basic Techniques

In contrast to radiographic intravenous pyelography that demonstrates well-defined morphology of the kidney and collecting system but little functional information, the GFR scan yields poor structural information but clinically important functional information. The importance of the GFR scan lies in the fact that individual renal function can be assessed and compared. The correlation between inulin clearance and a GFR scan using ^{99m}Tc-diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA) has been reported to be 0.94 in dogs[73] and 0.81 in cats.[74]

Figure 100-23 Partial tear of the cranial cruciate ligament. Regional increased uptake is seen within the left stifle joint *(long arrow)* on soft tissue phase images. The normal right stifle shows the typical photopenic triangle that corresponds to infrapatellar fat pad *(short arrow)*.



The glomerulus acts similar to a sieve type of filter, only allowing particles of a certain very small size to pass into the ultrafiltrate. Renal function is commonly assessed with BUN and serum CR assays; however, it is known that up to 75% of the nephrons must be destroyed before these values may increase. Plasma clearance can be used to express the ability of the kidneys to remove a substance from the blood and is more accurate in assessing renal function. The plasma clearance of a substance can be calculated using the following equation:

$$\text{Clearance}_x = \frac{(U_x \text{mg/mL}) \times (V \text{mL/min})}{(P_x \text{mg/mL})}$$

Where Clearance_x = rate of clearance of substance_x per unit time (mL/min)

U_x = concentration of substance_x in urine (mg/mL)

V = volume of urine per minute (mL/min)

P_x = concentration of substance_x in plasma (mg/mL)

Figure 100-24 Stress fractures of the left tibia. Focal areas of intense uptake are seen in the mid-to distal diaphyseal region of the left tibia. Normal areas of focal uptake exist in the metaphyseal regions in this young animal.

For plasma clearance to be accurate, the substance must be (1) completely filtered at the glomerulus; (2) not synthesized, destroyed, reabsorbed, or secreted by the renal tubules; (3) physiologically inert; and (4) not significantly bound to plasma proteins. Classically, inulin clearance has been used to measure GFR; however, it is cumbersome and usually reserved for the research setting. CR clearance has also been used but is not as accurate, owing to the small amount of tubular secretion and its ability to only measure total GFR, not individual kidney GFR. Radionuclide techniques have been developed to measure both total GFR and differential GFR.

370

371

Figure 100-25 Fracture of the ulnar carpal bone, left limb. A focal intense area of uptake is seen in the lateral aspect of the left carpus secondary to a small chip fracture of the ulnar carpal bone.

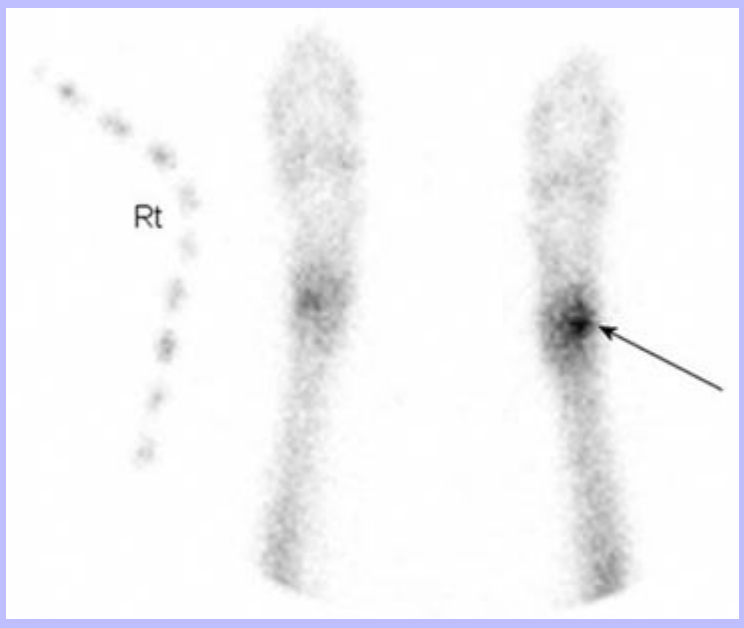


Figure 100-26 Dynamic ("arterial") phase images. Dorsal pelvic images obtained immediately after injection of a bolus of ^{99m}Tc-MDP. Images were obtained at 2 seconds per frame.

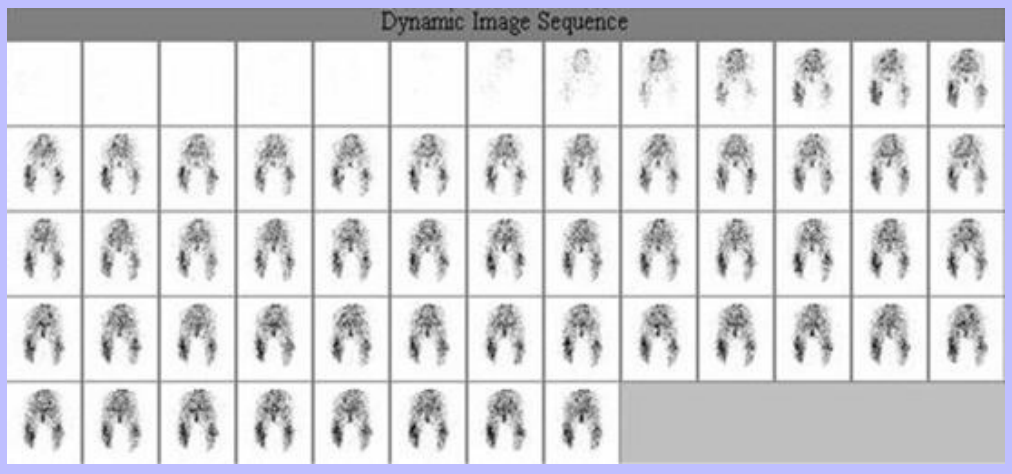

^{99m}Tc-DTPA is a radiopharmaceutical that diffuses evenly throughout and stays within the vascular space; it satisfies the requirements as a glomerular agent and can be used to accurately estimate total GFR (comparable to inulin clearance). By using a gamma camera, interfaced computer system, and proper software, both total and differential GFR (right kidney and left kidney) can be determined. Nuclear processing software uses the integral activity within ROIs placed over each kidney and separate ROIs for background subtraction during the 1-to 3-minute or 2-to 3-minute time period after the initial bolus of activity is seen within the kidney ROIs. Gates[75] first introduced this method that uses the following equation:

$$\mathrm{GFR} = \frac{\left\{\left[\left(\frac{\text{RKid ROI counts} - \text{bkgd}}{e^{-0.153 \times \text{kid depth in cm}}}\right)\right] + \left[\left(\frac{\text{LKid ROI counts} - \text{bkgd}}{e^{-0.153 \times \text{kid depth in cm}}}\right)\right]\right\}}{(\text{Preinjection counts} - \text{postinjection counts}) \times 100 \times 9.756 - 6.198 \text{ for CR clearance}}$$

Figure 100-27 Soft tissue ("blood pool") phase image. Static images of the bilateral rear limbs and pelvis obtained 3 to 5 minutes postinjection of ^{99m}Tc-MDP.

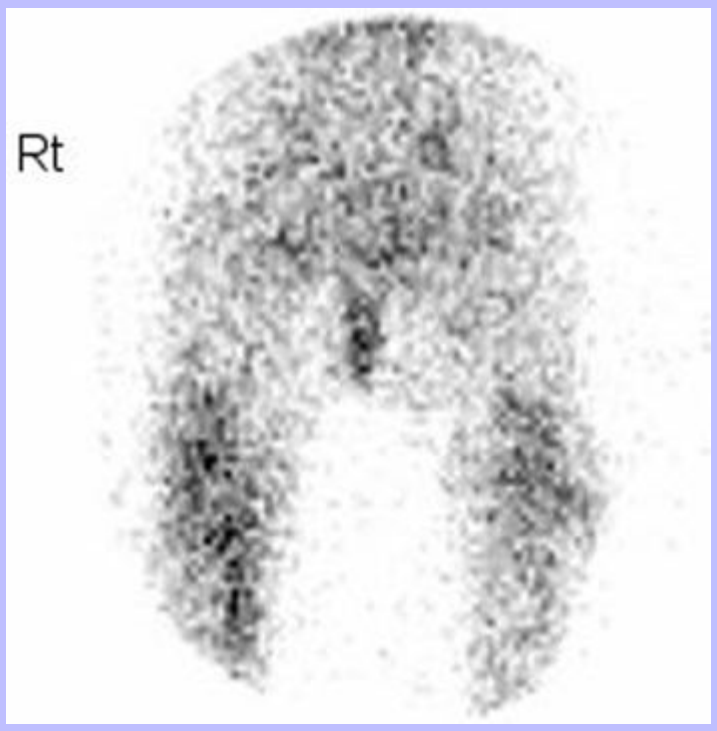

Figure 100-28 Loose acetabular and femoral components after total hip replacement. Focal areas of intense uptake of radiopharmaceutical are seen in the caudal cortex of the mid-diaphyseal region of the right femur *(short arrow)*, which corresponds to the level of the distal tip of the femoral stem, the caudal cortex of the proximal femur, and acetabular rim *(long arrow)*.

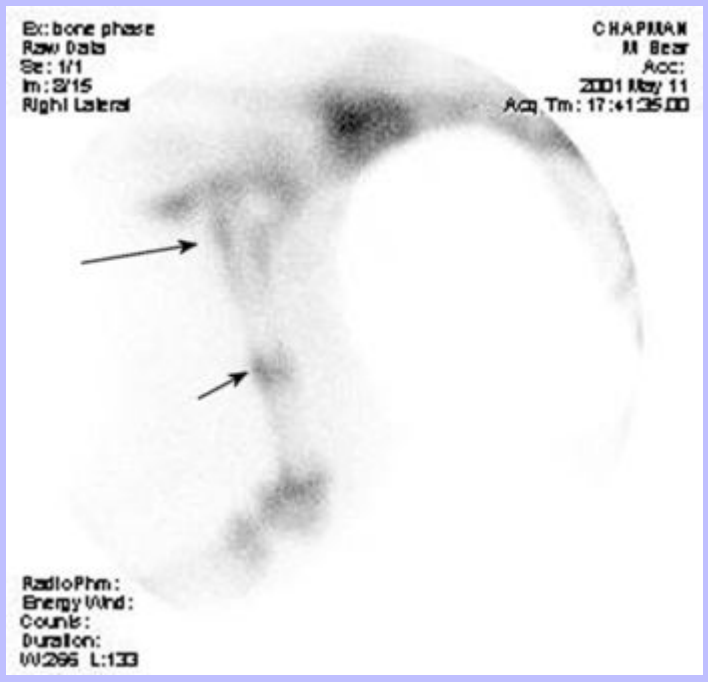

Figure 100-29 Septic total hip prosthesis. Left lateral bone phase image **(A)** and ventral soft tissue phase image **(B)** demonstrate marked uptake associated with the entire portion of the left femoral and acetabular prosthetic implants.

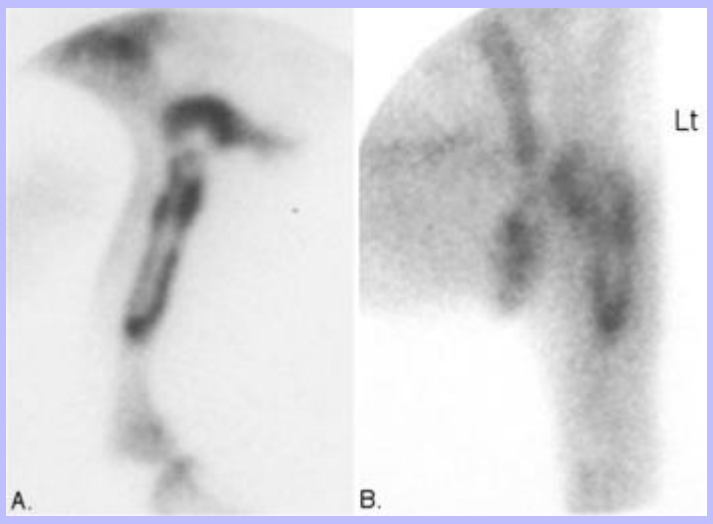
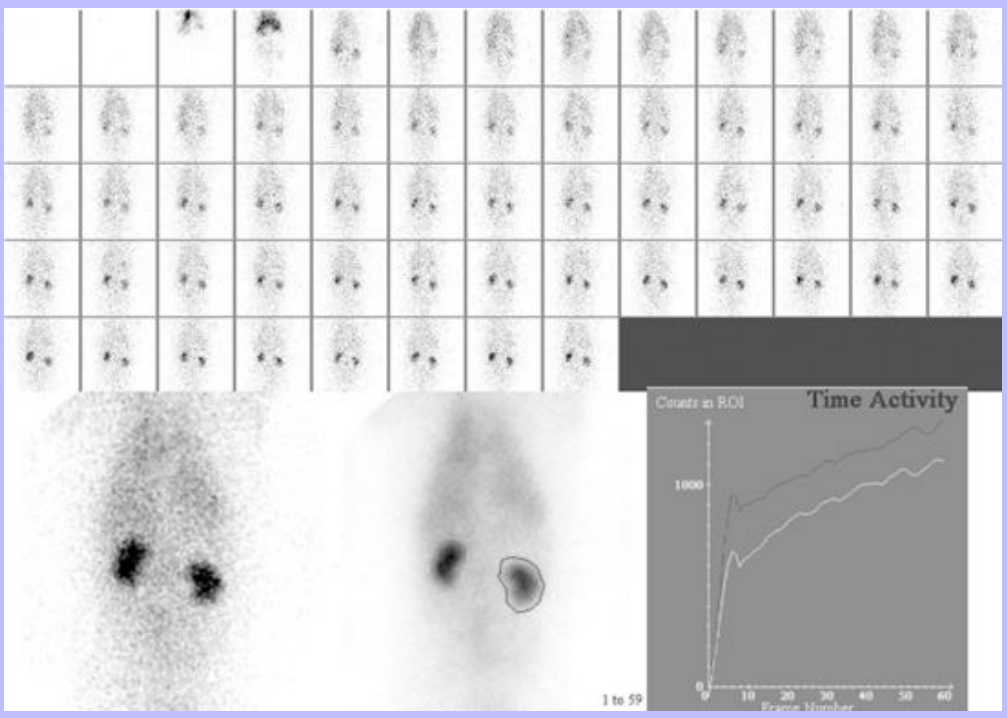


371

372

With minor modifications to the acquisition and processing, the same can be used for noninvasive estimates of renal function in dogs[73] and cats.[74] In human medicine, GFR results are reported in milliliters per minute and uses the assumption that all humans are approximately the same size (1.75 m^2). Due to the wide range of size differences in animals, it has become convention to normalize these values and report the GFR quantification as milliliters per minute per kilogram. Caution should be taken in that if nuclear medicine processing software designed for evaluation of human GFR scans is used in dogs and cats, the results will not be accurate for these species because the "r" value used to correct the mathematic formula used to calculate GFR is different for dogs and cats as compared with humans.

Figure 100-30 Normal glomerular filtration rate (GFR) scan. These dorsal images were obtained immediately after a bolus injection of ^{99m}Tc-DTPA at 6 seconds per frame. Dynamic, dorsal composite images with and without regions of interest (ROIs) drawn around the kidneys and time activity curves. Normal, intense, symmetrical uptake is seen within each kidney.



100.5.2 Indications for Performing a Glomerular Filtration Rate (GFR) Scan

Although the GFR scan will yield a total GFR that is more sensitive to abnormalities in the kidneys than elevated BUN or CR values, the primary indication for performing a GFR scan in small animals is to evaluate differential (individual) renal function in cases where a known abnormality exists that has altered the function of one kidney. The GFR scan is performed to correlate a suspected lack of function for the abnormal kidney and, at the same time, evaluate the opposite kidney for normal function. The scan is typically performed prior to scheduled unilateral nephrectomy of the diseased kidney to ensure that the nondiseased kidney has retained enough function to maintain life once the diseased kidney is removed. A GFR scan is not accurate in animals with significantly impaired renal function as demonstrated by severe azotemia because the kidneys may not be well visualized.

100.5.3 Image Acquisition

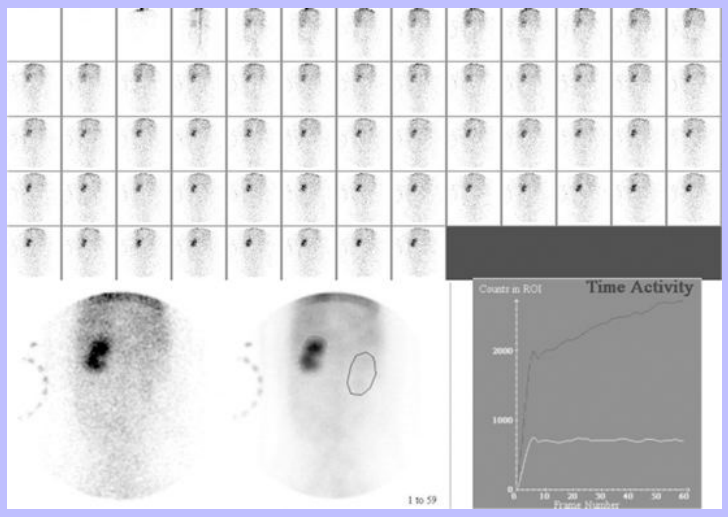
A dynamic acquisition is obtained at 6 seconds per frame for a total of 5 minutes (Figures 100-30 and 100-31). All images are made with the gamma camera centered over the dorsum of the patient's kidney region. The patient may be imaged while in right lateral recumbency (camera behind the patient) or in dorsal recumbency (camera underneath the patient). It is imperative that the patient not move during the 5-minute acquisition; therefore either a very cooperative patient (with skilled animal handlers) is needed, or mild sedation or general anesthesia is usually required. It is preferable not to administer tranquilizers or anesthetics because these agents will invariably affect the GFR quantification, rendering a less than optimal nonphysiologic measurement.

It is important that the radiopharmaceutical be administered in a bolus fashion, and it is preferable to inject through a preplaced patent catheter using a three-way stopcock apparatus and adequate sterile saline flush. To prevent the gamma camera from blushing with activity from the syringe and catheter itself during acquisition, a sterile intravenous extension tube can be used; however, care must be taken to ensure an adequate volume of fluid is available to flush the entire extension tubing. The bolus of activity should be injected as quickly as possible, preferably in less than 2 seconds. Immediately prior to injection, the acquisition should be started. By starting the acquisition computer just prior (4 to 6 seconds) to injection of the bolus, a “blank” frame will be obtained.

372

373

Figure 100-31 Glomerular filtration rate (GFR) scan with unilateral renal disease. Dynamic, dorsal composite images with and without regions of interest (ROIs) drawn around the kidneys and time activity curves show normal uptake in the right kidney and no uptake in the left kidney. The reader should note that the time activity curve of the left kidney and individual dynamic images show no evidence of normal excretion. This animal had severe left-sided hydronephrosis and mild hydronephrosis of the right kidney secondary to bilateral ureteroliths.



Within only seconds, activity will be seen first entering the right heart, lungs, left heart, and aorta; then a kidney blush will be seen. As the acquisition progresses, it is common to see activity within the urinary bladder. Ureters are rarely defined.

100.5.4 Interpretation and Analysis

At the end of the acquisition, a total of 50 individual images will be available for viewing, each representing a 6-second timed acquisition. These images should be examined subjectively and objectively using the computer's particular method of GFR analysis (visual inspection). The images can usually be run in a cine mode to create a movie appearance, which can be repeated over and over for evaluation.

Subjective analysis of the study should include rapid uptake of the radiopharmaceutical by both right and left kidneys. Cats will especially demonstrate rapid and intense uptake by the renal cortex. The kidneys should be inspected for size and shape, and the amount of uptake should be symmetrical. An initial intense blush is followed by further concentration of the Tc-DTPA within the kidneys until maximum concentration is seen (2 to 3 minutes), followed by gradual decrease in intensity as the kidneys excrete the activity into the ureters and bladder. During the scan, there will be a moderate amount of activity seen in the soft tissues, which should decrease to hardly noticeable amounts by the end of the scan. Activity within the urinary bladder is normal in the latter frames and should gradually increase over the time of the acquisition. Activity within a ureter is rarely seen; when present it often suggests hydroureter.

Calculation of GFR begins with summating all of the individual dynamic images into a single “composite” image. This image is then subjected to a spatial and temporal smoothing algorithm that helps define the boundaries of each kidney. Manual or automated ROIs for each kidney, as well as appropriate background ROIs for each kidney, are then placed. An ROI can also be drawn around the urinary bladder. Estimation of kidney depth performed with ultrasound or from an additional lateral view of the abdomen using the gamma camera can be used to correct for soft tissue attenuation of the technetium. Correction for kidney depth has been shown to increase the correlation between the calculated GFR and inulin clearance in the dog,[73,76] but not in the cat.[74] The amount of radiopharmaceutical within the summated kidney ROIs and background ROIs during a time period of 1 to 3 or 2 to 3 minutes postinjection is used to calculate the total GFR. Differential GFR is then determined by calculating the percent contribution of the total GFR by each kidney. Because most standard nuclear medicine software is designed for human use and the equation used to calculate GFR is different for dogs and cats, it is often necessary to export the appropriate numbers to another program, such as Microsoft Excel, for the results to be meaningful.

Besides the calculation of a total GFR and differential GFR, the time activity curves for each ROI should also be inspected. The normal kidney time activity curve should have a very sharp initial increase (which represents the initial arterial bolus of activity within each kidney), followed closely by a slight decrease in activity, then a longer “uptake” period (as the radiopharmaceutical is concentrated by the kidney), and finally a gradual and longer “washout” period (as the radiopharmaceutical is excreted from the kidney into the collecting system). In normal animals, kidney activity should peak at approximately 2.5 to 3.5 minutes postinjection. A delay in the time to peak (with a normal bolus peak) is consistent with glomerular disease. Animals undergoing diuresis may demonstrate a shorter time to peak activity. Each kidney's time activity curve should be similar in activity and may closely superimpose each other. A delayed onset or blunted initial “bolus” peak is consistent with a fragmented bolus injection, vascular abnormality, or significant renal disease. A lack of concentration by either kidney signifies renal insufficiency. A lack or delay of the excretory phase (washout) is suggestive of obstructive urinary disease. The time activity curves for each background area should be flat and not change

over time. If included, the urinary bladder ROI should start off at the *x*-axis and rise slowly during the entire acquisition.

For most animals the total GFR should be greater than 2.0 ml/minute/kg and be evenly distributed between each kidney (i.e., each kidney should have a differential GFR of 1.0 ml/minute/kg or greater). A total GFR value of 1.8 ml/minute/kg or greater is considered normal in older cats (values less than these imply some degree of renal insufficiency). Like most imaging procedures, an abnormal total GFR result is extremely nonspecific; in all but a few rare cases, the cause for the renal disease cannot be determined.

101 CHAPTER • 101 Endoscopic and Cytologic Procedures for Evaluation of the Gastrointestinal Tract

Michael E. Matz

101.1 ENDOSCOPIC PROCEDURES

Gastrointestinal (GI) endoscopy is a minimally invasive, atraumatic technique that permits direct visualization of the mucosa of the esophagus, stomach, small bowel, and colon. GI endoscopy can provide valuable information when evaluating GI disorders. Diagnostically, it allows clinicians to obtain samples for cytologic and histologic examination with relative ease. Therapeutically, it can be used for the removal of foreign bodies, dilation of esophageal or colonic strictures, and placement of gastric or jejunal feeding tubes. These endoscopic procedures offer an alternative to surgical intervention. This section will focus on the technique involved in performing diagnostic upper GI endoscopy, proctoscopy (examination of the rectum), and colonoscopy.

101.2 ENDOSCOPIC EQUIPMENT

Both rigid and flexible endoscopes can be useful in GI endoscopy. Rigid endoscopes are available in several sizes. This type of endoscope is inexpensive and easy to use. Rigid endoscopes are most valuable for performing proctoscopy and colonoscopy. Poor visualization, limited maneuverability, and relatively short length compared with flexible endoscopes, limit the use of rigid endoscopes for other diagnostic procedures.

A number of flexible endoscopes of different makes, lengths, diameters, and functions are available for use in evaluating the GI tract. Fiberoptic endoscopes use fiber-optic bundles to deliver bright light to the tip of the endoscope and transmit the image to the eyepiece. The quality of the image is dependent on the number, size, and quality of the fibers. Numerous, small-diameter fibers produce a better image than larger, less numerous fibers. Video endoscopes replace the image fiber bundle with a computer chip camera that transmits an electronic signal to a processor where it is converted to a video image and displayed on a high-resolution monitor. Image quality is superior with video endoscopes.

Versatility is important because veterinary patients vary greatly. A flexible endoscope to be used for GI endoscopy in dogs and cats should possess the following characteristics: a working length of at least 100 cm (ideally 125 cm); an insertion tube diameter of less than 10 mm, optimally less than 8 mm; a minimum instrument channel diameter of 2.0 mm, with an ideal size being 2.8 mm; four-way distal tip deflection with at least 180 to 210 degrees in one direction and 90 to 100 degrees in the other three directions; automatic air-water insufflation; suction capabilities; a forward direction of view; an angle of view of 90 to 120 degrees; a depth of field of 3 to 100 mm; and comfortable handling. Light sources for the endoscope should be halogen or preferably xenon. An external vacuum source (portable or central) is necessary.

Additional instrumentation required for flexible diagnostic endoscopy include biopsy forceps and cytology brushes. The author prefers fenestrated ellipsoid biopsy forceps. For rigid endoscopes, alligator biopsy forceps (punchtype preferred) are necessary.

101.3 ENDOSCOPIC TECHNIQUE

101.3.1 Upper Gastrointestinal Endoscopy

Diagnostically, upper GI endoscopy is indicated for evaluation of dysphagia, persistent regurgitation, chronic vomiting, acute vomiting with hematemesis, melena, chronic small bowel diarrhea, and unexplained weight loss or anorexia.

It is essential for the animal to be fasted to prevent ingesta from interfering with the examination. In most cases an 8-to 12-hour fast is sufficient; however, a longer fast may be necessary if evidence of delayed gastric emptying exists. Upper GI endoscopy should not be performed within 24 hours of a barium contrast study. This allows for clearing of residual barium that often adheres to mucosal surfaces even though radiographically it may appear that the barium has been cleared from the GI tract. Appropriate preparation is essential for maximizing examination efficiency and for ensuring patient safety.

General anesthesia with placement of a cuffed endotracheal tube is necessary for upper GI endoscopy. The choice of anesthetic regimen should be made with respect to the animal's general condition and suspected disease processes. Narcotics (morphine, meperidine, butorphanol) increase antral motility and may increase pyloric tone, potentially interfering with the passage of the endoscope into the duodenum. The animal should be positioned in left lateral recumbency with a mouth speculum placed to protect the endoscope.

The insertion tube of the endoscope is passed initially over the endotracheal tube and through the oropharynx and upper esophageal sphincter. Once the endoscope is in the esophagus, air is insufflated until the esophagus is adequately distended to visualize the lumen. The endoscope is centralized in the esophageal lumen and then slowly advanced toward the gastroesophageal junction. *The endoscope should only be advanced when the lumen is clearly visible*. It is important to examine the esophagus completely during the insertion of the endoscope because it may become traumatized during passage of the endoscope. Normal esophageal mucosa is smooth, pale, and glistening. Submucosal vessels are not normally visualized in dogs, but are easily observed in cats. Little or no fluid is normally found in the esophageal lumen. In the proximal esophagus, an impression of the trachea can be seen. Pulsations of the heart and aorta are visualized in the thoracic esophagus. In the distal one-third of the esophagus of cats, concentric circular rings are observed because of the presence of smooth muscle. The gastroesophageal sphincter (GES) is usually closed in the normal animal. The bright pink to red color of the gastric mucosa may be visible at the GES, creating an irregular rosette appearance. At the GES, a slight directional change is necessary to align the tip of the endoscope with the center of the sphincter. Insufflation of air, while gently advancing the endoscope, should result in passage into the stomach. When properly directed there should be minimal resistance to advancing the endoscope into the stomach.

The large lumen of the stomach means the endoscopist must develop and maintain a systematic approach to gastroscopy so that completeness and reproducibility are ensured. During initial examination of the stomach it is important to obtain at least a cursory view of the mucosa as the endoscope is advanced to avoid misinterpreting endoscope-induced trauma as an abnormality during endoscope withdrawal. Normal gastric mucosa is smooth, glistening, and pink. Submucosal vessels are not normally observed, except in the cardia. The presence of ingesta or fluid, ease of distensibility of the gastric wall during insufflation, and the appearance of the rugal folds should also be evaluated.

Upon entry into the stomach, the endoscope will lie along the greater curvature. The stomach will be collapsed and prominent longitudinal rugal folds will be visible. Air should be insufflated into the stomach only until

spatial orientation is achieved. Care must be taken not to overinflate the stomach. Overdistension of the stomach can occur quickly in cats and small dogs because of their relatively small stomach size. The endoscope should continue to be advanced along the greater curvature until the junction between the antrum (characterized by the lack of rugal folds) and the body comes into view. A frontal view of this area is usually accomplished in dogs. In the cat, the antrum is often hidden behind the incisura angularis, a narrow shelf of tissue that separates the pyloric antrum from the lesser curvature of the gastric body. To enter the antrum the endoscope is advanced further along (dogs), or deflected off (cats), the greater curvature.

Once in the antrum, the endoscope can be slowly advanced toward the pylorus. The pylorus in most dogs and cats is readily visible. The appearance and location of the pylorus will vary. In general, the pylorus has clean margins and is not obscured by excessive folds. It may be closed or open. Passing the endoscope tip through the pylorus into the duodenum can be the most difficult part of upper GI endoscopy. It is most easily accomplished by gradually advancing the endoscope while keeping the pylorus aligned in the center of the field of view. Rapid and forceful advances of the endoscope should be avoided. If gastric distension is minimized the pylorus is usually in a more relaxed state, facilitating duodenal intubation. If the pylorus cannot be properly aligned, repositioning of the dog or cat (dorsal or right lateral recumbency) may help to improve alignment. Just past the pylorus the cranial duodenal flexure is encountered. To negotiate this sharp turn, the tip of the endoscope should be deflected downward and to the right while insufflating and gently advancing the endoscope. During this advancement the mucosa will be seen sliding by the viewing lens. Once the tip of the endoscope has successfully negotiated the flexure, centralization of the tip of the endoscope within the lumen will be possible. Normal intestinal mucosa is paler, more granular in texture, and more friable in nature than the gastric mucosa. The major duodenal papilla is observed on the medial wall of the duodenum in most dogs and in some cats. Careful examination may reveal the minor duodenal papilla in dogs. The papillae may be best visualized as the endoscope is slowly retracted back into the proximal duodenum because of their close proximity to the duodenal flexure. In dogs, Peyer's patches are often observed as shallow, pale craters on the lateral aspect of the nondistended descending duodenal wall. The endoscope should be advanced until it reaches its full working length, as long as only minimal resistance is encountered.

A more thorough evaluation of the duodenal and gastric mucosa is often best accomplished as the endoscope is withdrawn. Diagnostic procedures are also performed at this time. Once the endoscope has been retracted into the stomach, the pylorus, antrum, and incisura angularis are examined carefully. A frontal view of the angularis can usually be obtained while the endoscope is removed from the antrum. The endoscope is then withdrawn along the greater curvature and retroflexed 180 degrees to allow visualization of the lesser curvature, fundus, and cardia—the latter region being defined by the location of the entrance of the endoscope into the stomach and the presence of submucosal vessels. Torquing the endoscope at this point will provide complete (360 degrees) evaluation of this area. Once the proximal stomach has been thoroughly evaluated, the scope tip is straightened and the endoscope is slowly retracted. At this point, insufflation of the stomach should be sufficient to cause flattening of the rugal folds without causing overdistention, facilitating observation of the entire gastric mucosa. Before retraction of the endoscope into the esophagus, all air or residual fluid is suctioned from the gastric lumen. The esophagus should be carefully reexamined as the endoscope is removed.

101.3.2 Proctoscopy and Colonoscopy

Proctoscopy and colonoscopy are relatively easy to perform in dogs and cats because their large intestines are anatomically simple. For this reason, clinicians with an appreciation of normal and abnormal endoscopic anatomy can become proficient in performing proctoscopy and colonoscopy within a relatively short period of time.

Endoscopic examination of the rectum and colon can be accomplished with either a rigid or flexible endoscope. Rigid endoscopes limit visualization to the rectum and descending colon. Flexible endoscopes allow evaluation of the rectum, entire colon, cecum, and possibly the distal ileum.

Indications for proctoscopy and colonoscopy include chronic large bowel diarrhea, obstipation or tenesmus, dyschezia, or hematochezia that accompanies formed feces. Because most inflammatory diseases of the large intestine in the dog and cat are diffuse, their presence is usually detected in the descending colon, allowing rigid endoscopy to be a valuable procedure.

One of the keys to successful proctoscopy or colonoscopy is adequate patient preparation. Various protocols can be used depending on the extent of the examination to be performed, the availability of support staff to complete the necessary work, and the degree of patient cooperation. Proper preparation for colonoscopy requires complete evacuation of fecal material from the colon and production of a clear ileal effluent. Food should be withheld for a minimum of 24 to 36 hours before the procedure. If flexible endoscopy is to be used, use of an oral GI lavage solution is recommended, such as one containing polyethylene glycol as the main nonabsorbed solute (GOLYTELY®, NuLytely®, Colyte®). These are isosmotic solutions that result in a severe diarrhea with virtually no net absorption or secretion of electrolytes, bicarbonate, or water. This method has been shown to result in superior colonic preparation compared with multiple enemas in dogs. Disadvantages are that fairly large volumes of the colon electrolyte lavage solution need to be used, and administration via orogastric or nasoesophageal intubation is usually necessary. Although dose guidelines have not been firmly established for the dog and cat, two doses of a lavage solution are recommended at 30 mL/kg via orogastric (dog) or nasoesophageal (cat) tube 2 to 4 hours apart in the afternoon prior to the examination. In addition, a warm-water enema (20 mL/kg body weight) should be given after the first dose of lavage solution the morning before colonoscopy. The well-lubricated enema tube should be inserted a length equal to that from the anus to the last rib. Enemas should be avoided in animals with rectal pain.

For rigid endoscopy, patient preparation does not have to be as vigorous as the protocol outlined previously. Preparation may be limited to withholding food for an appropriate time (usually 36 to 48 hours) and administering multiple warm-water enemas 1 to 2 hours apart on the afternoon before the procedure. Enemas should be given until the water exiting the rectum is repeatedly clear. A final enema is given the next morning 2 to 4 hours before the procedure is begun.

These or similar protocols generally result in adequate rectal and colonic cleansing. It is essential that the rectum and colon be as clean as possible before endoscopy. Lesions may easily be missed if this is not accomplished.

General anesthesia is generally recommended for colonoscopy, although heavy sedation may be adequate for proctoscopy or rigid colonoscopy. Passage of a flexible endoscope into the transverse and ascending colon and cecum may cause painful stretching of mesenteric attachments.

Before performing endoscopy, a digital rectal examination should be done to rule out the possibility of anal and rectal lesions or perineal hernias. Insertion of a digit is also useful for straightening the rectal lumen, making it easier to insert the endoscope into the colon. Rigid endoscopy is usually performed with the animal in right lateral recumbency. Right lateral recumbency reduces gravitational flow of fluid and fecal material into the distal colon. The well-lubricated rigid endoscope is advanced into the rectum. Rigid endoscopes have a smooth obturator that facilitates advancement of the endoscope through the anal sphincter. The obturator is removed after entering the rectum and the hinged viewing lens is closed tightly over the end of the endoscope. Air is insufflated to distend the colon, and the endoscope is advanced under direct visualization until the entire length

of the endoscope has been inserted. With a rigid endoscope, air insufflation is done manually with a bulb-pumping device. The normal colon should have a pale pink, smooth, glistening mucosa with visible submucosal blood vessels. Lymphoid follicles, seen as 2 to 3 mm plaques (often with umbilicated surfaces) are normally observed in the descending colon and cecum.

Flexible endoscopy is performed with the animal in left lateral recumbency to prevent compression of the area of the ileocolic valve by abdomial viscera. After the endoscope is inserted into the rectum, air is insufflated. It is often necessary, especially when small-diameter flexible scopes are used, to have an assistant apply digital pressure around the anal orifice to prevent insufflated air from escaping from the colon. Insufflation distends the colon and flattens out mucosal folds, which are most prominent in the rectum and distal descending colon. The endoscope tip is then centralized and advanced slowly. *The endoscope should only be advanced if the lumen is clearly in view.* At the junction of the descending and transverse colon, a flexure (splenic) will be observed. The tip of the endoscope should be deflected around the flexure and advanced slowly along the mucosa. The mucosa should be seen sliding freely across the viewing lens. After passing the flexure, the tip of the endoscope can again be centralized within the lumen of transverse colon. The transverse colon is short in the dog and cat. Another flexure (hepatic) will be encountered at the junction of the transverse and ascending colon. This flexure can be passed in a manner similar to the splenic flexure. In the cat, distinct flexures delineating the boundaries between the sections of the colon are generally not observed as clearly as in the dog. Upon entering the ascending colon, the ileocolic junction is visualized. The ileocolic sphincter often protrudes into the lumen. If the ileum is to be entered, the tip of the endoscope should be centralized within the lumen of the sphincter and the endoscope advanced using gentle pressure combined with air insufflation. If the scope cannot be advanced into the ileum, blind biopsy specimens can be obtained by passing the biopsy forceps through the ileocolic sphincter. Using this blind biopsy technique does, however, increase the risk of perforation. The cecocolic junction may be partially open or, if closed, appear as a flat sphincter. The cecum usually can be entered. In the dog, the scope should be advanced into this spiral structure (8 to 30 cm in length) until the blind end is reached. The cecum of the cat is comma shaped and short (2 to 4 cm) in length.

A more thorough evaluation of the colon should be performed as the scope is withdrawn. Diagnostic procedures are performed at this time. The endoscope should be slowly retracted while making necessary directional adjustments to ensure that the entire circumference of the colon is carefully evaluated. As the rectum is approached in dogs greater than 15 kg, the flexible endoscope should be retroflexed 180 degrees to allow better visualization of the terminal rectum.

101.4 DESCRIPTIVE ENDOSCOPIC TERMINOLOGY

The esophageal, gastric, duodenal, jejunal, and colonic mucosa should be described using the following: hyperemia, friability, granularity, and erosion or ulceration, degree of luminal narrowing, stricture and visibility of submucosal vessels. The presence of an intraluminal mass or foreign body should be noted. Mucosal hyperemia should be carefully interpreted because it can be affected by a number of factors, including anesthesia, warm-water enema, and mild trauma from the endoscope. The amount of insufflation can alter the appearance of the mucosa and should be considered during evaluation. With experience, the endoscopist will learn to distinguish normal from abnormal GI mucosa. A description of the position and size of any lesions should be recorded. Size can be estimated by comparing the lesion to an open biopsy forceps.

376

377

101.5 ENDOSCOPIC BIOPSY SAMPLES

Flexible endoscopic biopsy samples are small, 2 to 3 mm mucosal specimens obtained through the instrument channel of the endoscope. In view of the small size of these biopsy samples, multiple biopsies using sharp biopsy

forceps and good technique are essential to provide diagnostic material. To obtain a biopsy sample with the flexible scope, the tip of the endoscope should be placed in close proximity to the intended biopsy site. If possible, the tip should be directed at a 90-degree angle to the mucosal surface to be biopsied. Removing the majority of luminal air will facilitate attaining a perpendicular orientation of the tip in narrower tubular lumens such as the small intestine. A biopsy forceps is placed into the biopsy channel and advanced until it protrudes from the endoscope tip and is clearly visible. The endoscopic assistant opens the forceps, and the endoscopist advances the forceps towards the mucosa. The forceps should be advanced with gentle pressure until resistance is met. The assistant then closes the forceps, and the endoscopist pulls the biopsy instrument back into the biopsy channel. This tears the mucosa, capturing a small tissue sample.

As previously noted, biopsy specimens are obtained while the endoscope is gradually withdrawn from the area of the GI tract being investigated. In instances where a focal mucosal lesion is identified, multiple directed biopsy specimens should be taken. In instances where the abnormality is diffuse or where no gross abnormalities are visualized, multiple biopsy specimens should be obtained from various anatomic sites. For upper GI endoscopy, these sites include the duodenum jejunum (minimum of 8 to 10 biopsies), and antrum/angularis/lesser curvature, greater curvature, and cardia of the stomach. For colonoscopy, these sites include the cecum ascending colon transverse colon and proximal, middle, and distal descending colon.

To obtain biopsy specimens with a rigid endoscope, the tip of the endoscope should be placed 1 to 2 cm from the area to be sampled. The viewing lens is then opened, allowing the colon to collapse as air moves out. The area to be sampled should be visible in the tip of the endoscope. Alligator biopsy forceps are advanced through the endoscope, opened, and the area to be biopsied gently grasped. Before the tissue is pinched off, the biopsy forceps should be gently moved back and forth. If only mucosa or submucosa has been grasped, the tissue should be freely movable and the biopsy cups can be clamped down to obtain the sample. However, if the grasped tissue remains firmly attached to the colonic wall, this indicates that the forceps has gathered muscular tunics and colonic perforation is possible. In this event the forceps should be opened and a new site at least 1 cm away selected. A total of four to five samples should be obtained from the descending colon while the endoscope is progressively withdrawn.

Endoscopic biopsy specimens are delicate and easily damaged. Biopsy specimens should be handled gently and not allowed to dry. Placing the biopsy specimens on some form of support minimizes tissue contraction and preserves orientation. Transfer of the biopsy specimen directly from the biopsy forceps onto a moistened (normal saline) histopathology cassette sponge is recommended. Teasing the biopsy specimen from the biopsy forceps with a needle may damage the tissue. The sponge is placed in a labeled cassette and immersed in 10% formalin.

101.6 CONTRAINDICATIONS

Other than anesthetic considerations, GI endoscopy has no absolute contraindications. Endoscopic procedures are discouraged in inadequately prepared animals and in animals with bleeding disorders. Food within the stomach increases the risk of aspiration.

101.7 COMPLICATIONS

Complications of GI endoscopy include perforation of the GI wall, with resultant mediastinitis, pleuritis, or peritonitis. Perforation also can result from forceful insertion of the endoscope or biopsy forceps. *The endoscope should only be advanced if the lumen is visible*. Underlying disease in the bowel wall may predispose to perforation. Perforation usually results in the immediate development of air-filled body cavities (e.g., pneumoabdomen).

Overdistension of the stomach will cause cardiopulmonary compromise by impeding venous return, limiting tidal volume, and inducing vagal stimulation. Vagovagal reflexes can be induced by excessive traction on the mesentery. Significant hemorrhage can occur after biopsy procedures, but is rare. Enteropathogenic bacteria may be transmitted by poorly disinfected endoscopes. Gastric dilatation and volvulus can occur because of the inadequate removal of insufflated air.

101.8 CYTOLOGIC PROCEDURES

Cytologic samples can be used for the diagnosis of inflammatory, infectious, and neoplastic disorders of the GI tract of dogs and cats. Appropriate samples can be obtained manually (fecal smear, rectal scraping) or endoscopically.

The clinician prepares fecal smears by obtaining a fleck of mucus or a sample of feces from the surface of a stool and smearing the sample thinly on a microscope slide. To obtain a rectal scraping for cytologic evaluation, a gloved finger or small curette is inserted into the rectum and scraped along the mucosal surface. The sample collected should be thinly smeared on a microscope slide. After staining with new methylene blue or Wright's stain, the fecal smears and rectal scrapings can then be evaluated for the presence of inflammatory cells, pathologic organisms (e.g., *Histoplasma capsulatum*, *Prototheca* spp., *Campylobacter jejuni*, *Clostridium perfringens*), and neoplastic cells.

Cytologic examination of exfoliative specimens obtained endoscopically can be a useful adjunct to mucosal biopsy for the diagnosis of GI inflammation and malignancy in dogs and cats. It can also be useful for identification of *Helicobacter* in the gastric mucosa. Cytologic preparations can be obtained by brush or touch cytologic techniques (or both). The basic technique of brush cytology involves advancing a single-use guarded brush through the instrument channel, extending the brush beyond its protective sheath, and vigorously brushing the area of interest to exfoliate cells. The brush is then retracted into its sheath and removed from the endoscope. Finally, the brush is extended from its sheath and gently rolled across a glass slide. Theoretically, brush cytology offers the advantage of allowing for sampling of a larger surface area than biopsy. The touch cytology technique involves the transfer of an endoscopic mucosal biopsy to a glass slide. The clinician then makes multiple cytologic imprints by placing a second slide on top of, and at right angles to, the first slide and applying gentle pressure. Proper cytologic evaluation of samples obtained using these techniques requires an experienced GI cytopathologist.

102 CHAPTER • 102 Rhinoscopy, Nasal Flushing, and Biopsy

Mark J. Acierno

Mary Anna Labato

102.1 INDICATIONS

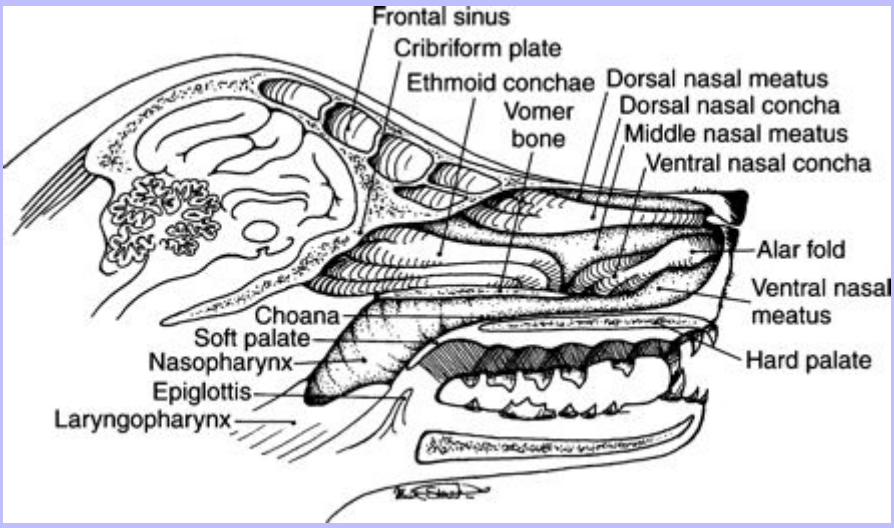
Clinical signs of acute and chronic nasal disorders vary but often include an obstruction of one or both nasal passages and a discharge that can be clear, mucoid, or hemorrhagic. Some dogs and cats respond to empirical therapy; others take a progressive and insidious course. These pets benefit from further diagnostics.

Nasal flushing and rhinoscopy are a part of the diagnostic workup for nasal diseases. Radiographic imaging should precede any invasive diagnostic procedure. Historical questions of interest include the onset and duration of the condition, whether one or both nostrils are involved, and the clinical progression of the disorder. The physical examination should include both the general physical and a detailed examination of muzzle, nasal planum, and nares. Looking at the condensation that forms on a glass slide placed in front of the nares is a convenient way to assess airflow. Diagnostic imaging is important not only because it may reveal a characteristic lesion but also because it may also provide information that can be used to direct the efforts of the nasal flush and rhinoscopy. Although computed tomography (CT) and magnetic resonance imaging (MRI) are significantly more sensitive in detecting and characterizing internasal lesions, skull radiographs taken under general anesthesia are often helpful. When used together, the history, physical examination, blood work, and diagnostic imaging provide an important foundation.

102.2 ANATOMY

A basic understanding of nasal anatomy is essential if consistently rewarding diagnostic procedures are to be performed (Figure 102-1). The left and right nasal cavities are separated by the bony nasal septum. The vestibule, located just within the nostril, contains the cartilaginous alar fold. The rostral aspect of each cavity is then divided into four airways (dorsal, middle, ventral, and common meatus) by the simple dorsal nasal concha and the more complex scroll-like ventral nasal concha. These conchae are primarily composed of cartilage rostrally and become increasingly calcified caudally. Nasal conchae are covered with a ciliated pseudocolumnar mucosal lining that serves to warm, humidify, and filter air as it travels through the meatus. The caudal aspect of the nasal cavities is filled with ethmoid conchae. These delicate, mucosa-covered scroll-like structures arise from the ethmoid bone; they extend to the cribriform plate and up to the sinuses. The cribriform plate, which also arises from the ethmoid bone, separates the nasal cavities from the cranial vault. Although dogs and cats have a complex arrangement of sinuses, these are rarely visualized during endoscopic procedures. All inspired air leaves the nasal cavity by passing from the ventral meatus to the nasopharynx via the choanae. The choanae is dorsal to the hard palate and funnels air from the two nasal sinuses into the common nasopharynx. The nasopharyngeal space, which is delineated ventrally by the soft palate and dorsally by the vomer bone, directs the flow of air into the oropharynx and eventually the trachea.

Figure 102-1 Nasal anatomy of canine. (Drawn by Mariah Steinwinter.)



102.3 NASAL FLUSH

The nasal flush is the least invasive method of obtaining diagnostic samples from the nasal cavity; however, this procedure has several limitations. Samples collected are obtained by infusing saline into the caudal aspect of the nasal cavity and collecting it as it leaves the nares. Therefore only cells and debris that are easily dislodged are collected. Many tumors will not exfoliate sufficient cells to permit diagnosis. In addition, no attempt is made to visualize the structures of the nasal cavity. This allows for gross abnormalities to escape detection. Lastly, although sterile saline is infused into the nasal cavity, it is collected as it flows out of the nares allowing for contamination by bacteria from outside the nasal cavity.

378
379

The anesthetized patient is placed in sternal recumbency with its nose pointed toward the floor. A cuffed endotracheal tube should always be used to prevent possible aspiration. A mouth gag is placed and a soft catheter (red rubber) is inserted into the nasopharynx so that its tip is pointed rostrally and the end of the catheter exits via the mouth. Sterile saline is then forcibly injected into the end of the catheter and fluid is collected as it leaves the nares. Depending on the size of the patient, 5 mL to 60 mL of infused saline should be sufficient to obtain samples for bacterial culture, fungal culture, and cytologic study. The flush can be repeated several times to improve diagnostic yield.

102.4 MODIFIED NASAL FLUSH

A second technique for nasal flushing has been described. Briefly, the tip of a polypropylene urinary catheter is cut to form a jagged edge. The distance from the nares to the eyes is measured and then marked on the catheter. This line estimates the distance from the nares to the cribriform plate; the catheter should never be advanced beyond this distance. The patient is then positioned as described previously and the catheter is inserted into the nares and advanced into the nasal cavity. While using the syringe to both flush saline into the nasal cavity and then suction the fluid back out, the sharpened catheter tip is used to scrape the nasal mucosa. Although this procedure has the theoretic advantage of active exfoliation of cells and larger samples, it is still performed blindly and has

not been proven to provide greater diagnostic sensitivity. Some samples collected in this fashion may be suitable for histopathology.

102.5 RHINOSCOPY AND BIOPSY

A thorough examination of the upper respiratory tract requires direct visualization of each nasal cavity, nasopharynx, oropharynx, and larynx. The oropharynx and larynx can be examined in a sedated patient using only a laryngoscope, whereas visualization of the nasal cavities and nasopharynx requires general anesthesia and specialized equipment and techniques. Although no currently available endoscopic system will allow visualization of the entire nasal cavity and nasopharynx, the combined use of carefully selected rigid and flexible scopes will allow examination of most of the nasopharynx and nasal cavity.

Bacterial and fungal cultures should always be collected prior to rhinoscopy because the procedure is likely to introduce contamination. Once the patient is anesthetized, a nasal flush is performed and the sample submitted for culture. Alternatively, culture swabs are carefully inserted into the nasal cavity and then removed; contact with the external nares is avoided. Additional samples can also be retrieved during the rhinoscopy procedure if bacterial or fungal infection is suspected.

Examination of the nasopharynx is best achieved using a small flexible endoscope. Two commonly used instruments are the 5 mm bronchoscope and the 2.5 mm cystoscope. Although placement of the scope into the nasopharynx initially appears difficult, it is a skill that is easily mastered. The anesthetized patient is placed in sternal recumbency with the nose pointed slightly toward the floor. A cuffed endotracheal tube should always be used to prevent the aspiration of secretions, blood, or saline. In addition, a mouth gag is always used to prevent possible damage to the scope and facilitate proper scope placement. The scope is flexed to 180 degrees. Then, with the tip of the retroflexed scope parallel to the lower jaw, the scope is inserted into the oral cavity and advanced. Once past the caudal aspect of the soft palate, the scope is rotated so that the tip is pointing up and perpendicular to the lower jaw. By moving the scope slightly rostrally, the tip “hooks” the nasopharynx and proper placement of the scope is achieved.

Once inside the nasopharynx, a careful examination of the relevant structures can begin. It is important to remember that because the scope is flexed, the image will be inverted; therefore the soft palate will be viewed dorsally. The entire nasopharynx should be examined by moving the tip of the scope rostrally until the choanae can be clearly visualized. The nasopharynx and choanae should be assessed for texture, contour, and patency. The soft palate should be pink, smooth, and flexible, whereas the dorsal wall of the nasopharynx is smooth, dome shaped, and rigid. A cobblestone appearance to the mucosa may be evidence of lymphoid follicular hyperplasia (inflammation) or lymphoma. Fungal colonies will often appear as gray or yellow plaques. Large masses or polyps can protrude into the airway. Chronic inflammation, infectious diseases, or surgery all may result in scarring and stenosis of the nasopharynx, whereas a membranous obstruction of the choanae (atresia) can be caused by a congenital abnormality. Foreign material that has been vomited into the nasopharynx resulting in inflammation and obstruction may be visualized.

Any deviation from the normal anatomic structure should be investigated by biopsy and histopathology or culture. A biopsy instrument should not be passed through the scope's instrument channel when it is maximally flexed because the scope may sustain permanent damage. Therefore it is recommended that the scope be removed from the nasopharynx and straightened before the instrument is passed though the channel. The biopsy instrument should be positioned so that its forceps lie at the tip of the scope. Once in this position, the scope can be retroflexed and reinserted as described previously. This maneuver must be repeated for each biopsy sample.

Although the rostral most aspect of the nasal cavity can be examined by inserting a nasal speculum or flexible endoscope into the nares, a complete and through examination of the turbinates necessitates the use of a small-diameter rigid endoscope. One such instrument is the 2.7 mm universal telescope (Karl Storz Veterinary Endoscopy). When combined with a 4.0 × 5.5 mm oval cystoscopy cannula, this scope provides the user with a 16.5 cm working length and a 5 French (F) biopsy channel, which also allows for irrigation. The primary advantage of this system is that it allows direct visualization of a large portion of the nasal cavity and guided placement of biopsy forceps.

The anesthetized patient is placed in sternal recumbency with the nose pointed slightly toward the floor. The use of a cuffed endotracheal tube is essential to prevent aspiration. In addition, the placement of gauze sponges in the oropharynx may provide additional protection to the airway. Although the bleeding associated with rhinoscopy and biopsy can sometimes be a source of concern, instilling the nasal cavity with 0.25 to 0.5 mL of a dilute (1:10) mixture phenylepinephrine and lidocaine just prior to the procedures can be helpful in minimizing hemorrhage. The scope is inserted into the nasal cavity by lifting the flap of the nasal planum laterally and directing the scope over the alar fold. The scope can then be directed into the dorsal, middle, or ventral meatus. If the scope is equipped with a suitable channel, warm saline should be infused. This assists in visualizing the nasal structures by keeping the lenses free of blood, mucus, and debris. The scope is directed caudally to examine both the turbinates and air-filled meatus; however, the clinician should never advance the tip of the scope past the level of the eyes. The preliminary diagnostic workup may provide important information in regards to the location of a nasal lesion, yet a through examination of the entire nasal cavity is always recommended so as not to miss more subtle lesions.

379

380

The turbinates should be examined for color, texture, and contour. They should be smooth, scroll-like, and covered with a shiny pink mucosa. Each meatus should be patent, free of debris, and contain minimal mucous. In addition, the air passages will gradually taper in the caudal aspect of the nasal cavity, and sudden widening or narrowing is evidence of a lytic or proliferative lesion. Abnormal endoscopic findings include increased mucus production, swelling of the turbinates, changes in the color or texture of the turbinates, foreign bodies, destruction or proliferation of the turbinates, fungal colonies, polyps, or tumors.

Increased mucus production, swelling of the turbinates, and changes in the appearance of the turbinates are nonspecific inflammatory findings that can be associated with allergic rhinitis, lymphoplasmacytic rhinitis, foreign bodies, bacterial infections, fungal infections, dental disease, and neoplasms. When a thorough endoscopic inspection fails to reveal a foreign body, mass, or fungal plaques, then biopsies of nasal mucosa should be submitted for histopathalogic examination and bacterial and fungal culture. It is important to remember that the source of the nonspecific inflammatory changes may be the result of dental disease. Therefore a thorough dental examination should always be performed while the patient is anesthetized.

Destruction of the turbinates is often associated with fungal rhinitis *(Aspergillus*, *Penicillium)*, bacterial rhinitis, viral rhinitis (cats), foreign bodies, and malignancies. Once again, if endoscopic examination does not reveal fungal colonies, a foreign body, or evidence of malignancy, then samples should be taken for histology and fungal and bacterial culture. As always, the teeth should be considered as a possible underlying cause of the turbinate destruction.

The appearance of masses in the nasal passage is variable but usually causes some degree of turbinate destruction, mucous production, and tissue proliferation, which obstructs the meatus. It is important to note that some fungal organisms, including *Rhinosporidium* and *Cryptococcosis*, can induce masslike formations rather than turbinate destruction. The appearance of any deviation in the normal appearance is sufficient reason to obtain a biopsy specimen and bacterial and fungal cultures.

103 CHAPTER • 103 Thoracic and Pericardial Taps and Drains

Lynette D'Urso

103.1 THORACOCENTESIS

Thoracic radiographs provide evidence that fluid or air exists within the pleural space. They show the location of the fluid and if pockets of fluid are present. If the patient is severely dyspneic and auscultation of the thorax indicates the presence of fluid or air, the clinician should proceed directly to thoracocentesis without taking radiographs. Care and good medical judgment are important factors in the decision to tap prior to radiography. For example, if a diaphragmatic hernia or solid mass was the origin of the pleural fluid then performance of thoracocentesis without initial diagnosis of the condition could lead to a puncture of an intestinal loop or the liver. Performing thoracic ultrasound prior to thoracocentesis is ideal due to the ease and rapidity at which it can be performed to identify fluid location.

Thoracocentesis is the technique used to remove air or fluid from the pleural space. Cytologic and chemical analysis of the pleural fluid assists in understanding the etiology and significance of abnormal fluid collection.

Materials required to perform thoracocentesis may include a butterfly catheter or 20-, 18-, 16-gauge needle or over-the-needle catheter, a three-way stopcock, an extension set, a large syringe (35 or 60 mL), tubes for fluid collection (EDTA and plain tubes), and slides for cytologic preparation.

The site for thoracocentesis varies with the individual patient and the amount and location of fluid or air. The seventh or eighth intercostal space is appropriate for a moderate to large quantity of fluid usually at the midthoracic level for fluid or more dorsally to remove air. In cats, an appropriate location is at the cranial right second to third or third to fourth intercostal space. The insertion site should avoid the caudal aspect of the ribs and therefore the intercostal vessels. If performance of thoracocentesis is ventral, the vessels along the sternum must be avoided. Similarly one must avoid the crura of the diaphragm and the liver, which lies just adjacent and caudal to the diaphragm.

A sterile three-way valve and 3-or 6-cc syringe are attached to the needle or tubing of the catheter. An extension set may also be used from the needle to the three-way valve to compensate for patient movement. The needle is advanced through the thoracic wall while gentle traction is maintained on the syringe. Once fluid is observed in the tubing, the needle is held in place or the needle angled so that it lies parallel to the chest wall. The first sample collected should be saved for analysis. Once a sample is collected a large (35-or 60-cc) syringe is attached and as much fluid as possible is drawn off. Holding the needle along the thoracic wall will decrease the chance of lung tissue laceration. The needle should be withdrawn if there is excessive patient movement or coughing to avoid a lung laceration. Fibrin clots may clog the end of the needle during the procedure. The needle may need to be moved to different locations or fluid occasionally injected into the pleural space through the needle to remove the clots.

An over-the-needle catheter may be used to avoid potential complications of lung laceration. Once inserted into the pleural space, the catheter is advanced and the needle removed. The extension set and stopcock are immediately attached. If repeated thoracocentesis is necessary, the catheter can be sutured in place; however, caution must be exercised. The patient must be properly restrained to avoid tampering with the catheter and the needle must be properly capped to avoid iatrogenic pneumothorax, as well as making sure it is very securely sutured in place. Too large an amount of fluid removal and/or removing fluid too quickly can lead to reexpansion lung injury. Removal of less fluid may be safer and will quickly help to stabilize the patient.

Following thoracocentesis, radiographs or ultrasound can be performed to assess the quantity of fluid remaining or to identify iatrogenic pneumothorax.

103.2 PERICARDIOCENTESIS

Pericardiocentesis confirms the suspicion of pericardial fluid and provides diagnostic and therapeutic benefit by relieving decreased cardiac function (cardiac tamponade).

Materials required for pericardiocentesis include 6-, 12-, 60-mL syringes; +/– three-way stopcock and IV fluid extension line; 16-gauge, 3¼-inch, or 5-inch over-the-needle Angiocath catheter; sterile gloves; lidocaine for local anesthesia; a scalpel blade; and tubes for collection and culture of fluid.

The most important consideration is a strong clinical suspicion of fluid collection in the pericardial sac. Physical examination findings include increased venous pressure, decreased heart sounds, and decreased peripheral blood pressure. Signs of right-sided heart failure may be observed (ascites and peripheral venous distension). Radiographs of the thorax aid in supporting the diagnosis if rounding of the entire cardiac silhouette is observed on both lateral and dorsoventral views. The heart appears globoid rather than elliptic in shape. The pericardial sac can become distended so that it contacts the thoracic wall. Ultrasound provides a definitive diagnosis of pericardial effusion and cardiac tamponade (see Chapter 205).

The suspicion of pericardial fluid is supported on ECG by a generalized decrease in electrical amplitude of the complexes or electrical alternans. If pericardial fluid has been confirmed by ultrasound there are no contraindications to the procedure except for a bleeding diathesis or ruptured left atrium leading to continual bleeding into the pericardial space.

Complications of pericardiocentesis could include puncture of the ventricular wall, which could induce an arrhythmia, puncture of a coronary blood vessel, or epicardial laceration.

Sedation can be used if necessary but acepromazine should be avoided to prevent exacerbation of preexisting hypotension. Most pericardiocenteses are performed without sedation and often with use of only lidocaine at the site of skin and thoracic wall puncture. The patient should be gently restrained either standing or in sternal or left lateral recumbency. ECG monitoring of the heart rate and rhythm during the procedure is recommended but not essential.

A wide area of the right ventral hemithorax is surgically prepared from the third to the eighth intercostal space (ICS) to avoid trauma to the lung by entering the pleural triangle where there is no lung tissue. One milliliter of lidocaine is infiltrated into the skin and down to the parietal pleura at the site of entry (costochondral junction over the fifth or sixth ICS). A stab incision is made through the skin to permit needle entry. A 6-or 12-cc syringe is attached to the end of an angiocatheter and it is advanced into the thorax through the incision cranial to the rib (the intercostal vessels caudal to each rib are avoided) while maintaining gentle traction on the syringe plunger. The needle and syringe are held perpendicular to the chest wall and directed medially and slightly dorsally (Figure 103-1). A small “pop” may be felt when passing through the pericardium. When fluid appears in the syringe, a small amount for evaluation is collected and the catheter is advanced into the thorax all the way to the hub while the stylet is held steady (Figures 103-2 and 103-3). The stylet is removed and a 60-cc syringe is attached to the angiocatheter. Negative pressure is not present within the pericardial sac and usually pericardial fluid continues to pulsate out of the catheter. If the catheter rubs on the myocardium, ventricular premature contractions (VPCs) may be observed; the needle should be withdrawn slightly.

Figure 103-1 Placement of the angiocatheter at the sixth intercostal space at an angle perpendicular to the chest wall to perform a pericardiocentesis. Gentle suction is applied to the end of the catheter with a 12-cc syringe while the needle is advanced into the thorax and pericardial sac.

If pericardial fluid is bloody it should be monitored for signs of clotting (Figure 103-4). If clotting is observed then acute bleeding from a ruptured vessel or the tapping of blood directly from within the heart is suspected and the catheter removed. Comparing clotting time and hematocrit of peripheral blood often assists in determination of the fluid type.

The amount of fluid removed should be recorded. Depending on severity and duration of the condition 1000 cc or more may be obtained from the pericardial sac of a large dog. The fluid sample should be submitted in a plain tube and a tube containing an anticoagulant for cytology and chemical analysis. A sample may be considered for culture.

Following the procedure a thoracic radiograph or ultrasound should be performed to determine if the fluid is re-accumulating or if total fluid withdrawal has been accomplished. When ultrasound availability is not present, a pneumopericardial study should be considered.

Figure 103-2 Pericardial fluid is first observed within the syringe. Advancing the needle is discontinued here.

381

382

Figure 103-3 The catheter is advanced with one hand in one smooth motion while the other hand holds the stylet steady and prevents it from injuring the epicardium.

103.3 CHEST TUBE PLACEMENT

Temporary indwelling chest tubes are indicated for conditions requiring repeated thoracocentesis such as pneumothorax, tension pneumothorax, pyothorax, chylothorax, postoperative thoracotomy, or pleurodesis.

Appropriately sized tubes selected according to weight and tube size should comfortably fit in the intercostal space (Table 103-1). As a guide, the inside diameter of the chest tube should be the same size as the main stem bronchus

on radiographs if the fluid is viscous or contains clots. A smaller tube (12 French) can be used to evacuate a pneumothorax.

Types of tubes used include silicone rubber (does not easily occlude but difficult to place without a stylet), red rubber (irritating and non-radiopaque), and polyvinylchloride (commercially available).

Commercially available chest tubes have fenestrations (holes) preplaced. Additional holes can be made that encompass less than 30% of the tube circumference so as to not weaken it. To make such a hole the tube is prebent and a tiny amount at the angle of the tube is cut. The hole size will be approximately four times as large as the piece removed so the cut should be conservative. All holes must be within the portion of the tube placed within the thorax.

Figure 103-4 A 60-cc syringe is attached to the catheter and gentle traction is applied until all fluid has been removed. Appearance of the pericardial fluid is often bloody as seen here. This part of the procedure is no longer sterile.

Table • 103-1 Recommended Tube Sizes for Cats and Dogs

WEIGHT	TUBE SIZE (FRENCH)
<7 kg	14–16
dogs 7–15 kg	18–22
dogs 16–30 kg	22–28
dogs >30 kg	28–36

The clinical condition of the patient must be assessed prior to restraint or sedation for tube placement. The desired length of tube is premeasured from the tenth intercostal space (ICS) to the ipsilateral elbow.

Iatrogenic pneumothorax, laceration of a lung lobe or vessel, and tube migration within the thoracic cavity are potential complications to be considered with chest tube placement. Additional considerations include pain, lung or pleural irritation, and the presence of ventricular premature contractions with cardiac-induced pleural effusion.

The patient is gently restrained in lateral recumbency with the side for the tube placement facing up or is maintained sternally. Hair is clipped from shoulder to last rib and to the dorsal and ventral midline. Surgical preparation or cleaning of the skin follows. The tube is placed approximately mid-thorax at the seventh ICS. If air is suspected the tube is placed at the junction of upper third and lower two thirds of the chest wall. If fluid is to be removed, the tube is placed at the junction of the lower third and upper two thirds of the chest wall.

A local infiltrative block is performed directly at the site of tube placement or an intercostal or line block along the seventh ICS. There are two different techniques for incisions:

1. Incision is made using a blade over the tenth ICS (previously locally anesthetized). The tip of trocar is placed through skin incision and it is advanced subcutaneously cranially to the seventh ICS.

2. A gloved assistant pulls skin cranially starting just behind the elbow. A blade is used to incise the skin over the seventh ICS. The subcutaneous and intercostal muscles can be incised with the blade or dissected with Mayo scissors. The trocar is inserted through the full incision.

The trocar is placed in a vertical position perpendicular with the thoracic wall and the tip directed toward the opposite elbow. With one hand the trocar is held securely 2 to 3 cm above the skin to avoid penetration of the thoracic cavity too deeply. The palm of the other hand is placed on the head of the stylet and firm consistent pressure is applied to penetrate the trocar into the pleural space in a single motion. Once the pleura is penetrated, the trocar is angled so that it is parallel with the ribs and directed dorsally to remove air or ventrally for fluid. The stylet is pulled back very slightly and the tube and stylet advanced to the desired length. The tube is clamped with the handle portion of a hemostat as the stylet is removed to prevent pneumothorax. The skin is released and it will migrate caudally and form a tunnel to seal the hole just created. A tube adaptor and a 3-way stopcock with ports closed are attached to the tube.

A purse-string suture is used at the skin incision in addition to a Chinese finger trap or Roman sandal suture pattern to secure the tube to the chest wall. Alternatively, a “butterfly” is made out of 1-inch white tape around the tube just distal to the skin incision and suture the wings to the skin. 382 383

A thoracic radiograph confirms tube placement. Antibiotic ointment and sterile gauze are placed over the insertion site followed by a comfortable chest bandage. The bandage and skin incision should be checked at least several times daily. All connections must be secure with no leaks.

The tube can be removed when there is less than 2 mL/kg/day of fluid accumulation. One continuous rapid motion is used to remove the drain. Sedation is not necessary. Overwrap with a thoracic circumferential bandage for 1 to 2 days.

An E-collar or other method of preventing access to the tube must be utilized at ALL times. Initially the tube should be monitored and evacuated every 1 to 2 hours, more often if the patient becomes tachypneic or dyspneic. A large (35-or 60-cc) syringe can be used to provide intermittent suction in small dogs and cats, whereas continual suction may be required in large dogs. One additional consideration is that some patients may have a complete mediastinum due to pathology within the thorax. This may require chest tube placement on both sides of the thorax to completely remove fluid or air.

104 CHAPTER • 104 Transtracheal Wash and Bronchoscopy

Brian C. Norman

Transtracheal wash and bronchoscopy are diagnostic procedures used in the diagnosis of bronchopulmonary airway disease. The transtracheal wash is used to obtain tracheobronchial cells and secretions for cytology and microbiologic evaluation. The bronchoscope is a more specific procedure that allows visualization of the trachea and airways while obtaining samples. The choice of procedure should be based on stability of the patient, diffuseness of disease, and operator skill level.

104.1 TRANSTRACHEAL WASH

A transtracheal wash can be performed in animals with a diffuse disease that cannot undergo prolonged sed ation. The ventral portion of the patient's neck is clipped and aseptically prepared. The patient is then placed in sternal recumbency with an assistant holding the head and pointing the nose up. Sedation with Propofol (Diprivan) or a short-acting barbiturate anesthetic is preferred. In dogs, a 16-gauge through-the-needle jugular catheter is inserted between proximal tracheal rings or the cricothyroid membrane and advanced down the airway. In cats, an open-end polypropylene urinary catheter or 5 F red rubber catheter can be placed through a sterile endotracheal tube. The catheter is slowly advanced down the trachea. Warm sterile saline is infused through the catheter: 5 mL is infused for cats and small dogs up to a maximum of 20 mL in large dogs. After 5 to 10 seconds, the operator attempts to retrieve the sample by applying gentle negative pressure several times with the syringe. Generally, 50% of the original volume will be retrieved. Several drops of the sample should be placed on a culture swab for culture and sensitivity, and the remainder should be placed in a sterile tube or container for cytology.

Pneumomediastinum and subcutaneous emphysema are complications of this procedure that may need to be addressed.

104.2 BRONCHOSCOPY

Bronchoscopy is best performed with a flexible fiber-optic bronchoscope. The patient is anesthetized with Propofol® and maintained on a drip or gaseous anesthesia. In larger animals, an endotracheal tube may be placed and the bronchoscope can go through the tube. In smaller animals, the bronchoscope is too large and the animals cannot be intubated during the procedure. After the animal is lightly anesthetized, the bronchoscope is inserted through the arytenoids and into the trachea. Inspection of the trachea should include the appearance of the mucosa, the amount of secretions, and any evidence of collapse. The carina should then be identified, and each lung lobe should be systematically examined. (Figures 104-1 and 104-2). The operator must note the presence of mucus plugs, foreign bodies, dynamic collapse of airways, masses or nodules, and parasites.

The bronchoscope offers several options to sample the airways. The first method uses a bronchoscope brush. The brush is covered by plastic that can be pulled back once the brush is in its desired location. With the bronchoscope in the desired location, a small sampling brush is passed through the sampling channel. When the brush is visualized, the brush is extended and gently scraped against the airway. The brush is then pulled back into its casing and removed from the scope. The brush can be cultured and then gently rubbed on a glass slide for cytology.

The second sampling method uses a biopsy instrument. In a similar method, the bronchoscope is placed in the desired location and then the biopsy instrument is inserted into the sampling port. The bronchoscope is then used

to guide the instrument to the desired location and the biopsy is taken. The sample can be submitted for culture and histopathology.

The third sampling method is bronchial or bronchoalveolar lavage. This is performed after all lobes have been inspected. The bronchoscope is directed into the desired lung and then advanced until it is wedged or is occluding the airway. The clinician should instill 10 to 30 mL of warm sterile saline into the sampling port, and (5 to 10 seconds later) aspirate the sample using a syringe. Approximately 40% to 50% of the sample should be retrieved. It is helpful if the patient is not heavily sedated. The lightly sedated animal will cough, producing a better sample. This procedure can be repeated several times. Several drops of the sample should be cultured, and the rest should be placed in sterile tubes for cytologic evaluation.

Figure 104-1 Diagram of normal bronchoscopic image of the division of the carina, demonstrating the position of the right and left main stem bronchi.

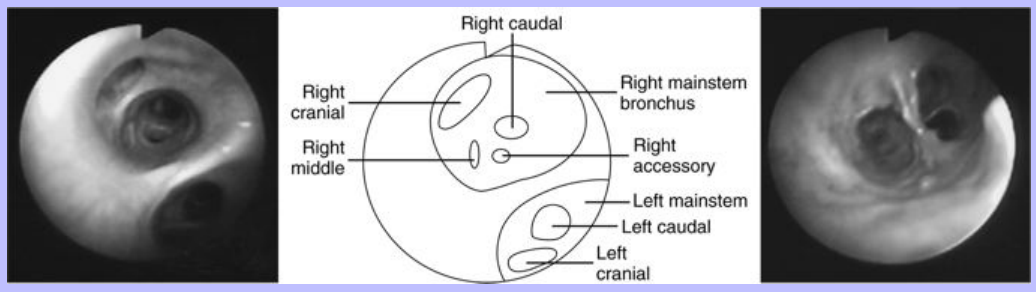


Figure 104-2 Diagram of normal bronchial anatomy in dogs. Each lobar bronchus is subdivided into segmental bronchi: *V1,* first ventral segmental bronchus; *V2,* second ventral segmental bronchus; *D1,* first dorsal segmental bronchus; *D2,* second dorsal segmental bronchus; *C1,* first caudal segmental bronchus; and *R1,* first rostral segmental bronchus. Segmental bronchi are subdivided into subsegmental bronchi: *V1a,* first subsegmental bronchus; *V1b,* second subsegmental bronchus. *LB1,* Lobar bronchus of left cranial lung lobe; *LB2,* lobar bronchus of left caudal lung lobe; *LPB,* left main stem bronchus; *RB1,* lobar bronchus of right cranial lung lobe; *RB2,* lobar bronchus of right middle lung lobe; *RB3,* lobar bronchus of accessory lobe; *RB4,* lobar bronchus of right caudal lung lobe; *RPB,* right main stem bronchus. (From Amis TC, McKiernan BC: Systematic identification of endobronchial anatomy during bronchoscopy in the dog, *Am J Vet Res* 47:2649, 1986.)

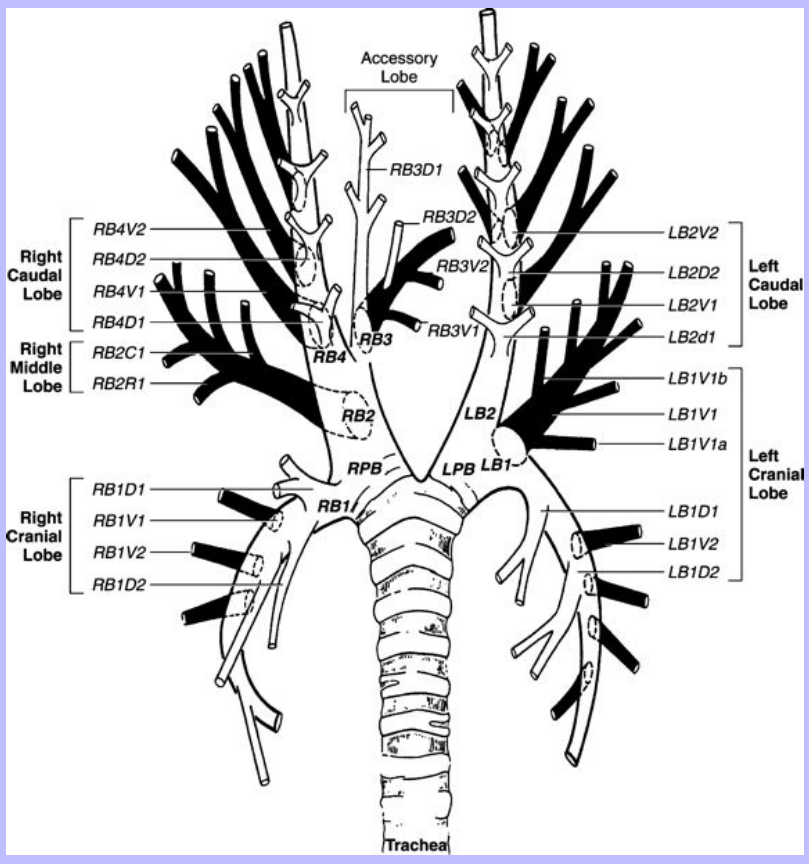


105 CHAPTER • 105 Unblocking the Urethra of the Male Cat

Mary H. Bowles

The male cat may have an obstructed urethra due to inflammation, spasms, trauma, congenital defects, urethral or periurethral masses, foreign bodies, uroliths, and urethral plugs. The length and narrow diameter of the urethra predisposes these cats to obstruction. The urethral plug is the most frequent cause of obstruction.

Cats with feline lower urinary tract disease often display similar clinical signs regardless of the cause or the presence or absence of obstruction. Dysuria, hematuria, and frequent attempts to urinate are common but not exclusive signs of urethral obstruction. However, when these signs are combined with vocalization, licking the prepuce or penis, or systemic evidence of illness (e.g., depression, loss of appetite), it is likely that the animal has a urethral obstruction. Palpation of a distended bladder that is difficult to express is a key feature of urethral obstruction.

When urethral obstruction is suspected, a thorough assessment of the cat's physical condition is indicated prior to catheterization, especially if the cat is systemically ill. In addition to establishing further evidence of urethral obstruction by bladder palpation and inspection of the distal penis, special attention should be paid to the cardiac status because hyperkalemia-related arrhythmias may be present that affect the treatment plan. Quick assessment tests (QUATS) (e.g., blood urea nitrogen [BUN], glucose, packed cell volume [PCV]) are indicated in any cat prior to catheterization to evaluate both anesthetic risk and overall condition. Appropriate blood samples should be saved for subsequent complete blood count (CBC) and biochemistry profile evaluation, especially in systemically ill cats. Bladder decompression by cystocentesis provides optimum samples for urinalysis and culture, alleviates distress, and may facilitate flushing obstructive material back into the bladder when necessary. Urethral catheterization usually requires general anesthesia unless the cat is moribund. Anesthetic agents requiring renal excretion should be used with caution.

105.1 UNBLOCKING TECHNIQUE AND INDWELLING CATHETER PLACEMENT

The cat should be placed in lateral recumbency. The clinician should then clip the hair in the perineal area and surgically scrub the prepuce and tip of the penis, taking care to avoid undue trauma to the penis. The tail and hindlimbs should be drawn forward toward the head to provide better exposure of the preputial area. Using sterile technique, the prepuce should be pushed back toward the body, exposing the distal end of the penis. Because urethral plugs often lodge near the external urethral orifice, the exposed distal penis should be gently massaged to loosen any obstructing material present and extrude it from the urethra. The lubricated tip of an open-ended tomcat catheter (3.5 F polypropylene, 4.5 to 5.5 inches in length) or a Minnesota olive-tipped feline urethral catheter (22 G × ½-to 1½-inch E-JAY International, Inc., Glendora, Calif.) is then inserted into the external urethral orifice, extending the penis caudally and dorsally until it is parallel to the spine to facilitate advancement of the catheter (Figure 105-1). Once the obstruction has been reached, the clinician should attach a syringe (ε20 mL) filled with saline or lactated Ringer's solution to the catheter either directly or by an intravenous extension set. A liberal amount of flushing solution is then injected into the urethral lumen, allowing fluid to run back out of the urethral orifice. The clinician should periodically attempt to cautiously advance the catheter toward the bladder, noting evidence of relief of obstruction, such as debris emerging from the orifice or a decrease in reflux of flushing solution. Applying moderate pressure to the bladder wall and occasionally repeating gentle massage of the extruded penis between flushings may facilitate dislodgement of a urethral plug or urolith.

If the previously described technique does not result in relief of obstruction, the clinician should continue to flush while manually occluding the urethra around the catheter tip, attempting to dilate the urethral lumen and force the

obstructive material back into the bladder. As pressure builds up in the obstructed urethra, the clinician should try to carefully advance the catheter toward the bladder. To prevent iatrogenic damage to the urethra, excessive force should be avoided when advancing the catheter and when injecting flushing solution from the syringe into the manually occluded urethra.

If the urethra is successfully unblocked, a catheter should be inserted into the bladder lumen and the majority of urine aspirated from the bladder, saving a portion for urinalysis +/– culture if not obtained previously by cystocentesis. The bladder should be flushed repeatedly with saline or lactated Ringer's solution until aspiration of the flushing solution appears relatively free of blood and particulate material. If a urethral plug or urolith was obtained during the unblocking procedure, it should be saved for analysis. Urethral plugs can be examined cytologically, and uroliths can be submitted for quantitative analysis +/– culture.

Figure 105-1 Proper positioning of the feline penis for urethral catheterization with a 3.5 F polypropylene catheter. The penis is extended caudally and dorsally while the tail and hind limbs are drawn forward toward the head.

385

386

If the unblocking techniques previously described are unsuccessful, the bladder can be serially decompressed by cystocentesis or a cystostomy tube can be placed for temporary urine diversion. These procedures provide relief while the cat receives supportive therapy and has diagnostic imaging performed to further define the source and location of obstruction; they also allow for alternative treatment plans to be developed.

Monitor urination for at least 24 hours after relief of obstruction. Express the bladder manually at least three times daily if the cat is not voiding regularly or a large amount of urine is retained in the bladder after voiding. Place an indwelling catheter immediately after the unblocking procedure if a strong urine stream is not present on expression, the cat is systemically ill, excessive hematuria exists, or relief of obstruction was difficult. An indwelling catheter may be placed up to several hours later if the patient reobstructs or has difficulty urinating due to an atonic bladder. Ideally, a 5 French (F) (the 3.5 F. size may be used but becomes obstructed more easily) red-rubber (polyvinyl) or Foley catheter should be used because these catheters are more pliable than the polypropylene variety and less likely to cause injury to the urethral and bladder mucosa. Placement may require the use of a wire guide due to the increased pliability. The application of a generous amount of lubricant is often required to facilitate passage, especially for the balloon portion of the Foley catheter. To minimize bacterial contamination after insertion into the bladder lumen, the clinician should attach the indwelling catheter to a sterile, closed urine collection system available as a commercial product (Cook Urological, Spence, Ind.) or constructed from a recently emptied intravenous (IV) fluid bag attached to a sterile IV administration set. The clinician can

reduce tension placed on the indwelling catheter by the collection system by using elastic wrap and suture to attach the apparatus to the cat (Figure 105-2). Indwelling catheters should be removed as soon as possible, generally within 1 to 3 days after placement. Although indwelling catheters predispose the cat to urinary tract infection, antibiotic therapy is not recommended unless evidence of urinary tract or systemic infection exists.

Figure 105-2 Indwelling 5 F. Foley urethral catheter attached to a sterile, closed urine collection system. Elastic wrap attaches the urine collection system to the tail, and an elastic wrap flange is loosely sutured in the preputial area to reduce the tension on the urethral catheter and help keep it in place.

106 CHAPTER • 106 Venous and Arterial Puncture

Harold Davis

106.1 VENIPUNCTURE

The most commonly used veins for venipuncture are the cephalic (dog and cat), lateral saphenous (dog), medial saphenous (cat), and jugular (dog and cat). The ear veins (dog and cat), sublingual veins (dog and cat), and abdominal veins (dogs) have also been used. Any visible vein is an option for venipuncture.

The most important aspects of any venipuncture technique are the proper restraint of the animal and proper distention and immobilization of the vessel. These objectives are most easily accomplished when the procedure is done as a two-person project. The phlebotomist should only attempt the venipuncture when the vessel can be clearly delineated. Blind venipuncture attempts, in the hopes of accidentally "skewering" the vein, are doomed to failure and create unnecessary patient discomfort. If the phlebotomist is unable to locate the vessel (by visual inspection or digital palpation), the manner in which the vessel is distended and immobilized must be changed.

Awake animals need to be restrained for any of these procedures, but excessive restraint should be avoided because it may incite more resistance from the animal than the venipuncture procedure itself. All venipunctures (and arterial punctures) must be done aseptically. The hair should be clipped and the skin prepared with antiseptic solutions as if for surgery.

106.2 CEPHALIC VEIN VENIPUNCTURE

The dog or cat may be positioned in sternal or lateral recumbency. The restrainer leans over the top of the animal and grasps the leg of interest at the elbow. The other hand or arm can be used to restrain the animal's head if the animal is awake, to prevent an aggressive response to the skin puncture. If the animal is in sternal recumbency, the restrainer should lean on his or her elbow to help prevent the animal from withdrawing its leg at some critical time during the procedure. The thumb or forefinger is wrapped around the leg at the level of the elbow. Pressure at this point occludes the cephalic vein. The skin is then rotated outward to roll the vein to the top (anterior) of the leg.

The phlebotomist grasps the leg with one hand at the level of the metacarpus and further extends the leg. In loose-skinned animals, it may be necessary to flex the carpus. The objective is to tether the vein between the two points of traction (at the elbow and at the carpus) so that the vein is both distended and does not roll from side to side. It should not be necessary for the phlebotomist to use his or her thumb to help immobilize the vein; this may only serve to collapse the vein, making venipuncture more difficult.

The needle is directed, as much as possible, along the longitudinal axis of the vein. The needle is inserted through the skin with the bevel facing up. It is not necessary to achieve both skin and vein puncture in the first movement. The skin puncture is the painful part, and animals will often move in response to it. Once the animal has settled down, the needle can be directed into the vein. If blood does not spontaneously flow into the hub of the needle, the phlebotomist should gently aspirate to determine if the needle is or is not in the vein. If it is not in the vein, the needle should be advanced a bit further and the process repeated. The needle can be advanced to its full length. If at this point the venipuncture has not been successful, the needle will have to be withdrawn to its subcutaneous position (it should not be removed entirely, because another skin puncture will then be necessary). It is most important to withdraw the needle slowly, while gently aspirating. The deep wall of the vein may have been inadvertently penetrated, and the lumen will thereby be found as the needle is withdrawn.

Figure 106-1 The various positions used for dog and cat venipuncture. **A,** Dog positioned for venipuncture of the lateral saphenous vein. **B,** Cat positioned for venipuncture of the medial saphenous vein. **C,** Dog positioned for venipuncture of the jugular vein. **D,** Cat positioned for venipuncture of the jugular vein.

Once the blood sample is taken or the drug is administered, the needle is withdrawn from the vein and digital pressure applied over the venipuncture site for at least 30 seconds. The site should be monitored for bleeding or hematoma formation for an additional several minutes.

106.2.1 Lateral Saphenous Venipuncture

Dogs are usually positioned in lateral recumbency for this procedure (Figure 106-1, *A*). The restrainer grasps the upper leg at the stifle. The other hand or arm can be used to restrain the animal's forelegs and head if the animal is awake. Circumferential pressure is applied at the stifle to occlude and distend the vein. The phlebotomist grasps the leg with one hand at the level of the metatarsus. In loose-skinned animals it may be necessary to extend the leg and flex the tarsus to better tether and immobilize the vein. It should not be necessary for the phlebotomist to use his or her thumb to help immobilize the vein. The venipuncture is performed as described previously.

106.2.2 Medial Saphenous Venipuncture

Cats are usually positioned in lateral recumbency for this procedure. The restrainer grasps the lower leg at the stifle while reflecting the upper leg caudally with the forearm. The other hand or arm can be used to restrain the animal's forelegs and head if the animal is awake. Circumferential pressure is applied at the stifle to occlude and distend the vein. Alternatively, in the cat, the phlebotomist should grasp it by the scruff of the neck and place in lateral recumbency (Fig 106-1, *B*). The upper hind leg is abducted and flexed to expose the medial surface of the bottom leg. Applying pressure with the edge of the hand that abducts and extends the upper leg distends the vein. The phlebotomist grasps the leg with one hand at the level of the metatarsus. In loose-skinned animals it may be necessary to extend the leg and flex the tarsus to better tether and immobilize the vein. It should not be necessary for the phlebotomist to use his or her thumb to help immobilize the vein. The venipuncture is performed as described previously.

106.2.3 Jugular Venipuncture

Dogs and cats may be positioned in sternal or lateral recumbency for this procedure. In sternal positioning, one convenient technique includes backing the animal into a corner, between the legs of the holder (Fig 106-1, *C*). Alternatively, the dog or cat can be restrained on a table in sternal recumbency (Fig. 106-1, *D*). One hand grasps the legs at the carpel joint and stretches the legs over the edge of the table. In any position the head will need to be extended. Either the restrainer or the phlebotomist occludes the vein by applying occlusive pressure at the thoracic inlet. Care must be taken not to compress the trachea or impair breathing. Vein distention and immobilization can be maximized by pressing into the thoracic inlet in a caudal direction and by further extending the head. Extensive longitudinal traction, however, can collapse the vein. With optimal positioning, the vein is easy to palpate (or visualize) and does not roll much from side to side. In sternal positioning, the venipuncture is usually done in a cephalad direction; in lateral positioning the venipuncture is generally done is a caudal direction. The venipuncture is performed as described previously.

106.2.4 Arterial Puncture

The dorsal metatarsal (pedal) and femoral arteries are most commonly used for arterial blood sampling. The dorsal metatarsal is smaller but the interstitial connective tissues around it are tight (compared with the femoral artery), which facilitates vessel positioning and minimizes postpuncture hematoma formation. The radial, brachial, aural, and sublingual arteries have also been used.

Arterial puncture is usually done with the animal in lateral recumbency; however, it can be accomplished when the animal is standing if it resents the lateral recumbent positioning. The pulse is palpated with one or two fingers of one hand. The needle is inserted through the skin but not into the artery. Once the animal settles down from the skin puncture, the needle is aligned with the longitudinal axis of the artery (bevel up). The tip of the needle and the artery are simultaneously palpated with the one finger, and the needle inserted into the artery. Blood should spontaneously flow into the hub of the needle in an animal with normal blood pressure; however, gentle aspiration on the plunger may be required in animals with low blood pressure or when small needles are used. If the arterial puncture is unsuccessful, the needle can be inserted a bit further. As for venipuncture, when the needle is withdrawn, it should be done slowly and with gentle aspiration applied to the plunger in case the deep wall of the artery was inadvertently punctured during needle introduction. The needle is withdrawn to its subcutaneous position and the arterial puncture is reattempted.

Once the sample collection is complete, the clinicians should withdraw the needle and apply digital pressure over the puncture site for at least 1 minute; then the animal should be monitored for bleeding or hematoma formation for another 4 minutes. If blood gas measurements cannot be done immediately, the sample should be stored in ice water to minimize in vitro metabolic changes in the measured parameters.

107 CHAPTER • 107 Skin Scrapings and Skin Biopsies

Sonya V. Bettenay

Ralf S. Mueller

107.1 GETTING THE MOST FROM SKIN SCRAPINGS

Skin scrapings in veterinary dermatology are used to identify ectoparasites or to evaluate cells and organisms from the skin surface cytologically. The focus of this chapter is obtaining skin scrapings to diagnose cutaneous ectoparasites.

107.1.1 Superficial Skin Scrapings

107.1.1.1 Indication

Superficial skin scrapings are taken to detect mites living on the skin surface, such as *Cheyletiella* spp. or *Otodectes cynotis*, or to identify mites burrowing in the stratum corneum, such as *Sarcoptes scabiei* or *Notoedres cati*. All these mites can cause pruritus (which is seen least commonly in cheyletiellosis). Particularly in any severely pruritic small animal, where itching began suddenly or where other animals or humans in the household are affected (or both occur), scabies should be suspected. The preferred anatomic sites vary with the ectoparasite. Scabies most commonly affects the elbows, ear margins, hocks, and ventrum. *Notoedres cati* in cats most commonly affects the face. In both dog and cat, the dorsum is most commonly affected with *Cheyletiella* mites, which typically cause scaling. Superficial skin scrapings should thus be performed in any scaly or pruritic dog or cat.

107.1.1.2 Procedure

Mineral oil or pyrethrin eardrops should be put on the scalpel blade *and* affected skin. The authors select nonexcoriated sites, preferably in scaly or papular areas. It is important to scrape a large area. In hairy dogs with suspected scabies, it is recommended to clip the hair first. It is important not to remove the surface scale or crust that may be present, should such clipping be necessary. *Sarcoptes* mites are located superficially within the epidermis and may be dislodged with such cleansing. Clipping is contraindicated in animals with possible cheyletiellosis. Mineral oil is applied to the affected skin, gently scraped off the surface, and translocated onto a microscope glass slide. Scrapings are done in the direction of hair growth. The oil on the skin will facilitate gathering of debris and increase the chance of positive results. When evaluating a sample microscopically for ectoparasites, a cover slip is applied to distribute debris evenly. This minimizes the chance of missing mites covered by debris and enables a rapid yet thorough scanning at low magnification without the need for continuous adjustment of focus. The condenser of the microscope should be lowered for easy identification of parasites.

107.1.1.3 Interpretation

For scabies or cheyletiellosis, one mite or egg is diagnostic and adequate for initiating miticidal therapy. In canine scabies, 50% of affected dogs may be negative on several scrapings and trial therapy may be needed. Occasionally, a short-bodied *Demodex* mite may be found on superficial skin scrapings. These short-bodied

mites are supposed to live in the epidermis rather than the follicles, and their detection should trigger deep skin scrapings because they may occur in combination with a proliferation of follicular *Demodex* mites.

107.1.2 Deep Skin Scrapings

107.1.2.1 Indication

Deep skin scrapings are performed to detect *Demodex* mites. In the dog, *Demodex canis* lives in the hair follicle; a longer-bodied *Demodex* mite is suspected to live in the sebaceous glands. Papules, pustules, and crusts characterize canine demodicosis. Comedones, scales, and alopecia also may be seen. Demodicosis is on the list of differential diagnoses in almost any dog presented with skin disease. A deep skin scraping is one of the most common diagnostic procedures performed in veterinary dermatology. Demodicosis in the cat is less common, usually affects the head, and typically occurs secondary to systemic disease.

107.1.2.2 Procedure

A small area of affected skin (1 to 2 cm^2) is scraped in the direction of hair growth until capillary bleeding is observed. A blade covered with mineral oil should be used. Follicular papules or pustules are particularly suited for scraping. Because *Demodex* mites live in the hair follicles, it is useful to squeeze the skin prior to and during the scraping in an attempt to push the mites out from the depths of the follicles. A survey conducted by summer dermatology students revealed a 50% higher mite count when the skin was squeezed prior to scraping. Paws and faces are difficult to scrape, and skin biopsies may be needed in some of these dogs to confirm the diagnosis. Old English sheepdogs, Scottish terriers, and especially Shar Peis with demodicosis are anecdotally reported to be negative on scrapings and may have to be biopsied for diagnosis. Although not documented, it is thought that these breeds have more tortuous and deep hair follicles. Trichograms (hair plucks) provide an alternative test in these situations. Hairs are plucked with a hemostat and placed in mineral oil on a glass slide for examination. Approximately half of all dogs with demodicosis will show positive trichograms; a negative result does not rule out the disease, and the clinician must initiate further testing.

107.1.2.3 Interpretation

Although *Demodex canis* is a normal part of cutaneous fauna (and thus an occasional mite can be found on skin scrapings of normal dogs), one should never see more than one *Demodex* mite on a dog not affected by demodicosis. If only one mite is found, further scrapings or a biopsy are recommended. When evaluating deep skin scrapings, it is important to assess and to note in the record the site of scraping and the relative numbers of adults, larvae, nymphs, and eggs per low-power field (LPF). In subsequent visits, assessment of response to therapy relies on the comparison of such numbers. It is recommended that repeat scrapes at the same sites take place monthly when monitoring.

107.2 GETTING THE MOST FROM A SKIN BIOPSY

Skin biopsies are recommended as useful in textbooks and by dermatologists, yet the results are often “inconclusive.” The manner in which a biopsy sample is obtained can significantly influence the end results.

Lesions have “lives,” disease is a dynamic process, and the biopsy section is like a single frame taken from a roll of movie film. If clinicians set the “film” on a developing lesion, it would display many different appearances

throughout its evolution. Because a single biopsy reveals only one "snapshot," the clues as to the cause of the disease may simply not be present at that point in time. *Taking multiple samples* from well-chosen clinical sites exhibiting a variety of lesions will potentially help to avoid inconclusive results. In a pustular disease, erythematous macules develop into papules, then pustules, and finally crusts and erosions. Sampling every single one of these stages and then several of the most exciting lesions, the pustules, will give the pathologist the widest range of lesion development and hence the best chance to come up with some helpful comments.

107.2.1 Selection of the Site

Site selection requires careful examination of the entire animal for the most representative range of lesions. With the exception of a solitary nodule, multiple tissue samples are taken. Pustules or vesicles are fragile lesions, that have to be handled with great care to prevent rupture.

Depigmenting lesions should be biopsied *in an area of active depigmentation* (i.e., gray color) rather than the final stage (i.e., white). Once the pigment has been lost from the epidermis, active disease is probably absent; a biopsy of a depigmented area should be expected to reveal loss of melanocytes and pigment but not necessarily the reason for the depigmentation.

Alopecia should be biopsied *in the center of the most alopecic area*, as well as in junctional and normal areas. The clinician should remember that the glabrous (nonhaired) areas of the body normally contain fewer hair follicle units and smaller sebaceous glands; therefore if possible, these areas should be avoided if diseases with follicular pathology are on the list of differential diagnoses.

Ulcerated areas should also be avoided, unless they are sampled *in addition* to other areas or unless one is looking for a deep dermal, vascular, or pannicular pathologic disease.

Adjacent normal skin should be sampled where possible. In a bacterial folliculitis and furunculosis with a possible underlying allergy or endocrinopathy, the presence of a lymphocytic infiltrate consistent with hypersensitivity or follicular atrophy seen with hormonal diseases can be completely obliterated by the inflammation of a severe secondary pyoderma so that only a diagnosis of deep infection can be made. Clues in regard to the primary diagnosis may be present only in adjacent skin.

107.2.2 Preparation of the Site

Surgical preparation of the site should not be performed at all. Crusts should be left on the skin. If they are accidentally dislodged, they should still be placed in the formalin. It may be helpful to wrap them inside a piece of lens-cleaning tissue paper prior to placement in the formalin container to prevent accidental loss. Crusts may contain microorganisms, inflammatory or acantholytic cells (epidermal cells that have become detached from their neighbors and "rounded up"), which will help establish a diagnosis. Infection as a result of this lack of surgical preparation is almost never seen.

389
390

107.2.3 Helping the Laboratory Technician to Orient the Sample

After formalin fixation, it is impossible even for the most experienced technician to recognize most lesions because the sample appears as gray amorphous tissue. Drawing a line in direction of the hair growth on the skin prior to biopsy using a waterproof pen will help the technician to orient the tissue appropriately (Figure 107-1).

107.2.4 Surgical Technique

The overlying hair should be clipped and gently removed. If crusts are present, scissors may be less traumatic to use than electric clippers. No aseptic preparation is performed (except when excising solitary nodules). If manual restraint or sedation is planned, then the subcutaneous injection of 1 or 2 mL of Xylocaine without adrenaline will usually provide adequate local anesthesia. The needle entry point should be kept outside the proposed biopsy area to avoid disruption to the tissue in the biopsy. The clinician should draw a line in the direction from nose to tail to enable easy relocation of the site and to aid laboratory orientation. General anesthesia is indicated for facial or paw biopsies.

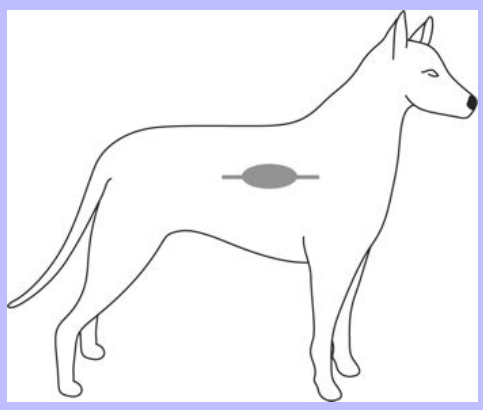
107.2.5 Wedge versus Punch Biopsy

The punch biopsy is quick, relatively atraumatic, and usually used with suspected infectious, inflammatory, and endocrine dermatoses. Disposable biopsy punches are readily available in 4, 6, and 8 mm diameter sizes (8 mm punches are routinely used). However, in small dogs and cats, 6 mm punches may be used (4 mm punches are reserved for biopsies of footpads, nasal planum, mucocutaneous junctions, or eyelids).

107.2.5.1 Punch Biopsy Sampling

The clinician should hold the punch at a vertical angle to the surface of the skin, firmly brace the surrounding skin, and rotate the punch in one direction with continuous pressure. When the skin no longer tries to “turn” with the rotation of the punch, a sufficient depth has been reached to free the dermis from its underlying attachment. The punch is then removed, and any blood is carefully blotted. The tissue is gently grasped at the base—which should be the panniculus—and the subcutaneous attachments severed. Fine instruments (e.g., iris scissors, forceps) should be used. Under no circumstances should the dermis or epidermis be grasped with forceps because this leads to “crush artifact.” Crushed tissue may be misinterpreted as scarring at best; at worst it renders the sample worthless. The specimen should be placed in formalin immediately.

Figure 107-1 Draw a line from nose to tail to help orient the laboratory technician. This technique has revolutionized the interpretation of follicular pathology. The clinician should not draw over fragile lesions like pustules, which may rupture with pressure.



Note: The punch technique is not suitable for biopsy of the skin when lesions of the panniculus or deep dermis are suspected.

The wedge biopsy is used as an excisional technique when removing solitary nodules and fragile lesions such as vesicles or as an incisional technique when complete excision is not possible or desirable. Biopsies of deeper tissues such as in suspected cases of panniculitis cannot be adequately taken using a punch and must be taken with a wedge technique. Finally, when an area of skin exhibits a range of changes radiating from the center to the edge of a lesion, a wedge may be preferable—a punch should not be used in the margin of a lesion (Figure 107-2). Ulcers are best sampled with a wedge biopsy extending from the center of the ulcer to adjacent normal tissue.

107.2.5.2 Excisional and Incisional Sampling

Tissue is surgically excised and closed routinely. The tissue is rolled on gauze to gently blot the blood from its surface. The clinician should use a minimum volume of formalin of (approximately) ten times the volume of the sample. Nodules should be sectioned into 1 cm thick pieces to allow adequate penetration of the formalin into the center of the lesion. They should not be sectioned through completely but should be left attached at the base (fat tissue side), so they are held together in the original piece. Cytology from the impression of the freshly excised surface is a valuable adjunctive test.

107.2.6 When Should a Skin Biopsy Be Performed?

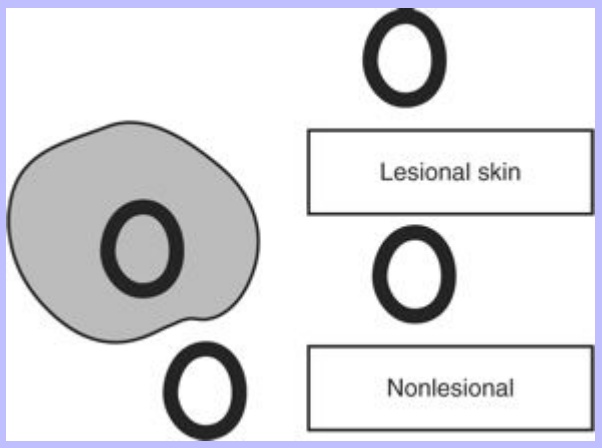
A skin biopsy should be performed for the following reasons:

- When lesions appear unusual to the clinician
- When lesions fail to respond to empiric therapy
- When nodular lesions are present
- When neoplasia is a differential diagnosis

107.2.7 Interpretation—Brief Comments

One of the major reasons to perform a skin biopsy is to rule out other diagnoses. “I think this is an allergy but…” In this situation the biopsy report of “chronic hyperplastic dermatitis with mononuclear perivascular infiltrate,” although not confirming allergy, has at least ruled out the common infectious agents and unusual dermatoses. A supportive pathologic diagnosis interpreted in conjunction with the clinical impressions may be just as useful as a confirmatory diagnosis.

Figure 107-2 Rule of thumb: The clinician should include 100% lesional or nonlesional skin when sampling with a punch biopsy.



The skin has only a limited number of ways to react to the infections, parasites, and allergens. Therefore many conditions share the same microscopic changes. Most dermatoses are diagnosed using a combination of the signalment, clinical presentation (distribution, type of lesions), history (in particular previous response to therapy), and *supportive* histopathologic changes.

107.2.8 Differential Diagnosis List and Submission of Biopsy Samples

A differential diagnosis list is important to any clinical case, but it is essential in dermatology. If the list of clinical differentials fails to correlate with the histopathology, a further review of the sections is undertaken. If the submission clearly states that a deep infectious process is suspected, then special stains may be done to rule out infectious organisms. If an immune-mediated dermatosis is the major differential diagnosis and convincing supportive evidence is not seen on the first section, then recuts may reveal this. When the pathologist is supplied with sufficient clinical information, he or she will likely initiate further examinations (rather than waiting until prompted by a phone call).

To obtain a better skin biopsy result, the clinician should:

1. Not prepare the skin surface.
2. Thoroughly look for a representative range of lesions.
3. Select multiple samples (six is a good rule of thumb) that represent the range of lesions from normal to most severely affected.
4. If possible, include a normal sample collected from haired skin of the dorsum or flank, not the ventrum.
5. Draw an orientation line in the direction from the nose to the tail tip.
6. Use 6 to 8 mm punches or an excisional biopsy except on noses and paws.

7. Handle the biopsy specimen carefully; treat it like tissue paper even when excising.

8. Give the pathologist a complete history, signalment, and physical-findings report, with a list of at least 4 differential diagnoses.

9. Choose a pathologist with an active interest in dermatopathology or a dermatologist with advanced dermatopathology training.

108 CHAPTER • 108 Inhalation Therapy for Airway Disease

Patricia M. Dowling

The latest approach to the management of inflammatory airway disease is inhalation therapy using metered dose inhalers (MDIs). With inhalation therapy, high drug concentrations are delivered directly to the lungs and systemic side effects are avoided or minimized. The onset of action for inhaled bronchodilators and anti-inflammatory drugs is substantially shorter than for oral or parenteral formulations. Nebulizers have been used for a long time in veterinary patients, but the overall efficiency of drug delivery is low, and the equipment is cumbersome and inconvenient for owners. Administration of medications with an MDI is now commonplace in the treatment of human asthma and appears beneficial in the management of veterinary patients as well.

Human MDIs are designed for actuation during a slow, deep inhalation for optimal lung delivery. This is obviously impossible to control in infants and animals. The addition of a spacer enables the MDI to be used in young children and small animals. Spacers decrease the amount of drug deposited in the oropharynx (up to 80% of the actuated dose with the MDI alone), thereby substantially reducing systemic drug absorption and other potential side effects, such as yeast overgrowth (thrush), coughing, and dysphonia.

The drugs currently available in MDI formulations include beta$_2$ agonists, glucocorticoids, ipratropium bromide, cromolyn sodium, and nedocromil. Each product delivers a set amount of drug per actuation (puff). In the United States, MDIs are labeled according to the amount of drug delivered at the mouthpiece, whereas in Canada and the European Union, they are labeled according to the amount of drug delivered from the valve. The U.S. system is used in this chapter.

For client convenience, MDIs are color coded to aid identification. (For a pictorial guide to MDIs, see the website www.peds.arizona.edu/allergyimmunology/southwest/devices/inhalers-asthma/mdikeyhtml.htm.) Even in human medicine, the relative potencies, risks of adverse effects, and optimal dose of the different inhaled asthma medications are still unclear. The results of clinical use in asthmatic cats and dogs with chronic bronchitis have been promising but anecdotal, and clinical trials are needed to determine the most efficacious therapies.

108.1 BETA$_2$ AGONISTS

108.1.1 Albuterol

Albuterol is available in the United States under the trade names Ventolin (GlaxoSmithKline, Research Triangle Park, North Carolina) and Proventil (Schering Corp., Kenilworth, New Jersey). It is marketed as salbutamol in Canada and the European Union. Albuterol is a short-acting beta$_2$ agonist that is the medication of choice for treating acute exacerbations of bronchoconstriction. It relaxes smooth muscle and increases airflow within 5 minutes of administration. Albuterol's effects last 3 to 6 hours. Although effective for symptomatic relief of bronchoconstriction, albuterol does not control inflammation. Monotherapy may exacerbate airway disease and increases morbidity and mortality in human asthmatics. Tolerance may develop with chronic therapy from down-regulation of beta$_2$ receptors. The Proventil MDI is dark blue, and the Proventil MDI is light orange. Each actuation delivers 90 µg of albuterol.

108.1.2 Salmeterol

Salmeterol (Serevent [GlaxoSmithKline]) is a long-acting $beta_2$ agonist. Its onset of action is slow (15 to 30 minutes), but its duration of action is long (over 12 hours). It is not recommended for use in acute bronchoconstriction, but it improves symptom control when used daily in addition to glucocorticoids, more than would simply increasing the glucocorticoid dose. The salmeterol MDI is green, and each actuation delivers 21 µg.

108.1.3 Glucocorticoids

Inhaled glucocorticoids are the most potent inhaled anti-inflammatory drugs currently available. In human beings, early intervention with inhaled glucocorticoids improves asthma control and normalizes lung function and may prevent irreversible airway damage. Improvement after inhaled administration of glucocorticoids can occur within 24 hours of beginning treatment, although maximum benefit may not be achieved for 1 to 2 weeks or longer after starting treatment. When glucocorticoids are discontinued, asthma stability may persist for several days or longer. The potential risk of adverse side effects of glucocorticoids is well balanced by their efficacy in chronic management of inflammation. Oral candidiasis (thrush), dysphonia, and reflex cough and bronchospasm are the most common adverse effects in humans; all of these effects are reduced by the use of a spacer. The risks of systemic side effects, such as suppression of the hypothalamic-pituitary axis, are less than with oral prednisone or prednisolone therapy. Inhaled glucocorticoid formulations include fluticasone (Flovent [GlaxoSmithKline]); beclomethasone (Beclovent [GlaxoSmithKline] and Vanceril [Schering Corp.]); budesonide (Pulmicort [AstraZeneca, Wilmington, Delaware]); and Proventil [Schering Corp.]); and triamcinolone (Azmacort [Aventis Pharmaceuticals, Bridgewater, New Jersey]). Currently, fluticasone is considered the most potent glucocorticoid formulation with the longest duration of action. Because of its large molecular size, systemic absorption is minimal. Fluticasone MDIs are orange. Fluticasone is available in three sizes; each actuation delivers 44, 110, or 220 µg.

108.2 ANTICHOLINERGIC DRUGS

Ipratropium bromide (Atrovent [Boehringer Ingelheim Pharmaceuticals, Ridgefield, Connecticut]) is a quaternary derivative of atropine that lacks its adverse side effects. In asthmatic humans, ipratropium bromide is used as an additional reliever medication to reverse bronchoconstriction when inhaled short-acting $beta_2$ agonists do not give enough relief. Its anticholinergic action also decreases mucous secretions. In an experimental model of feline asthma, long-term antigen sensitization caused an augmented muscarinic receptor response to acetylcholine. Modulation of muscarinic receptors with anticholinergic drugs may be useful for treatment of asthmatic cats. Currently, there are no published reports of the use of ipratropium in the cat; however the drug has shown efficacy in horses. It is not well absorbed after inhalation and therefore does not cause systemic cholinergic effects. The Atrovent MDI is encased in a clear holder with a white mouthpiece and green cap; it delivers 18 µg per actuation.

108.3 MAST CELL STABILIZERS

Cromolyn sodium (Intal [Aventis Pharmaceuticals]) and nedocromil sodium (Tilade [Aventis Pharmaceuticals]) are chloride channel blockers that modulate mast cell mediator release and eosinophil recruitment. Cromolyn and nedocromil both have strong human safety profiles, but nedocromil has a broader spectrum of efficacy. In human beings, the clinical response to either of these drugs is less predictable than the response to glucocorticoids, therefore cromolyn and nedocromil are usually used as adjunctive therapy to treatment with bronchodilators and

glucocorticoids. Currently, there are no published reports of the use of cromolyn or nedocromil in asthmatic cats or dogs with bronchitis; however, pretreatment with nedocromil aerosols attenuated viral-induced airway inflammation in beagle puppies. Because of the sensitivity of the cat to serotonin released from degranulating mast cells, these drugs should be further investigated in asthmatic cats. The cromolyn MDI is white and delivers 800 μg per actuation. The nedocromil MDI is also white and delivers 1.75 mg per actuation.

108.4 SPACERS

Human MDIs (OptiChamber [Respironics HealthScan Asthma and Allergy Products, Cedar Grove, New Jersey] and Aerochamber [Forest Pharmaceuticals]) may be modified for use in dogs and cats. Also, recently a small animal–specific spacer has become available (AeroKat [Trudell Medical International, London, Ontario, Canada]). The OptiChamber must be modified with a suitable face mask, such as the type used to "mask" cats for anesthesia. The Aerochamber is available with a variety of face masks intended for infants, children, and adults that will conform to a variety of veterinary patients. The Aerochamber is color coded according to the type of face mask (orange for infants, yellow for children, blue for adults). Both the OptiChamber and the Aerochamber are equipped with one-way valve leaflets that allow the owner to actuate the inhaler away from the cat or dog and then apply the spacer. The AeroKat spacer is valveless, therefore actuation must occur with the mask applied. The device fits cats and most small dogs. Human spacers can be purchased at most pharmacies.

108.5 TECHNIQUE FOR USING MDIS AND SPACERS IN DOGS AND CATS

The steps for using the MDI are as follows:

1. Prime the MDI prior to first use or if it has not been used recently, because the initial actuation contains higher drug concentrations than subsequent actuations.

2. Immediately before each use, shake the inhaler.

3. Remove the cap from the mouthpiece and insert the mouthpiece into the spacer.

4. Keep track of the number of actuations administered. Some manufacturers include a "check off" list in the patient directions. For daily maintenance medications, divide the number of actuations per canister (printed on the canister) by the number of puffs to be taken each day to calculate how many days the device will last and when the MDI should be replaced. The widely used method of immersing the inhaler in water to see if it floats is inaccurate. Discard the canister after the labeled number of actuations.

5. If using the AeroKat spacer, position the inhaler over the animal's face prior to actuation. If using a valved MDI, the device can be actuated before placing the mask on the animal's face (Figure 108-1).

6. Press down firmly and fully on the top of the metal canister with the index finger. Hold the mask in place over the animal's face for 5 to 10 seconds. Wait 30 to 60 seconds and then shake the inhaler again. Repeat these steps for each inhalation as prescribed by the veterinarian.

Figure 108-1 Albuterol MDI can be actuated into the Aerochamber prior to placing the mask over a cat's nose and mouth.

NOTE: When a beta$_2$ agonist is used in conjunction with a glucocorticoid or anticholinergic drug, it should be administered 5 minutes before the glucocorticoid or anticholinergic drug. The resulting bronchodilation results in increased deposition of the glucocorticoid or anticholinergic drug in the smaller airways.

7. Replace the mouthpiece cap after each use and make sure to clean the inhaler thoroughly and frequently. Remove the metal canister and clean the plastic case and cap by rinsing thoroughly in warm, running water at least once a day. (Do not immerse metal canisters containing cromolyn or nedocromil.) After thoroughly drying the plastic case and cap, gently replace the canister in the case with a twisting motion and replace the cap.

8. The manufacturer's recommendations for care of the spacer should be followed. Typically, the spacer only needs to be soaked weekly in a diluted dishwashing solution and air dried. It is not necessary to rinse the device, because the soap helps disperse aerosol particles that come in contact with the spacer's surface.

108.6 SUGGESTED TREATMENT REGIMENS

108.6.1 Dyspnea

For emergency management of dyspnea, two to four puffs of albuterol should be given every 20 minutes until clinical signs resolve. Additional therapy may include oxygen administration and an intravenous dose of a rapid-acting glucocorticoid.

108.6.2 Feline Asthma and Chronic Canine Bronchitis

The current recommended chronic therapy for feline asthma and chronic canine bronchitis is salmeterol, the long-acting bronchodilator, at a dosage of one puff (21 µg) twice a day and 220 µg of fluticasone twice a day. For initial therapy of moderately affected animals, a 5-day course of oral prednisone (1 mg/kg) may be helpful.

Severely affected animals may require 1 mg/kg of prednisone every other day. Adjunctive therapy with ipratropium or nedocromil or cromolyn may be useful in some patients. Therapy must be individualized for the patient.

109 CHAPTER • 109 Acid-Base, Oximetry, and Blood Gas Emergencies

Marie E. Kerl

Acid-base and oxygenation disorders occur commonly in emergency and critical care medicine as a response to respiratory or metabolic abnormality from trauma, intoxication, or naturally occurring disease. Technologic advances in point of care testing have made laboratory assessment of these disorders accurate, practical, and affordable in the veterinary emergency setting. A working knowledge of acid-base and respiratory physiology and pathophysiology, as well as appropriate therapies, is imperative for achieving successful patient outcomes.

Testing of blood gas samples may be performed with arterial or venous blood. Arterial blood must be used to assess oxygenation. Acid-base parameters other than partial pressure of oxygen (PO_2) may be evaluated using either arterial or mixed venous samples. In most emergent patients, venous blood is easier to obtain. Samples should be drawn into syringes that are coated with 1:1000 heparin to prevent clot formation. Immediately after sample acquisition, the syringe should be made airtight to prevent contamination with room air, which could alter gas measurements. The sample should be analyzed within 15 minutes or placed on ice.

109.1 BASIC ACID-BASE PHYSIOLOGY

The following is a brief description of traditional acid-base physiology; in-depth discussion is beyond the scope of this publication. For further information, the reader is referred to the Suggested Readings.

An *acid* is a hydrogen ion (H^+) (i.e., proton) donor, and a *base* is a proton acceptor. Acids typically are represented by the notation HA, which signifies a hydrogen ion and any negatively charged particle. When placed in solution, HA dissociates into H^+ (acid) and A^- (base). Hydrogen ions are nonvolatile or fixed acids produced by normal metabolism of proteins and phospholipids and are renally excreted. A base combines with an acid to lower the amount of acid in solution, or to buffer the solution.

Carbon dioxide (CO_2) is a volatile acid, or fat-soluble gas, that can combine with water in the presence of carbonic anhydrase to form carbonic acid (H_2CO_3). Carbon dioxide is formed during normal carbohydrate and fat metabolism and is excreted via the respiratory system. These two sources of acid (H^+ and CO_2) are interrelated, as is shown in the carbonic acid equation:

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow H_2O + CO_2$$

This equation can go either direction, depending on the availability of substrate on either side of the formula. The enzyme carbonic anhydrase catalyzes this reaction, and any cell containing carbonic anhydrase is capable of this reaction.

By definition, *pH* is the negative log of the hydrogen ion concentration. A gain of H^+, or acid gain, results in a decrease in blood pH (acidemia), whereas a loss of H^+ results in an increased pH (alkalemia). Acid can be gained systemically from abnormal renal elimination of a naturally occurring compound or from ingestion of an exogenous acid source. Changes in CO_2 influence the H^+ concentration, as evidenced by the carbonic acid equation. As CO_2 is eliminated by increasing alveolar ventilation, carbonic acid dissociates to form more CO_2,

and H+and bicarbonate (HCO_3-) combine in turn to form carbonic acid. This effectively lowers the H^+ concentration and increases pH. Conversely, as CO_2 increases from ventilation impairment, pH decreases.

Buffers act to bind H^+ to prevent large fluctuations in pH. A variety of buffer systems exist in the body, including nonbicarbonate buffers (proteins and phosphates), which are primarily intracellular, and HCO_3-, which is the primary extracellular buffer. Bicarbonate is an effective buffer system because it exists in relatively large concentrations compared with other buffers, and it participates in the carbonic acid formula to produce CO_2 gas, which can be eliminated through ventilation. The HCO_3-buffer system, therefore, is considered an *open system,* which can continue to buffer as long as the respiratory system is functional. When $HCO_3-$is lost excessively from the urinary or gastrointestinal system, CO_2 and H_2O combine to form carbonic acid, which dissociates to increase H^+ and cause acidemia.

109.2 ACID-BASE DISORDERS

According to the Henderson-Hasselbalch equation, which is

$$pH = 6.1 + \log \{HCO_3^-/0.03PCO_2\}$$

pH can be characterized by changes in $HCO_3-$and partial pressure of carbon dioxide (PCO_2). Because a predictable change in HCO_3- occurs with gain or loss of H^+ ions, HCO_3-can be used to correctly identify acid base abnormalities arising from metabolic disorders. Acidemia or alkalemia resulting from a respiratory disorder should show an increase or a decrease in PCO_2. Respiratory acidosis results in an increase in PCO_2, and respiratory alkalosis causes a decrease in PCO_2. In metabolic acidosis, an H^+ increase shifts the carbonic acid equation to; and in metabolic alkalosis, an H^+ cause a decrease in HCO_3-decrease has the opposite effect on HCO_3-. Blood gas analyzers typically measure pH and PCO_2 and calculate HCO_3-.

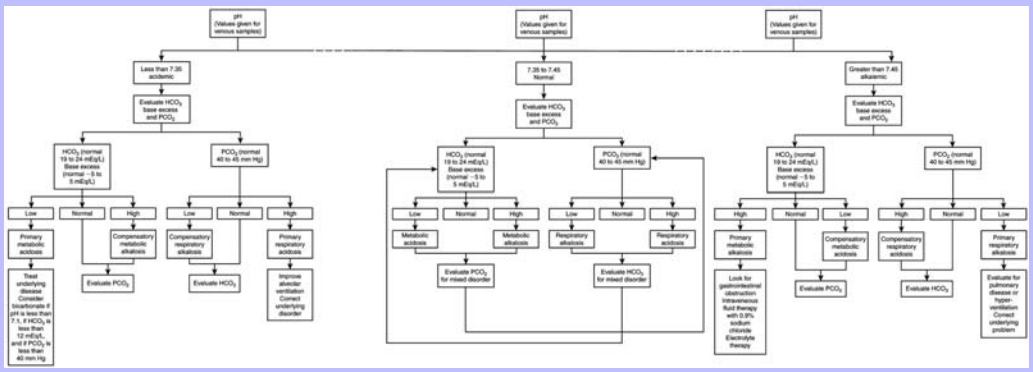
This equation can also be used to predict how compensatory mechanisms engage to reduce the degree of change in the pH. When metabolic acidosis develops, the respiratory system is stimulated to increase the respiratory rate to eliminate CO_2 from the lungs and create respiratory alkalosis. Likewise, with a primary respiratory disorder, the opposite metabolic disorder is generated. The respiratory system provides rapid compensation, changing within minutes of onset of a metabolic disorder. Metabolic compensation occurs more slowly, becoming maximally effective in days. With either system, compensatory mechanisms should slow down as the pH improves, and compensation should never completely normalize the pH.

Base excess, which is expressed in milliequivalents per liter (mEq/L), is a value in which the amount of base above or below the normal buffer base is calculated, taking into account the expected change in HCO_3-secondary to acute changes in PCO_2. The general rule of thumb is that the HCO_3-concentration rises about 1 to 2 mEq/L for each acute 10 mm Hg increase in $PaCO_2$ above 40 to a maximum increase of 4 mEq/L, and that the HCO_3-concentration falls 1 to 2 mEq for each acute 10 mm Hg decrease in $PaCO_2$ below 40, to a maximum decrease of 6 mEq/L. Some authors refer to a negative base excess as a base deficit.

396

400

Figure 109-1 Algorithm for interpretation of blood gas values.



By convention, a simple acid-base disorder is limited to the primary disorder and the appropriate compensatory response. A mixed disorder is one in which at least two separate abnormalities occur simultaneously. Normal values at sea level for venous blood gas interpretation are pH, 7.35 to 7.45; PCO_2, 40 to 45 mm Hg; and HCO_3−, 19 to 24 mEq/L. Base excess normally should be −5 to 5 mEq/L.

Respiratory acidosis results from an increase of CO_2 in the blood (hypercapnia). Hypercapnia can be caused by anything that prevents normal gas exchange in the lungs, including impaired pulmonary circulation, reduced respiratory rate, circulation of blood to nonventilated portions of the lung, or impairment of gas diffusion. Diffusion impairment is the least likely cause of hypercapnia, because CO_2 is approximately 20 times more diffusible than oxygen. Disorders in which respiratory acidosis occurs include circulatory failure from cardiopulmonary arrest, central nervous system disease, respiratory muscle failure, physical impairment of ventilation (e.g., pleural space disease, pain, thoracic wall disease, external constriction), or primary pulmonary disease (e.g., alveolar flooding, interstitial disease, pulmonary thromboembolism). Iatrogenic respiratory acidosis results from inadequate ventilatory monitoring and assistance under general anesthesia. Clinical signs of hypercapnia are consistent with the underlying disorder. Situations that might cause respiratory acidosis must be anticipated and diagnosed with appropriate monitoring.

Treatment for respiratory acidosis involves correcting the underlying disorder by increasing alveolar ventilation. Chronic respiratory acidosis should be corrected slowly. Sodium bicarbonate should not be administered, because this drug exacerbates hypercapnia. Increasing the inspired oxygen concentration may be lifesaving; however, with severe hypercapnia, stimulation for respiration becomes driven by hypoxia. Resolution of the hypoxia may result in decreased voluntary respiration. The hypoxic drive for respiration remains adequate below a dissolved oxygen content of arterial blood (PaO_2) of 60 mm Hg.

Respiratory alkalosis results from an increase in the ventilatory rate, resulting in elimination of more CO_2 than is produced by normal metabolic function. Hypocapnia develops, and alkalemia ensues. Causes of respiratory alkalosis include hypoxemia caused by pulmonary or circulatory abnormalities, primary pulmonary diseases that stimulate ventilation independent of hypercarbia, central nervous system disorders, and iatrogenic tachypnea with assisted ventilation. Most disorders of respiratory alkalosis result in hyperventilation. Chronic respiratory alkalosis is usually well compensated

Treatment for respiratory alkalosis should be directed at normalizing the underlying disorder. Clinical signs are minimal, and no other therapy should be needed if the first treatment goal can be achieved.

Metabolic acidosis results most commonly from a gain of H^+ through ingestion of an acid into the body, increased production of an endogenous acid, or failure of elimination of an acid load at the renal tubular cells. Metabolic acidosis can also be caused by a loss of HCO_3^- buffering ability. Differentiating these two types of metabolic acidosis can assist diagnosis of the underlying cause.

When acid accumulates in the circulation, H^+ combines with HCO_3^- to buffer the acid load. When the acid dissociates, the anion remains in solution. Because electroneutrality must be maintained, another anion in circulation must decrease correspondingly. Anion gap (AG) is a formula that was created to classify disorders that cause metabolic acidosis. Anion gap, which is calculated from four common cations and anions from a serum chemistry profile, states:

$$AG = [Na^+ + K^+] - [Cl^- + HCO_3^-]$$

In normal animals, AG is 16 ± 4. Elevated anion gap metabolic acidosis is caused by a gain of acid, whereas normal anion gap metabolic acidosis (hyperchloremic metabolic acidosis) is caused by loss of bicarbonate buffers or a failure to excrete H^+ ions, with a corresponding increase in chloride to maintain electroneutrality. Causes of anion gap metabolic acidosis include ethylene glycol intoxication, uremia, tissue hypoxia, diabetic ketoacidosis, salicylate intoxication, and other unusual intoxications (e.g., drugs, alcohol). Hyperchloremic metabolic acidosis is less common and is caused by renal tubular acidosis (failure of the renal bicarbonate buffer system) or by severe diarrhea and loss of intestinal bicarbonate, or it occurs iatrogenically after administration of an alkali-free chloride containing solution for intravenous volume replacement.

Clinical signs associated with metabolic acidosis include lethargy, decreased cardiac output, decreased blood pressure, and decreased hepatic and renal blood flow. These signs may be referable to the acidemia or to the underlying cause of the acid-base disorder. Compensatory mechanisms would cause an increase in the respiratory rate to eliminate CO_2 generated by carbonic acid formation.

Treatment should be aimed at correcting the underlying disorder by improving tissue perfusion with intravenous fluid therapy; eliminating ingested toxin; and correcting metabolic, renal, or gastrointestinal disease. With severe metabolic acidosis (pH of 7.1 and HCO_3^- <12 mEq/L), sodium bicarbonate may be administered judiciously according to the following formula:

$$\text{Bicarbonate dose} = (0.3)(\text{Body weight [kg]})(\text{Base deficit})$$

Half of this dose should be administered slowly intravenously over 6 hours, and the acid-base status should be re-evaluated prior to continuation of therapy. Chronic metabolic acidosis should be corrected slowly to avoid undesired side effects, including hyperosmolality, hypernatremia, hypokalemia, hypocalcemic tetany from a shift of calcium from the ionized to the protein-bound form, and iatrogenic metabolic alkalosis.

Metabolic alkalosis is generated by loss of chloride in excess of extracellular fluid volume, which occurs as a result of upper gastrointestinal (GI) fluid loss or sequestration or of administration of a thiazide diuretic, causing chloride wasting. Rarely, metabolic alkalosis may be caused by overzealous administration of sodium bicarbonate or another organic anion or by hyperaldosteronism, causing sodium retention in excess of chloride. The most commonly associated clinical disease in small animal practice is gastric obstruction, with loss of

chloride-containing gastric fluid. Renal compensation prevents an acid-base disorder until hypovolemia causes aldosterone release. Aldosterone increases renal uptake of sodium. During normal renal function, sodium is reabsorbed with bicarbonate or chloride or is exchanged for potassium. Gastric fluid has high chloride and potassium concentrations, and when these are depleted, sodium can be reabsorbed only with bicarbonate.

Clinical signs associated with metabolic alkalosis depend on the predisposing disorder. Muscle twitching and seizures have been reported. Signs associated with concurrent potassium depletion may include weakness, cardiac arrhythmias, renal dysfunction, and gastrointestinal motility disturbances.

Treatment of metabolic alkalosis is directed at resolving the predisposing disorder. Intravenous 0.9% sodium chloride (0.9% NaCl) should be initiated to restore intravenous volume. Fluids should not contain buffer. If vomiting is the underlying cause, use of drug therapy to minimize gastric hydrochloric acid (HCl) excretion may be warranted. Intravenous potassium therapy should be used to treat the hypokalemia frequently encountered with metabolic alkalosis.

401

109.3 OXYGENATION

Hypoxemia may be seen as a result of a low concentration of inspired oxygen, hypoventilation, diffusion impairment, dead space ventilation, or pulmonary shunting. Two methods are available to assess oxygenation in the emergency setting: measurement of PaO_2 and measurement of peripheral oxygen saturation (SpO_2) by pulse oximetry. A pulse oximeter is a noninvasive device that calculates hemoglobin oxygen saturation by measuring differences in absorption of two wavelengths of light (red and infrared) by oxygenated and deoxygenated hemoglobin. The measured light absorption values are applied to a preset nomogram, and a value for SpO_2 is determined. If tissue perfusion is adequate, SpO_2 approximates arterial hemoglobin saturation (SaO_2).

The advantage of oximetry as a monitoring tool is that it provides continuous, noninvasive determination of hemoglobin oxygen saturation. Technical aspects that help ensure accuracy include placing the probe on nonpigmented, moist skin with adequate perfusion (usually the tongue, the buccal, vaginal, or preputial mucosa, or the ear pinna), avoiding probe movement and light pollution, and monitoring the pulse rate to ensure accurate pulse signal transmittance. In poorly perfused tissues, the SpO_2 may be falsely low compared with the SaO_2. If inaccuracy of oximetry is suspected, the arterial blood gas PaO_2 may be obtained to evaluate oxygenation. In patients with alterations of hemoglobin concentration causing increased carboxyhemoglobin or methemoglobin, oximetry may be normal despite severe patient abnormality. Oximetry does not evaluate the PCO_2 and cannot be used to determine appropriate ventilation.

The hemoglobin saturation of oxygen and PaO_2 both contribute to arterial oxygen content (CaO_2) according to the following formula:

$$CaO_2\ (\text{mL } O_2/\text{dL}) = \{SaO_2\ (\%) \times \text{Hemoglobin (g/dL)} \times 1.34\ (\text{mL } O_2/\text{g})\} + \{PaO_2\ (\text{mm Hg}) \times 0.003\ (\text{mL } O_2/\text{dL/mm Hg})\}$$

Increasing the PaO_2 by increasing the inspired oxygen concentration has a minimal effect, whereas increasing the SaO_2 has a greater potential effect. In an anemic patient, increasing the arterial oxygen content would best be accomplished by increasing hemoglobin.

By the oxyhemoglobin dissociation curve, an SaO_2 of 90% corresponds to a PaO_2 of 60 mm Hg. This value is clinically important in that precipitous declines occur below these values, and small decreases in either parameter

may have tremendous clinical consequences. The goal of treatment for hypoxemia is to maintain the SpO_2 above 90% through supplemental oxygen therapy. Methods of increasing the inspired oxygen content include use of an oxygen chamber, tent or mask administration, placement of an indwelling nasal oxygen catheter, or mechanical ventilation with an increased fraction of inspired oxygen.

110 CHAPTER • 110 Acute Abdomen

Dez Hughes

The term *acute abdomen* is often used to refer to animals that have a rapid onset of abdominal pain; however, not all life-threatening intra-abdominal problems are painful. Furthermore, depressed mentation, including chemical sedation, may reduce response to painful stimuli. A more encompassing definition for the acute abdomen is any situation involving an acute onset of clinical signs referable to intra-abdominal pathology. Because this is a potentially life-threatening clinical syndrome rather than a definitive diagnosis, the underlying cause must be rapidly identified. Many causes (Box 110-1) require emergency surgery, and these animals must be promptly iden-tified to allow definitive treatment to optimize the chances of survival. Because acute abdomen has so many potential causes, it is important to prioritize the list of diagnostic differentials based on pertinent findings from the history, physical examination, and initial diagnostic testing. Diagnosis and successful treatment of the dog or cat with an acute abdomen is one of the greatest challenges in emergency and critical care.

110.1 SIGNALMENT AND HISTORY

A full history should be obtained for all animals suspected of having an acute abdomen; however, with critically ill patients, this may have to be delayed to allow initial evaluation and stabilization. The history may occasionally be extremely suggestive of the underlying cause; for example, bitches with dystocia, witnessed ingestion of a foreign body, or protracted dysuria and pollakiuria with urethral obstruction. More commonly, however, the owner reports vague, nonspecific signs such depression, anorexia, lethargy, vomiting, and diarrhea. The only premonitory sign in some severe cases is acute collapse. Most dogs with a complete intestinal obstruction or pancreatitis exhibit profuse and frequent vomiting; however, diarrhea may or may not be present, and the severity of clinical signs can vary. Any sick, intact female should be evaluated for pyometra, regardless of whether the classic signs of anorexia, lethargy, vomiting, polyuria, polydipsia, and vaginal discharge are present. Any older intact male with hypoperfusion or caudal abdominal pain could have prostate gland disease. Dogs with prostatic disease may also exhibit hindlimb stiffness or an abnormal hindlimb gait, in addition to hematuria, pollakiuria, or dyschezia. A history of trauma raises the possibility of hemoabdomen or rupture of the urinary or biliary tracts. Any prior medical therapy by a veterinarian or by the owner should also be determined. For example, an old dog receiving nonsteroidal anti-inflammatory agents may be at risk of developing gastric ulceration, hemorrhage, or perforation.

Colitis

110.1.1.2 Urogenital Tract

Pyometra/uterine rupture

Prostatitis/prostatic abscess

Dystocia

Cystic calculi

Urethral obstruction or rupture

Uroabdomen

Pyelonephritis

Renal abscess

Vaginal rupture

Testicular torsion

110.1.1.3 Hepatobiliary System

Necrotizing cholecystitis

Liver lobe torsion

Hepatic abscess

Bile peritonitis

Acute hepatitis/cholangiohepatitis

Biliary obstruction

110.1.1.4 Other Causes

Hemoabdomen (usually parenchymatous organ rupture)

Retroperitoneal hemorrhage

Neoplasia

Penetrating wounds/crush injury

Evisceration

Surgical contamination

Strangulated hernia

Splenic torsion

Splenic abscess

Pansteatitis

110.1.1.5 Conditions That May Mimic Acute Abdomen

Spinal disease with pain

Lead poisoning

Hypoadrenocorticism

Some extra-abdominal conditions may mimic signs of an acute abdomen, the most common being thoracolumbar intervertebral disk disease. Owners occasionally incorrectly assume that their animal has abdominal pain because the pet vocalizes when picked up beneath the abdomen. The clinician must always maintain a high index of suspicion that an acute onset of pain, especially in a chondrodystrophoid breed, may be spinal in origin. Even on physical examination, it can sometimes be difficult to differentiate between spinal and abdominal pain. The veterinarian must take care, especially with smaller animals, to avoid placing the thumbs along the spine when palpating the abdomen.

110.2 MAJOR BODY SYSTEM EVALUATION

Major body system evaluation initially is performed to identify and prioritize life-threatening problems of the cardiovascular, respiratory, and neurologic systems. Life-threatening problems should be addressed without delay while performing the initial examination. Hypovolemia may be mild, moderate, or severe. Animals with an inflammatory process and adequate circulating blood volume may demonstrate the classic signs of hyperdynamic systemic inflammatory response syndrome (SIRS), such as injected mucous membranes, strong pulses of short duration, fast capillary refill time (CRT), moderate tachycardia, and pyrexia. With severe hypovolemia, tachycardia is often severe (170 to 200 beats per minute in a dog), femoral pulses are weak, and the CRT is prolonged. Despite severe hypovolemia, dogs with peritonitis can have injected rather than pale mucous membranes, and this discrepancy in clinical perfusion parameters should prompt a search for an underlying cause of SIRS. Although a dog with an acute abdomen may exhibit tachypnea due to pain, animals that have been vomiting should always be evaluated for aspiration pneumonia.

When tympanic gaseous abdominal distension is present in a large breed dog, gastric dilatation and volvulus is the most likely diagnosis. Although pneumoperitoneum can occasionally cause abdominal distension, it is usually not tympanic. Dogs with a large volume of abdominal effusion may have an abdominal fluid "wave." However, smaller amounts of effusion may not be palpable, especially if the dog is recumbent. A fluid wave may also be detectable due to intra-abdominal fat, hepatomegaly, or fluid contained within a tubular viscus. Abdominal distension is not always noticeable in an animal with intra-abdominal fluid. For example, a dog with acute hemoabdomen after being hit by a car would likely be in severe hypovolemic shock before the slightest hint of abdominal distension would be noticed.

Bacterial peritonitis and pancreatitis almost always cause abdominal pain or discomfort in dogs, even in animals with severe hypoperfusion. When an animal in hypovolemic shock is rousable only by abdominal palpation, a diagnosis of peritonitis should be aggressively pursued.

Pyometra is not usually painful, and abdominal pain in conjunction with pyometra raises the likelihood of septic peritonitis. Pain appears to be an inconsistent finding with uroabdomen (acute uroabdomen tends to be more painful than chronic uroabdomen). Significant pain associated with a uroabdomen should prompt evaluation for septic peritonitis.

Occasionally dogs with cranial abdominal pain adopt the "prayer position"; however, this is the exception, not the rule. As a generalization, focal pain other than in the right cranial quadrant, or focal pain associated with the intestines, is often associated with a surgical lesion. The majority of animals with bile peritonitis are icteric unless the biliary tract rupture is recent.

A rectal examination should be performed in all animals with acute abdomen, but especially in older intact male dogs. When prostatomegaly has caused the prostate gland to descend over the pelvic brim, simultaneous abdominal and rectal palpation may be necessary to achieve a complete prostatic examination.

402

403

110.3 STABILIZATION

In a hemodynamically unstable patient, aggressive intravenous fluid therapy is often necessary. In many animals with peritonitis, especially septic peritonitis, hypoperfusion is due both to maldistribution (abnormally dilated arterioles) and to hypovolemia. Crystalloid infusion rates of 60 to 90 mL/kg/hour in the dog and 40 to 60 mL/kg/hour in the cat are often necessary. It is best to place two intravenous catheters to achieve this rate and to provide an alternative in case one catheter becomes dislodged or blood products are required. Fluid resuscitation with blood products or synthetic colloids (e.g., hydroxyethyl starch or dextran 70) may be more effective in animals with systemic and intra-abdominal vasculitis. Major body systems and perfusion parameters (mucous membrane color, CRT, pulse rate and quality, heart rate, and urine output) should be continually assessed during fluid resuscitation to ensure an appropriate response. Failure to respond adequately to intravenous fluids usually indicates the presence of sepsis or ongoing hemorrhage. In severely affected animals with sepsis, continuous-rate infusions of catecholamines may be required to maintain adequate blood pressure.

Broad-spectrum, bactericidal, intravenous antibiotics should be started as soon as a diagnosis suggests the possibility of leakage or translocation of gastrointestinal bacteria. Antibiotics with activity against gram-positive and gram-negative aerobes and anaerobes should be used. In septic peritonitis, intravenous administration has shown a trend toward improved survival compared with intramuscular or intraperitoneal routes. The most frequent isolates from cases of bacterial peritonitis are *Escherichia coli,* clostridia, and enterococci. Appropriate antibiotic combinations for these bacteria include ampicillin combined with cefoxitin, enrofloxacin, or amikacin; however,

the use of amikacin often is contraindicated in animals with hypovolemia, dehydration, and pyrexia. Metronidazole may be added for additional anaerobic coverage.

Corticosteroids have long been advocated in the treatment of sepsis, but because of equivocal clinical evidence, their use appears to be declining. They are potent inhibitors of transcription of interleukin-1 and interleukin-6 and tumor necrosis factor alpha; however, much of the evidence demonstrating a benefit from corticosteroids involves administration prior to the infectious insult.

Interestingly, improved survival has been shown in experimental studies of septic peritonitis when dogs are treated with heparin, ostensibly due to improved bacterial clearance from the abdomen or to reduction of disseminated intravascular coagulation.

Novel therapies include prophylactic use of recombinant human granulocyte colony-stimulating factor, which has a protective effect in bacterial peritonitis and results in better survival than antibiotics alone. Encapsulation of antibiotics in liposomes may prolong the drug's half-life and improve reticuloendothelial targeting, and better survival has been demonstrated in fecal peritonitis models compared with conventional methods of antibiotic delivery.

Most animals with hemoabdomen have suffered abdominal trauma or rupture of an intra-abdominal mass. To minimize ongoing hemorrhage, an abdominal pressure bandage should be applied prior to aggressive fluid resuscitation. As the majority of intra-abdominal hemorrhage is due to venous rather than arterial bleeding, the abdominal wrap need provide pressure only in excess of venous blood pressure (0 to 5 mm Hg), which can be achieved by a firm but not excessively tight bandage. In general, padding beneath the wrap should be avoided because it allows the bandage to move caudally rather than provide compression in the cranial abdomen, where it is most effective.

110.4 DIAGNOSTIC EVALUATION

Blood should be obtained for analysis when the intravenous catheter is placed. As a minimum, packed cell volume (PCV), refractometric total solids, glucose, and serum electrolytes should be evaluated. Parameters must be re-evaluated frequently in animals receiving aggressive intravenous fluid support. A low total solids concentration with a normal PCV should prompt a search for hemorrhage or severe vasculitis. Animals with septic peritonitis often have panhypoproteinemia, presumably due to exudation of protein into the peritoneal cavity. In the absence of hemorrhage or liver or kidney disease, an abnormally low serum total solids concentration in a dehydrated and hypoperfused animal should raise the possibility of severe vasculitis, most commonly bacterial peritonitis. Hypoglycemia should prompt a search for sepsis and pancreatic or hepatic neoplasia.

If in-house hematology and blood chemistry analysis are available, a complete blood count, serum biochemical analysis, urine analysis, and coagulation screen should also be obtained prior to fluid resuscitation. Depending on the severity and chronicity of the underlying condition, the neutrophil count may be increased, normal, or low, and a left shift may or may not be present. Most puppies with parvoviral enteritis have severe neutropenia. Serum chemistry changes can provide helpful information. For example, bile peritonitis often results in increased serum alkaline phosphatase, alanine transaminase, and total bilirubin concentrations. Unless it is peracute or the animal is still voiding urine, uroperitoneum is usually associated with an increase in blood urea nitrogen, creatinine, and potassium.

The main aim of the initial diagnostic evaluation of the animal with an acute abdomen is rapid identification of the patient that needs immediate surgery. If available, immediate abdominal ultrasound to detect abdominal effusion, followed by cytologic fluid analysis, is the fastest way to diagnose septic peritonitis. In early cases of peritonitis,

even with bowel rupture, little or no abdominal effusion may be present; in other words, the absence of abdominal effusion does not rule out peritonitis. Nevertheless, most animals with peritonitis have an abdominal effusion.

Abdominal ultrasonography may also identify the cause of the acute abdomen. Abscesses in parenchymal organs, pyometra, pancreatitis, abdominal masses, and abnormalities of organ blood flow, such as in splenic torsion, can all be detected by trained personnel. The accuracy of ultrasonography in detecting or ruling out gastrointestinal obstruction can vary, and caution should be exercised in the interpretation of ultrasound findings.

If ultrasound is not available, abdominal radiographs should be obtained as soon as the animal has been stabilized. Abdominal radiographs are superior to abdominal ultrasound in detecting intestinal obstruction or foreign material in the gastrointestinal tract. Abdominal radiographs may also demonstrate free gas and/or loss of intra-abdominal detail suggestive of fluid or increased soft tissue in the peritoneal cavity. Free gas may result from rupture of a hollow viscus, gas-forming bacteria, abdominocentesis, recent abdominal surgery, or penetrating injuries; however, many animals with penetrating abdominal injuries do not have free gas in the abdomen. Pneumoperitoneum can complicate radiographic and ultrasonographic evaluation of the postoperative abdomen. After experimental injection of air, radiographic evidence of intraperitoneal gas may persist for up to 18 days in dogs.

Abdominocentesis, with or without ultrasound guidance, is a quick, easy, and safe method for detecting and retrieving abdominal fluid. Contraindications to abdominocentesis are few but include coagulopathy, organomegaly, and distension of an abdominal viscus. If these conditions are a possibility, abdominal radiographs should be obtained prior to abdominocentesis or the tap should be performed with ultrasound guidance. Penetration of the gastrointestinal tract during abdominocentesis is unusual unless the viscus is dilated or adherent to the abdominal wall. Abdominocentesis may be performed by means of a single centesis, a four-quadrant approach, or diagnostic peritoneal lavage (DPL).

403

404

Prior to abdominocentesis, the site is clipped and prepared using standard aseptic technique. Closed needle abdominocentesis is performed using a 20-or 22-gauge hypodermic needle attached to a syringe. Initially, the ventral aspect of the right cranial quadrant is used (where fluid pools by gravity and diaphragmatic movement) to minimize the chance of splenic puncture. If blood is aspirated, the needle should be withdrawn and the blood observed to see if it clots. Blood from a vessel or organ clots, whereas blood from the abdominal cavity does not in all but the most peracute cases of hemoabdomen. Free air is not usually seen on radiographs after a closed abdominocentesis.

Diagnostic peritoneal lavage may be sensitive in detecting intra-abdominal pathology. The conventional method of DPL usually requires sedation and uses a peritoneal dialysis catheter with the animal in either lateral or dorsal recumbency. However, an over-the-needle catheter can be placed into the abdomen just caudal to the umbilicus and 10 to 20 mL/kg of isotonic crystalloid solution infused. This procedure should not require sedation. The catheter is then removed, and the abdomen is gently palpated. Thirty minutes later, a single or four-quadrant abdominocentesis is performed. Because DPL introduces free fluid into the abdomen and because it is not uncommon to retrieve only a small portion of the infused fluid, abdominal radiographs and ultrasound scans should be obtained prior to lavage.

Biochemical, cytologic, and microbiologic analysis of abdominal fluid is extremely useful in the diagnosis of the underlying cause. Initially the appearance of the fluid should be noted, followed by determination of the PCV, refractometric total solids concentration, and cytologic results to classify the fluid as a transudate, modified transudate, or exudate. Toxic degenerate neutrophils with intracellular and extracellular bacteria are indicative of bacterial peritonitis and warrant surgical exploration once the animal is hemodynamically stable. Rupture of the gastrointestinal tract is more likely if multiple bacterial species are seen and very likely if plant fibers are present.

Occasionally bacteria are not seen with bacterial peritonitis, and in these dogs and cats, differentiation from severe pancreatitis can be difficult. Both are associated with high numbers of degenerate neutrophils in the effusion.

The abdominal fluid amylase and lipase concentrations may be helpful in detecting pancreatitis; however, it is vital to appreciate that more than half the cases of septic peritonitis may have concurrent pancreatitis, therefore a diagnosis of pancreatitis does not preclude the presence of bacterial peritonitis. An abdominal effusion glucose concentration of less than 50 mg/dL is often indicative of bacterial peritonitis.

With uroabdomen, abdominal fluid almost always shows higher blood urea nitrogen (BUN), creatinine, and potassium concentrations than does serum; however, the difference can be relatively minor. Creatinine equilibrates more slowly with the intravascular space and can therefore more be more useful. To enable comparison of serum and abdominal fluid, samples must be obtained within minutes of each other. If a bolus of intravenous fluids is administered after the abdominal fluid sample is obtained, the serum levels can be diluted, and ascites of another cause may be misdiagnosed as uroabdomen.

When uroperitoneum is suspected, retrograde contrast urethrocystography and/or excretory urography should be performed to confirm the site of leakage. The most common causes of bile peritonitis are rupture of the biliary tract secondary to trauma or necrotizing cholecystitis. A green abdominal effusion is usually present, which sometimes contains dark green, brown, or black particulate matter. The bilirubin concentration should be higher in the effusion than in serum.

111 CHAPTER • 111 Cardiac Emergencies

Kirstie A. Barrett

The management of cardiac emergencies can be very rewarding if a prompt diagnosis is made and if the proper treatment is instituted without delay. Sometimes patients are not stable enough to handle extensive diagnostics, and treatment decisions must be made quickly. In such cases, an insightful history and physical examination are critically important, because the choice of further diagnostics may be limited.

Cardiac emergencies commonly seen in veterinary patients are arrhythmias, acute congestive heart failure, pericardial effusion, and arterial thromboembolism. Other cardiac emergencies or potential cardiac emergencies, described elsewhere in detail, include cardiopulmonary resuscitation (CPR), shock, syncope, hypertension, and hypotension.

111.1 ARRHYTHMIAS

Arrhythmias, which occur in a high percentage of critical patients, represent a disturbance in the rate, regularity, or site of cardiac electrical impulse formation. Their clinical significance is a result of a heart rate that is either too slow or too rapid, depressing cardiac output and potentially leading to heart failure or circulatory collapse. Cardiac arrhythmias are particularly ominous if they have the potential to deteriorate into an electrically unstable form, causing or exacerbating circulatory failure or cardiac arrest.

A correct electrocardiographic (ECG) diagnosis is essential to appropriate management and therapy and should always be interpreted in the context of the patient's history and current clinical status. Identification and correction of precipitating factors (e.g., cardiopulmonary disease, metabolic derangements, acid-base and electrolyte imbalances, current drug therapy) are equally essential to successful management of cardiac arrhythmias and to the clinician's decision on whether to initiate antiarrhythmic therapy.

Arrhythmias that cause clinical signs generally warrant therapy. Clinical signs that reflect decreased cardiac output may be acute or progressive and include weakness, exercise intolerance, syncope, collapse, ataxia, pulse abnormalities, congestive heart failure, and sudden death.

Arrhythmias present during cardiopulmonary arrest (CPA) include asystole (complete absence of QRS-T complexes), ventricular fibrillation (chaotic depolarization of the ventricles characterized by a lack of QRS-T complexes with unorganized fibrillation waves), and electromechanical dissociation (little or no myocardial contractile activity with a normal ECG tracing). All these arrhythmias require immediate intervention using standard CPR recommendations. Other potentially lethal arrhythmias include continuous (sustained) or intermittent (paroxysmal) ventricular tachycardia, ventricular flutter, paroxysmal or sustained supraventricular tachycardia, sick sinus syndrome (SSS), complete or high-grade second-degree atrioventricular block, and sinus standstill. Sinus bradycardia frequently precedes CPA in critically ill patients. Antiarrhythmic therapy should be initiated if treatment of the underlying disorder does not improve the arrhythmia; if hemodynamic impairment is identified; or if the risk of sudden death exists. Identification of the above arrhythmias and treatment options are discussed in detail elsewhere (see Chapter 202).

111.2 HEART FAILURE

Heart failure is a clinical syndrome caused by cardiac disease that results in systolic or diastolic cardiac dysfunction or both. Systolic failure describes decreased myocardial performance and diastolic failure results from abnormal filling of the ventricles during diastole.

Decompensated heart failure manifests either as congestion/edema (backward heart failure) or circulatory failure (low-output, forward heart failure). Right-sided congestive heart failure results in systemic venous congestion and may manifest as jugular distention, subcutaneous edema, hepatic congestion, ascites, and/or pleural effusion. Left-sided congestive heart failure presents as pulmonary edema.

Because the clinical signs of left-sided congestive heart failure can mimic those of pulmonary disease, it is important to determine accurately which condition is truly present. The signalment, history, and response to treatment can be helpful in making this distinction. The single most useful test for confirming congestive heart failure is a thoracic radiograph. However, the potential stress of any diagnostics must be seriously considered, because the anxiety associated with even minimal handling of a severely dyspneic animal can be life-threatening.

The goal of medical therapy in congestive heart failure is to improve cardiac output by increasing contractility, decreasing afterload, or normalizing a cardiac dysrhythmia. It is equally important to relieve clinical signs by reducing abnormal fluid accumulation. Furosemide is the diuretic of choice for relieving acute pulmonary edema and normalizing cardiac filling pressures. High doses of furosemide (up to 4 mg/kg given intravenously or intramuscularly every 2 hours) may be used initially to induce diuresis. Intravenous furosemide acts within 5 minutes, peaks within 30 minutes, and dissipates after 2 to 3 hours. Use of the intravenous route is preferred, but this must be weighed against the potential stress of administration.

Intramuscular administration of furosemide is an alternative. The dose is highly variable and depends on the response desired. The dose and frequency should be reduced as a clinical response (diuresis, respiratory rate reduction, and respiratory character improvement) is achieved. Cats tend to be more sensitive to furosemide than dogs and respond to lower doses (2 mg/kg).

In addition to the diuretic, a low dose of morphine (0.05 to 0.1 mg/kg given subcutaneously or intramuscularly) can reduce the anxiety associated with pulmonary edema and provide mild venodilatation.* The dose is repeated up to four times a day, as necessary, to achieve the desired effect. The primary adverse consequence of using morphine is respiratory depression, therefore it must be used with caution in hypoxic animals. Acepromazine (0.05 to 0.1 mg/kg given subcutaneously) is an anxiolytic that does not depress respiration. Acepromazine is an alpha-adrenergic blocker that decreases peripheral vascular resistance, which may also be beneficial.

Nitroglycerin, a venodilator, may further reduce congestion, although information in the veterinary literature is merely anecdotal. Nitroglycerin paste can be applied to the inner surface of the pinna of the ear (¼ to 1 inch every 6 hours in the dog; ⅛ to ¼ inch every 6 hours in the cat). Nitroglycerin is typically used for only 48 hours due to the drug tolerance that develops.

Hydralazine, a potent arteriolar dilator, can be used in the emergency management of a normotensive congestive heart failure patient (0.5 to 2.0 mg/kg given orally). Nitroprusside is both a potent venodilator and a potent arteriolar dilator for use in severe, refractory congestive heart failure (1 to 2 μg/kg/minute given intravenously initially). Continual blood pressure monitoring is essential with nitroprusside. Dobutamine (2.5 to 10 μg/kg/minute, intravenously), which is primarily a $beta_1$ agonist, is used to improve cardiac output by increasing

contractility in hypotensive patients with refractory congestive heart failure. Digoxin is especially beneficial in the emergency treatment of congestive heart failure when supraventricular tachycardia or atrial fibrillation is present.

Strict cage rest and prevention of stress are critically important to the management of a congestive heart failure patient. Additional measures that may benefit the patient are thoracocentesis and oxygen therapy. Cats with congestive heart failure often present with both pulmonary edema and pleural effusion. When congestive heart failure results in pleural effusion of significant quantity and the animal is dyspneic, thoracocentesis often results in prompt and dramatic improvement (the technique is described elsewhere in this text).

Dogs and cats with severe pulmonary edema are hypoxic due to the decreased ability of oxygen to diffuse from the alveoli into the pulmonary capillaries. Supplemental oxygen increases this pressure gradient, resulting in an increase in arterial oxygen tension. Therefore it is of critical importance that patients with severe edema have supplemental oxygen. This can be achieved using an oxygen cage (40% oxygen) adjusted to maintain a normal temperature (20°to 22°C [68°to 72°F]) and appropriate humidity (45% to 55%). Oxygen cages are generally better tolerated and less stressful than other means of administration. In a larger dog, oxygen can be administered through a nasal cannula. An oxygen mask is an alternative but should not be used if the animal is struggling against the mask.

Endotracheal intubation may be required in animals with extreme respiratory distress and fulminant pulmonary edema to provide controlled ventilation and 100% oxygen administration. In addition, copious amounts of pulmonary edema may be removed physically by suction or postural drainage. Intravenous fluids are rarely indicated in the treatment of acute, cardiogenic pulmonary edema because they often exacerbate the edema. 405 406

* Notably, morphine can cause agitation and aggression in cats.

111.3 PERICARDIAL EFFUSION

Pericardial effusion is an abnormal accumulation of fluid in the pericardial sac. The hemodynamic effects of pericardial effusion depend on the rate and volume of the fluid accumulation and the compliance of the pericardium itself. If the effusion develops slowly, the pericardium will expand and the intracardiac pressure will not increase enough to compromise cardiac filling. In contrast, acute cardiac tamponade is characterized by rapid accumulation of fluid in the pericardial space, leading to a rise in intrapericardial pressure. The results are restriction of ventricular filling, decreased cardiac output, and arterial hypotension. Clinical signs of right-sided congestive heart failure or reduced cardiac output predominate and include anorexia, lethargy, syncope, dyspnea, weakness, exercise intolerance, and abdominal distention (hepatomegaly, ascites). Common physical examination findings are muffled heart sounds, jugular venous distension, sinus tachycardia, and weak femoral pulses. Pulsus paradoxus (an exaggerated decline greater than 10 mm Hg in systemic arterial pressure during inspiration) is a valuable clinical sign that may also be appreciated in cardiac tamponade.

Although thoracic radiography typically demonstrates an enlarged, globoid cardiac silhouette, echocardiography is the most sensitive and specific noninvasive means of diagnosing pericardial effusion. The therapeutic goal for patients with pericardial effusion is to reduce the intrapericardial pressure quickly. Pericardiocentesis is the treatment of choice for initial stabilization of dogs and cats with pericardial effusion and cardiac tamponade (the technique is described in Chapter 205). Attempts to lower venous pressures with medical therapy (i.e., diuretics) should be avoided because the patient's cardiac preload depends on these elevated pressures. The result can be a significantly reduced cardiac output, manifested as hypotension or syncope or both.

111.4 ARTERIAL THROMBOEMBOLISM

Arterial thromboembolism is a common sequela to all types of feline myocardial disease (hypertrophic cardiomyopathy, dilated cardiomyopathy, and restrictive cardiomyopathy); it is uncommon in the setting of a structurally normal or mildly abnormal heart. Arterial thromboembolism results in significant morbidity and mortality. Systemic thromboembolism is rarely reported in the dog and is usually associated with neoplasia, sepsis, Cushing's disease, protein-losing nephropathy, or other hypercoagulable states. Distal aortic embolization (saddle thrombus at the distal aortic trifurcation) occurs in more than 90% of feline cases. Corresponding clinical signs may occur with embolization of other organs, such as the lungs (respiratory distress), kidneys (acute renal failure), brain (central nervous system signs), gastrointestinal tract (bowel ischemia), and right (more commonly than left) brachial artery (pain and paresis).

A distal aortic embolism presents as peracute paresis or paralysis with vocalization due to intense pain. The clinical consequences depend on the site, extent, and duration of the embolization, as well as the degree of functional collateral circulation. The *four Ps* characterize the clinical signs of changes observed in the extremities: paralysis, pain, pulselessness (lack of palpable femoral pulses), and pallor (cold, pale distal extremities and pads). Absence of bleeding from a cut nail on the affected limb may also be seen. Ten to 12 hours after the embolization, the anterior tibial and gastrocnemius muscles often become firm as a result of ischemic myopathy. In most cases these muscles become softer after 24 to 72 hours. Respiratory distress is commonly associated with systemic thromboembolism in cats because most have concurrent congestive heart failure. Acute aortic blockade by the thromboembolus increases afterload to the left ventricle. The clinician must differentiate the respiratory changes seen with congestive heart failure from those seen with pain.

A variety of therapeutic measures can be used to offset the consequences of a thromboembolism. These range from attempts to limit thrombus growth or formation and pain control to supportive care and treatment of accompanying congestive heart failure.

Although heparin has no effect on established thrombi, it is commonly administered in hopes of limiting thrombus growth.* Heparin can be administered at an initial dose of 220 U/kg given intravenously, followed by a maintenance dose of 70 to 200 U/kg given subcutaneously every 6 hours. Thrombolytic agents such as streptokinase, urokinase, and tissue plasminogen activator (t-PA) are used extensively in humans and infrequently in cats. These agents are expensive, have not been studied extensively, and are associated with high mortality and poor outcomes. Risks of bleeding complications, death from reperfusion syndrome (hyperkalemia, metabolic acidosis), and rethrombosis are common.

During the initial stages of the disease, most cats experience intense pain. The pain subsides as sensory nervous function is lost. Common choices for pain control include oxymorphone (0.05 to 0.15 mg/kg given intramuscularly or intravenously every 6 hours), butorphanol (0.1 mg/kg given intravenously or 0.02 to 0.4 mg/kg given intramuscularly or subcutaneously every 4 hours), and/or acepromazine (0.05 to 0.1 mg/kg given intravenously). Euthanasia should be considered as an option when severe, unrelenting pain is present.

General supportive care consists of maintaining hydration and normal electrolyte status, massaging firm muscles, expressing the bladder as necessary, and preventing self-mutilation. Management of concomitant congestive heart failure is discussed above.

* Heparin has never been proven to limit thrombus growth.

112 CHAPTER • 112 Cardiopulmonary Arrest and Resuscitation

Nishi Dhupa

***C**ardiopulmonary arrest* is defined as the cessation of effective ventilation and circulation. Resuscitative efforts should be aimed at patients with potentially reversible disease. The ultimate goals of cardiopulmonary resuscitation (CPR) are to maintain adequate tissue oxygenation and thereby preserve organ viability during the low-flow "arrest" state, to rapidly restore a spontaneous and effective cardiac rhythm, and to protect cardiovascular and neurologic function following resuscitation in order to improve the chances of survival as well as the return of acceptable cerebral and motor functions.

CPR may be divided into three phases. Basic life support (BLS) is the provision of artificial ventilation, oxygenation, and circulation in order to maintain vital organ perfusion. Advanced life support (ALS) involves the recognition and treatment of the arrest rhythm and other modalities to resuscitate the patient. Prolonged life support (PLS) covers post-resuscitative care. Guidelines for veterinary CPR are extrapolated from human medicine. The American Heart Association in collaboration with the International Liaison Committee on Resuscitation has recently reviewed and updated its guidelines on CPR.[1] Methods that improve coronary perfusion pressure are being prioritized in an effort to improve resuscitation rates and outcomes.

112.1 RECOGNITION OF CARDIOPULMONARY ARREST

Incipient cardiopulmonary arrest (CPA) may be recognized by bradycardia or other cardiac arrhythmias, slow or irregular respirations, mental obtundation, hypotension, and hypothermia. In dogs and cats, the most common "arrest rhythms" are asystole and pulseless electrical activity (PEA) (otherwise known as electromechanical dissociation); a lower percentage display ventricular fibrillation (VF). CPR must begin immediately in the unresponsive, breathless, and pulseless patient. The chances of recovery from CPA are increased in cases of respiratory arrest alone, anesthetic overdose, upper airway obstruction, trauma or hemorrhage, vagally mediated arrest, electrolyte abnormalities, or upper airway obstruction. Patients with terminal or multisystemic disease will have a poorer prognosis.

112.2 BASIC LIFE SUPPORT

BLS should be initiated as rapidly as possible after the recognition of CPA. Traditionally BLS has been carried out according to the "ABC" mnemonic (airway, breathing, circulation). The first step is to secure the airway through endotracheal intubation. If pulmonary edema fluid discharges through the endotracheal tube, postural drainage, with the head hanging below the body, and suction will aid in clearing of the airway. Once intubated, positive pressure ventilation should be initiated at 15 to 25 breaths per minute using a rebreathing (AMBU) bag attached to high flow oxygen. The chest should be observed and ausculted to verify appropriate ventilation.

The goal of circulatory support during CPR is to maximize cerebral and myocardial oxygenation in order to achieve a rapid return of spontaneous circulation (ROSC) and long-term neurologic recovery. Ventilation with 100% oxygen ensures maximal saturation of hemoglobin and improves arterial oxygen content. Cerebral perfusion depends on cardiac output and cerebral vascular resistance; perfusion pressure is determined by the difference between mean arterial pressure and intracranial pressure. Myocardial perfusion is determined by the difference between aortic diastolic and right atrial pressure. Various compressive and therapeutic strategies are used to maximize these perfusion pressures.

First, during closed-chest CPR, rapid chest compressions are initiated at a rate of 80 to 100 per minute. In smaller patients, compressions are performed directly over the heart, with the patient in lateral recumbency, in order to maximize forward blood flow. In larger patients, greater increases in intrathoracic pressure can be achieved by performing chest compressions over the point of the sternum, with the patient in dorsal recumbency. The optimal compression: relaxation ratio of 50:50 allows for diastolic filling of the heart and maximizes myocardial perfusion.

Alternating abdominal compressions may be used to improve cardiac preload and cardiac output. Greater intrathoracic pressure changes can also be achieved during simultaneous compression-ventilation. In hypovolemic patients, aggressive fluid therapy is essential to restore circulating blood volume. The effectiveness of chest compressions and adjunctive strategies must be evaluated through palpation of femoral pulses, detection of orbital vessel blood flow through Doppler ultrasound applied to the cornea, and end-tidal carbon dioxide measurement (a higher value following chest compression is indicative of improved pulmonary perfusion and gas exchange).

Open chest CPR, with direct cardiac massage, is indicated in patients with conditions that interfere with the generation of intrathoracic pressure, which is necessary for forward blood flow. These include pneumothorax, diaphragmatic hernia, flail chest, severe obesity, pericardial effusion, very large animals, and severe hypotension. Although this modality is superior in terms of generation of blood flow, it is an invasive procedure, associated with increased morbidity and intensive after-care.

Recently, the “CAB” mnemonic has been suggested as an alternative to “ABC.” This has some application in human patients in whom primary cardiac arrest is more common. In veterinary patients, in whom respiratory and vagally mediated arrests are common and hypoxia, hypercarbia and acidosis often precede cardiac arrest, the “ABC” approach, with its emphasis on early oxygenation, is still valid.

112.3 ADVANCED LIFE SUPPORT

ALS is initiated once effective artificial ventilation and circulation have been established. ALS consists of techniques to augment artificial circulation and encourage ROSC through arrhythmia recognition (using electrocardiography) and treatment with drugs and defibrillation. First, any anesthetic, analgesic, or sedative agents must be discontinued or reversed to minimize cardiorespiratory depression (Table 112-1). The most common arrest rhythms are treated as follows: asystole is treated with atropine and epinephrine; pulseless electrical activity with atropine and epinephrine; and ventricular fibrillation with electrical defibrillation (see Table 112-1). Emergency drugs are administered through either the central venous (preferred), endotracheal, or intraosseous route (see Table 112-1). Intratracheal administration is achieved by a doubling of the intravenous dose, dilution to 5 to 6 mL in saline, and administration at the level of the carina via a 5-to 8-French red rubber tube.

Atropine is a vagolytic agent that is indicated in the treatment of sinus bradycardia, asystole, or PEA (all seen in up to 70% of small animal CPA) due to the role of the parasympathetic nervous system in these arrhythmias (see Table 112-1).

Epinephrine is an adrenergic vasopressor that is the current drug of choice for asystole, PEA, and refractory VF. Its alpha-adrenergic activity results in increased aortic diastolic pressure and improved myocardial perfusion, thus encouraging ROSC. The beta effects (inotropy, chronotropy) may increase myocardial work and oxygen demand, with the potential for tachyarrythmias and myocardial dysfunction following ROSC.

Several newer drugs are undergoing extensive study and may have value in CPR protocols. Vasopressin (Pitressin, Monarch Pharmaceuticals, Bristol, TN) is a potent nonadrenergic vasopressor, acting through direct stimulation of

vasopressin (V1) receptors in vascular smooth muscle. Its advantages over epinephrine include the fact that the vaso-constrictive effects are not blunted in the presence of acidosis and, following ROSC, there is no increase in myocardial oxygen demand. In human CPA protocols, vasopressin is now being considered an alternative to epinephrine in refractory VF; it has also been used in asystole and PEA.[1] The single use of vasopressin, at a dose of 0.8 µ/kg IV, has been proposed for similar arrhythmias in veterinary CPR.[2] However, there is little data to support a strong recommendation at this time.

Table • 112-1 Drugs Used in Cardiopulmonary Resuscitation

DRUG	DOSAGE AND ROUTE	INDICATIONS
Amiodarone	5–10 mg/kg IV	Refractory VF
Atipamezole	0.1–0.2 mg/kg IV	α_2 adrenergic reversal
Atropine	0.04 mg/kg IV, IT, IO	Bradycardia, asystole
Calcium gluconate	50 mg/kg IV, IO	Hypocalcemia, hyperkalemia
Diltiazem	0.05–2 mg/kg IV 1–10 µg/kg/min IV	Supraventricular arrhythmia after ROSC
Dobutamine	5–10 µg/kg/min IV	Reduced cardiac output after ROSC
Dopamine	5–10 µg/kg/min IV	Hypotension after ROSC
Epinephrine	0.02–0.2 mg/kg IV, IT, IO;	Asystole. Repeat q 3-5 min
Flumazenil	0.02 mg/kg IV, IT, IO	Benzodiazepine reversal
Lidocaine	2–4 mg/kg (dogs), 0.5 mg/kg (cats), IV, IT, IO followed by 50 µg/kg/min IV	Hemodynamically unstable ventricular arrhythmias after ROSC
Magnesium sulfate	30 mg/kg IV, IO	Hypomagnesemic patients; polymorphous ventricular tachycardia
Mannitol	0.25–1 g/kg IV, IO	Cerebral edema
Naloxone	0.01–0.04 mg/kg IV, IT, IO	Opioid reversal
Sodium bicarbonate	0.5–1 mEq/kg IV, IO (NOT IT)	10 minutes into CPA; earlier if pre-existing acidosis; hyperkalemia
Vasopressin	0.8 µ/kg IV, IO	Asystole, refractory VF

IV, Intravenous; *IT*, intratracheal; *IO*, intraosseous; *VF*, ventricular fibrillation; *ROSC*, return of spontaneous circulation.

Aminophylline is an adenosine antagonist that has recently been used in human CPR in an effort to counteract the negative chronotropic effect, inhibition of catecholamine receptors, and vasodilation caused by endogenous vasodilators such as adenosine during CPA. Aminophylline can decrease defibrillation threshold and may be useful in refractory VF. More extensive studies into the use of this drug are underway.

Amiodarone is a newer antiarrhythmic agent that has been included in human CPR guidelines for use in ventricular arrhythmias refractory to lidocaine or procainamide, as well as for treatment of refractory VF.[1] To date, there is no data on its use in small animal CPR.

Aggressive fluid therapy during CPR can increase preload and interfere with cerebral and myocardial perfusion. However, as CPA progresses, increasing fluid volumes are required in order to maintain an effective circulating blood volume in the presence of systemic vasodilation. Fluid choice is dependant on volume status; colloids may augment isotonic crystalloid administration in hypovolemic patients.

Electrical defibrillation is the treatment of choice for VF, with the goal of conversion to asystole (with subsequent epinephrine administration) or a perfusing rhythm. In known VF, defibrillation may be carried out prior to the ABCs. Electrical countershocks are applied across the chest wall using hand-held defibrillator paddles coated with electrode gel, with the animal in dorsal recumbency. The initial electrical shock should be in the range of 3 to 5 J/kg. Two or three shocks are delivered in rapid succession, with increasing energy (5 to 10 J/kg) being applied if

necessary. For internal defibrillation, during open chest CPR, an initial dose of 0.5 to 1 J/kg is used. The ECG is evaluated and countershocks are discontinued when VF converts.

112.4 PROLONGED LIFE SUPPORT

Successful resuscitation is characterized by the return of a perfusing rhythm and effective respirations. A large percentage of successfully resuscitated patients will suffer a second arrest within a few hours. This is due to multiorgan failure secondary to hypoxic damage during low-flow CPA and CPR.

408
409

Aggressive monitoring and supportive care is required to optimize cardiac output, blood pressure, and vital organ function. Cardiovascular support is provided through appropriate fluid therapy, vasopressor or inotropic support, and the control of hemodynamically unstable arrhythmias (see Table 112-1). Stable and perfusing ventricular escape rhythms should not be suppressed with drug therapy. Ventilatory support may be essential for some hours following resuscitation, in order to maximize oxygenation and to prevent hypercarbia (and associated cerebral vasodilation). Neurologic recovery is also maximized by maintainance of mean arterial pressure (and therefore cerebral perfusion pressure) as well as by treatment for hypoxia-induced cerebral edema with Mannitol (see Table 112-1). Hyperglycemia has been associated with worse neurologic outcomes; for this reason, corticosteroids are not currently used in post-arrest protocols.

Good prognostic signs include the rapid recovery of upper airway function (coughing) and ocular reflexes, and rapid return of consciousness following cardiac arrest. The presence of prolonged unconsciousness, the absence of the oculocephalic (doll's eye) reflex, or any deterioration in neurologic status, following ROSC, suggests progressive cerebral ischemia and indicates a poor outcome. Blindness is a common but often reversible sequela to CPA.

113 CHAPTER • 113 Traumatic Brain Injury

Rebecca S. Syring

Traumatic brain injury (TBI) is an important cause of morbidity and mortality in veterinary medicine. The severity of brain injury after head trauma can be quite variable, with neurologic signs ranging from relatively minor deficits to life-threatening impairments. An understanding of the pathophysiologic changes that occur after TBI and the appropriate diagnostic and therapeutic interventions for the animal with head injury can help the clinician optimize the outcome.

113.1 PATHOPHYSIOLOGY OF BRAIN INJURY

TBI can be caused by blunt or penetrating trauma. Blunt force to the head is the most common category of TBI. With blunt trauma, the kinetic energy from the impact is diffusely dissipated across the surface of the body. Head injury may be overtly obvious in these dogs and cats or may be overshadowed by more severe injuries elsewhere in the body. Although less common, penetrating injuries to the head, such as gunshot, stab, or bite wounds, are more likely to result in isolated trauma to the brain, because the kinetic energy from the trauma is focally dissipated along the penetrating tract.

113.1.1 Primary versus Secondary Injury

Two phases have been described as following TBI: primary and secondary injury. *Primary injury* refers to pathologic changes that take place when the injury is sustained. Examples of primary injury include direct axonal damage, such as compression or laceration from forces applied to the skull during impact or displaced skull fractures, and vascular disruption, including focal hematomas or diffuse parenchymal hemorrhage. Primary injury is complete at the time of trauma and, with the exception of surgical evacuation for focal hematomas or decompression of depressed fractures, little can be done to alter its course.

Secondary injury refers to a variety of pathologic processes that occur after the primary insult and that result in progressive neuronal damage not only at the initial site of trauma but extending to the brain globally. Because the brain has high metabolic requirements, decreased cerebral oxygen delivery or hypoglycemia can rapidly result in adenosine triphosphate (ATP) depletion, cell membrane pump failure, and loss of ion homeostasis. This can lead to excitotoxicity, oxidative stress, cytotoxic and vasogenic cerebral edema, inflammatory mediator release, activation of the coagulation cascade, vasospasm, and cell death. With anaerobic metabolism, hyperglycemia has been documented to exacerbate neurologic damage by increasing lactic acid accumulation in the brain, resulting in neuronal and glial cell death. These are just a few examples of types of secondary injury that occur after TBI. Because secondary injury occurs after the initial insult and is progressive in nature, medical intervention should focus on preventing the development or limiting the side effects of this type of injury. Two factors that have a significant impact on the perpetuation of secondary injury are systemic hypoxia and hypotension, both of which can be easily recognized and treated clinically.

113.1.2 Intracranial Pressure and Cerebral Perfusion Pressure

In the healthy brain, pressure autoregulation ensures that cerebral blood flow (CBF) is maintained within an acceptable range over a wide spectrum of systemic mean arterial blood pressures (50 to 150 mm Hg). In response to changes in blood pressure, parallel changes in cerebral vascular resistance occur to maintain blood flow to the brain. Above and below these values, cerebral blood flow is directly proportional to systemic blood

pressure. This protective mechanism is often impaired (either globally or regionally) in animals with TBI, at which time cerebral blood flow becomes linearly dependent on systemic blood pressure.

Intracranial pressure (ICP) is defined as the pressure exerted between the skull and its intracranial contents. The components of ICP are the volume of blood, brain tissue, and cerebral spinal fluid (CSF) within the cranial vault. In dogs and cats with TBI, brain volume increases with hemorrhage or edema. The body attempts to maintain ICP with a compensatory decrease in the production of CSF or shunting of CSF into the cisterna magna or by arterial vasoconstriction to lower the blood volume. ICP increases when intracranial volume exceeds the system's capability for compensatory decreases in the other components. The normal ICP for cats and dogs is 5 to 10 mm Hg.

Cerebral perfusion pressure (CPP) is considered the primary determinant of cerebral blood flow in animals with TBI. With intracranial hypertension, CPP is equal to the systemic mean arterial blood pressure (MAP) less intracranial pressure:

$$CPP = MAP - ICP$$

Maintaining CPP above a minimum value of 70 mm Hg is recommended in order to optimize oxygen and nutrient delivery to the brain. CPP is a measure of global blood flow and does not necessarily reflect blood flow on a regional level. Because ICP is infrequently measured in veterinary medicine, determination of CPP is not always possible. However, this equation stresses the importance of optimizing blood pressure in head trauma patients. Relatively small increases in ICP (e.g., 15 mm Hg) can result in inadequate CPP with a normal MAP of 80 mm Hg. Additionally, with normal ICP, if pressure autoregulation is no longer intact, minor decreases in MAP result in inadequate CPP.

113.2 ASSESSMENT

In the evaluation of animals with TBI, it is imperative that the examiner assess all body systems, rather than focus solely on the brain, because head trauma often occurs coincident with traumatic injuries to other body systems. It has been reported that 50% to 65% of dogs with TBI have sustained blunt vehicular trauma, a common cause of multisystemic injury. Common injuries seen after blunt trauma, such as pulmonary contusions, pneumothorax, and hemoabdomen, can impair systemic oxygenation and perfusion and perpetuate secondary injury if not rapidly addressed. Developing a systematic approach to the traumatized pet that focuses on evaluation of the major body systems, cardiovascular and respiratory stabilization, followed by a secondary assessment and definitive medical therapy, can help the clinician prioritize treatment goals and can improve the outcome (see Chapter 117). A full neurologic examination is not necessary and may not be in the animal's best interest during the initial assessment. Instead, an abbreviated neurologic assessment that focuses on three main categories—level of consciousness, brain stem reflexes, and motor activity/posture—should provide ample information for initial assessment and stabilization.

An altered level of consciousness indicates abnormalities in the cerebral cortex or brain stem (reticular activating system). Level of consciousness can be divided into four main categories: alert, depressed/obtunded, stuporous, or comatose. Depressed to obtunded animals are aware of but less responsive to their environment. An obtunded animal should still respond to noise or touch. Stupor indicates a severely impaired level of consciousness, with response only to noxious stimuli. A truly comatose dog or cat exhibits no response to any type of manipulation, including repeated noxious stimuli. The use of these standardized categories to describe level of consciousness allows for uniform comparison of neurologic function over time in individual animals. In the assessment of pets with altered levels of consciousness, it is important to remember that shock (decreased tissue oxygen delivery) can cause moderate alterations in consciousness, which should improve with treatment that improves tissue perfusion.

Brain stem reflex assessment should focus on pupils (size, symmetry, and position), pupillary light responses, and physiologic nystagmus. Miotic pupils indicate a lesion above the brain stem leaving the oculomotor nerve, a pupillary constrictor, intact and unopposed from higher centers. Mydriatic pupils are seen in animals with brain stem lesions affecting the oculomotor nerve on the side of the injury. Anisocoria may indicate a neurologic lesion affecting one side exclusively or simply one side more than the other. In the absence of other underlying ophthalmologic disorders, lack of a pupillary light response, unilaterally or bilaterally, indicates disruption or compression of the oculomotor nerve tracts ipsilateral to the injury. Ventrolateral strabismus may also be seen with oculo-motor nerve damage. Physiologic nystagmus, a reflex that tests cranial nerves III and VIII, is intact when the normal tracking movements of the eye are seen in response to turning of the head from side to side. Absence of this reflex indicates injury to the central region of the brain stem, as may be seen with brain stem hemorrhage or compression caused by swelling or herniation.

Abnormalities in any of these brain stem reflexes can aid in the localization of neurologic lesions and in the grading of the severity of injury. Additionally, serial evaluation of these reflexes assists in the monitoring of progression or improvement of neurologic function. It is important to remember that pupils of normal size that are not responsive to light represent significant brain stem dysfunction and are only one step less severe than a fixed and dilated pupil. For example, if midrange or mydriatic pupils without a pupillary light reflex are present on initial examination and no progression is noted, brain stem hemorrhage may be suspected. These signs, in conjunction with a comatose state and loss of physiologic nystagmus, are associated with a grave prognosis. Alternatively, a gradual progression of pupils toward mydriasis or loss of pupillary light response may indicate the development of intracranial hypertension, as occurs with edema formation, which may potentially respond to therapy directed toward lowering ICP.

The animal's motor activity and posture may aid in the localization of neurologic lesions (e.g., focal subdural hematomas). Following TBI, ataxia, hemiparesis, or tetraparesis may be the result of a lesion in the cerebral cortex or brain stem. The presence of other cranial nerve abnormalities can help in the differentiation of intracranial from cervical neck lesions. Decerebrate rigidity (extension of all four limbs and opisthotonus) indicates a rostral brain stem lesion and is often associated with brain stem compression secondary to marked intracranial hypertension and/or herniation. Decerebellate rigidity (extension of the front legs with hindlimb flexion) indicates a cerebellar lesion, as may be seen with cerebellar herniation. Animals with decerebrate posturing have a markedly altered level of consciousness, whereas those with decerebellate posturing usually are alert and aware of their surroundings.

The Cushing (or CNS ischemic) response is a compensatory mechanism that can be seen with markedly elevated ICP. Intracranial hypertension results in decreased CBF, which is sensed in the vasomotor center of the brain. In response to local carbon dioxide (CO_2) accumulation from decreased blood flow, the vasomotor center emits a massive sympathetic discharge, resulting in peripheral vasoconstriction, which results in an elevation in MAP to maintain CPP. The increased blood pressure is sensed at baroreceptors, resulting in a reflex bradycardia. The combination of hypertension and bradycardia in an animal with a decreased level of consciousness should alert the clinician to the possibility of increased ICP and should prompt aggressive treatment.

113.3 THERAPEUTICS AND CARE

113.3.1 Extracranial Stabilization

It is essential that extracranial organ systems be assessed and stabilizing medical therapy be instituted before therapy directed at lowering intracranial pressure is begun. The goals of extracranial stabilization should be to

optimize systemic oxygenation, ventilation, and tissue perfusion. Abnormalities in these three areas are common, given the propensity for multisystemic injuries with blunt trauma and the possibility of direct damage to the respiratory center in the brain. Early stabilization of the extracranial system minimizes secondary neurologic injury.

Hypoxemia should be avoided at all costs. Episodes of desaturation have been shown to worsen the outcome in humans with head trauma. Oxygen supplementation should be provided to maintain a hemoglobin saturation above 97% or a partial pressure of arterial oxygen (PaO_2) greater than 90 mm Hg. When in doubt, especially when oxygenation cannot be measured, the clinician should provide supplemental oxygen to avoid any potential adverse consequences from hypoxemia. Oxygen can be supplemented by many routes, including oxygen cages, flow-by masks, and hoods. Intranasal and intratracheal routes should be avoided when possible, because they can cause sneezing or coughing, both of which transiently increase ICP. Insufficient oxygenation despite an inspired oxygen concentration up to 60% necessitates intubation and positive pressure ventilation.

Hypoventilation, resulting in an elevated partial pressure of arterial carbon dioxide ($PaCO_2$), can occur. Reasons for hypoventilation include direct damage to the respiratory center, sedatives, thoracic trauma that causes pain or pleural space disease, and head or neck trauma that causes mechanical airway obstruction. Acute hypercarbia results in a respiratory acidosis that is sensed at the central chemoreceptors. In response to this acidosis, vasodilatation of the cerebral vasculature occurs, thus increasing CBF and potentially exacerbating elevations in ICP. $PaCO_2$ should be maintained below 40 mm Hg in patients with TBI. If $PaCO_2$ concentrations cannot be maintained within a normal range, intubation alone or in combination with mechanical ventilation is required.

The primary goal of fluid therapy in the pet with TBI is rapid restoration of tissue perfusion and blood pressure such that CPP is maintained above 70 mm Hg. Restriction of fluids should be avoided, because only minimal decreases in ICP are achieved and the animal is placed at greater risk for hypovolemia, which detrimentally affects CPP and exacerbates cerebral ischemia. Fluid therapy should be directed toward restoration of euvolemia, provision of maintenance requirements, and replacement of ongoing losses while avoiding overhydration.

A variety of fluid types are available for intravascular volume replacement in veterinary head trauma animals, including isotonic crystalloids, hypertonic saline, artificial colloids, and blood products (see Chapter 114). No one fluid type is optimal for every situation. Hypotonic solutions (5% dextrose in water, 0.45% sodium chloride) should be avoided for resuscitation, because these types of fluids preferentially expand the intracellular space and may exacerbate cerebral edema. Hypertonic saline (7.5%) is considered by many to be a superior fluid for resuscitation because of its ability to rapidly restore euvolemia due to its hyperosmolarity, which allows small volumes (3 to 5 mL/kg given over 10 to 15 minutes) to be used for resuscitation. Additional attractive properties of hypertonic saline are its ability to lower ICP by means of an osmotic effect and its ability to minimize vasospasm, excitotoxicity, and the inflammatory response in the brain.

113.3.2 Intracranial Stabilization

Once the cardiovascular and respiratory systems have been addressed, steps may be taken to stabilize the brain. The goals of intracranial stabilization are to limit intracranial hypertension by decreasing cerebral edema and optimizing intracranial blood volume and to minimize elevation of the cerebral metabolic rate.

Cerebral edema is a common problem in TBI. It can cause a progressive increase of ICP. Mannitol has traditionally been the drug of choice to help decrease cerebral edema. In addition to its osmotic properties,

mannitol may scavenge free radicals involved in oxidative stress and improve microvascular flow within the injured brain. The concern that mannitol may exacerbate intracranial hemorrhage is unfounded, and the global beneficial effects of its use far outweigh this potential risk. Mannitol should not be administered unless euvolemia has been restored, because the osmotic diuresis resulting from its use will further intravascular volume contraction and potentially worsen CPP. With hypovolemia, hypertonic saline (7.5%) may be a better choice, because this fluid will both restore intravascular volume and exert osmotic effects on the brain.

The use of corticosteroids to decrease cerebral edema has fallen out of favor, because multiple prospective clinical trials in human head trauma patients have shown no benefit. This, in combination with the many adverse effects of corticosteroids (hyperglycemia, immunosuppression, gastric ulceration, delayed wound healing, and exacerbation of a catabolic state), precludes its recommendation for use in animals with TBI.

Another mechanism by which ICP can be lowered is optimization of intracranial blood volume. Elevating the head and neck uniformly 15 to 30 degrees above the rest of the body facilitates venous drainage from the brain. Angles higher than 30 degrees and kinking of the neck such that the jugular veins become occluded should be avoided because arterial inflow and venous outflow can be compromised. Hyperventilation can be used as a short-term method of decreasing intracranial blood volume, because cerebral vasoconstriction occurs in response to alkalosis. Care should be taken to avoid excessive hyperventilation ($PaCO_2$ no lower than 30 mm Hg), because this can worsen cerebral ischemia.

Although less common in veterinary medicine than in humans, space-occupying masses, such as subdural hematomas, may require surgical evacuation in the face of static or worsening neurologic status. Computed tomography (CT), rather than magnetic resonance imaging (MRI), is the diagnostic tool of choice for dogs and cats with TBI, because it provides good detail for bone, cerebral edema, and acute hemorrhage; it is more readily available; and it allows for greater access to the animal during the scan.

Minimizing elevations in the cerebral metabolic rate is another important concern for animals with TBI. Seizures should be controlled with anticonvulsants. Hyperthermia, which can be a result of direct trauma to the thermoregulatory center or of excitement, paddling, iatrogenic causes (heating pads), or pain, should be avoided.

113.3.3 Ancillary Therapeutics and Monitoring

Analgesia and nutrition are two important treatment concerns. Adequate analgesia is essential, using drugs that minimize cardiovascular and respiratory depression (e.g., butorphanol or hydromorphone). Barbiturates, propofol, and etomidate are acceptable anesthetic agents because they do not adversely affect cerebral blood flow or the cerebral metabolic rate. Ketamine, acepromazine, and xylazine do affect these functions and should be avoided. Immediately after head injury, a hypermetabolic state develops that persists for many days. Early institution of nutritional support is crucial in order to minimize protein catabolism and supplement important antioxidants needed to limit oxidative injury.

Careful monitoring and diligent nursing care are vital to successful management. Physical examination parameters that characterize tissue perfusion (i.e., mucous membrane color, capillary refill time, heart rate, respiratory rate, and pulse quality) should be assessed frequently. Oxygenation and blood pressure should be monitored continuously or as often as feasible in the early phase of treatment, with the goals of maintaining oxygen saturation above 97% (PaO_2 greater than 90 mm Hg) and mean arterial blood pressure above 80 mm Hg. Likewise, $PaCO_2$ should be monitored to assess for adequate ventilation. The blood glucose, hematocrit, and total protein concentrations should be checked at least twice daily to ensure adequate fuel, oxygen-carrying capacity, and oncotic pressure. Sampling from the jugular vein should be avoided, because even temporary

411
412

occlusion of this vessel can result in a rapid elevation in ICP. Given the propensity for excessive free water loss through the kidney with mannitol therapy, at minimum, electrolytes (particularly sodium) should be measured daily and urine output should be quantified. An effort should be made to adjust fluid input to account for ongoing losses.

Nursing care should focus on provision of adequate bedding, frequent turning, and passive range of motion physical therapy on the limbs to prevent pressure sores and limb contraction. The eyes should be lubricated frequently if the palpebral reflex is absent. Also, if an indwelling urinary catheter is not in place, the bladder should be manually expressed in animals that do not urinate voluntarily. Colonic enemas may be required.

Initially the neurologic status should be evaluated and recorded hourly to assess the response to treatment. The Small Animal Coma Scale, a modification of the Glasgow Coma Scale used in human medicine, has been developed for veterinary medicine to allow quantitative scoring of the severity of neurologic injury. This scale recently was validated retrospectively in dogs with head trauma and was shown to correlate with the 48-hour outcome. Serial evaluation of scores can be used to objectively evaluate improvement or deterioration over time.

Successful management of the dog or cat with severe TBI can be a rewarding experience. When neurologic signs have improved or reached a static level and the pet is able to maintain hydration and nutritional requirements (voluntarily or with a feeding tube), it can be sent home. Neurologic recovery may be completed over a period of time, or residual deficits may persist. Owners need to be dedicated and educated to the fact that substantial caretaking may be required of them once their pet has been sent home.

114 CHAPTER • 114 Crystalloid and Colloid Fluid Therapy

Rebecca Kirby

Elke Rudloff

The goal of fluid resuscitation and maintenance is to restore perfusion and hydration while preventing volume overload and its complications of pulmonary, peripheral, and brain edema. The choice of the type and amount of crystalloid or colloid fluid to use begins with determination of where the fluid deficit is located. Capillary dynamics and the composition of the fluids administered govern how those fluids are distributed. The challenge is to deliver the right fluid, in the right amount, at the right time.

114.1 FLUID COMPARTMENT AND CAPILLARY DYNAMICS

Fluids and solutes are dispersed among the intracellular, interstitial, and intravascular compartments. The rate and volume of distribution within these spaces depends on membrane permeability, capillary dynamics (Starling's forces), and osmotic forces (Figures 114-1 and 114-2). Intracellular compartments are surrounded by membranes permeable to water but not to most charged particles (e.g., sodium). The space between blood vessels and cells is the interstitial compartment. Filtering and exchange of interstitial fluid are critical for cellular metabolism and survival. The arteries, veins, and capillaries contain the fluid of the intravascular compartment. Starling's forces affect the volume of fluid exchanged between the intravascular and interstitial compartments.

114.2 FLUID CHARACTERISTICS

The number, charge, and size of the particles in water, together with capillary dynamics, determine the movement of that fluid throughout the different fluid compartments. The dynamics of the various fluid compartments change during critical illness and shock. Inflammatory mediator action at the postcapillary venule causes endothelial cells to contract, resulting in large interendothelial gaps. Intravascular albumin (69,000 daltons) and other similar-sized molecules pass across the capillary membrane into the interstitium. The characteristics of a particular fluid affect the distribution of that fluid between the fluid compartments.

By osmosis, water passes through the membrane toward the side with the greater concentration of solutes. *Osmolality,* the osmotic pressure generated by a solution (in milliosmoles per kilogram of H_2O), opposes movement of water across a membrane. Sodium is the most significant osmotic ion in the extra-cellular space. The ability of a solution to move water across the cellular membrane depends on the osmolality of the solution compared to the intracellular osmolality; this is called *tonicity*. The tonicity of the administered fluid determines the resultant fluid shifts between the body compartments (Figure 114-3).

Proteins are the only dissolved substances in the plasma and interstitial fluid that do not readily cross the capillary membrane. Proteins are responsible for the osmotic pressure at the capillary membrane, called the *colloid osmotic pressure (COP)* or *oncotic pressure*. A serum protein concentration of 5.2 to 5.4 g/dL creates a COP of 17 mm Hg. When the serum protein falls below this range, the intravascular COP may be reduced. The type of fluid selected for therapy depends on the fluid's osmotic and colloidal properties and on the compartment requiring fluid.

Figure 114-1 Cross section of a capillary. Lipid-soluble molecules, such as oxygen and carbon dioxide, diffuse through the interstitial and intravascular space. Non-lipid-soluble particles, to include water, must pass through intercellular clefts between endothelial cells. Colloid molecules that are too large to pass through the membrane cleft are retained in the capillary.

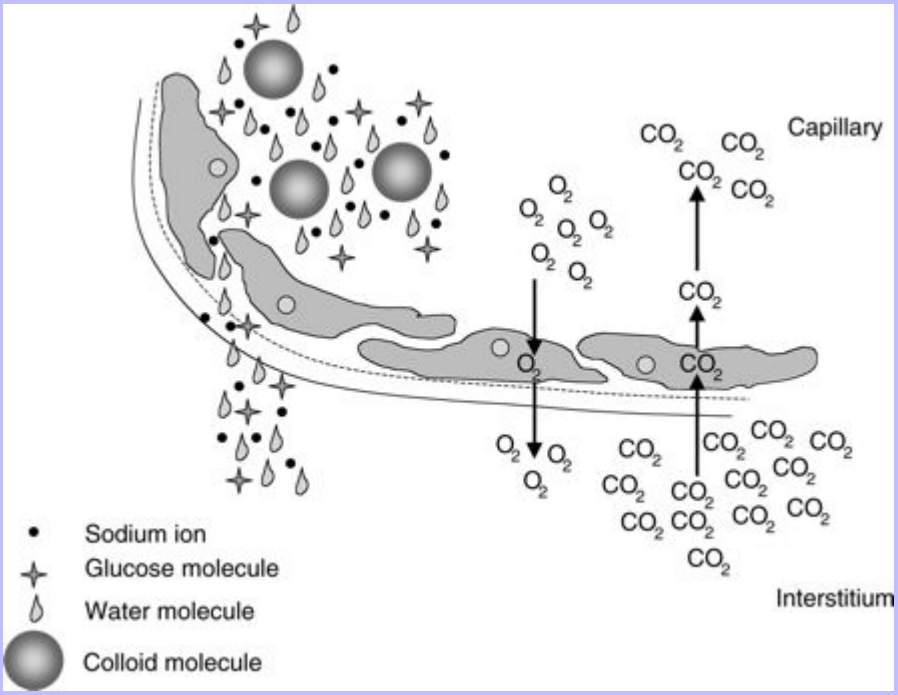

Figure 114-2 Illustration of Starling's forces between the intravascular and interstitial compartments. The intravascular and interstitial fluid compartments are separated by a semipermeable membrane. In solution in the intravascular compartment are large molecular weight molecules, called colloids, that cannot easily cross the membrane because of the minute size of the membrane pore. The force exerted on the membrane from the osmotic gradient created by these colloids is the colloid osmotic pressure (COP). The smallest and most numerous of the protein particles in plasma that create COP is albumin (~69,000 daltons). The overall negative charge of albumin increases its osmotic capability by 50% (called the Gibbs-Donnan effect). Whether fluid remains in the intravascular space or moves into the interstitium is the result of the cumulative effects of Starling's equation. The volume of fluid *(v)* that filters between the capillary *(c)* and interstitium *(i)* across the capillary wall depends on the interendothelial pore size *(sigma),* the pore's reflection coefficient *(kf),* and transcapillary forces of hydrostatic pressure *(P)* and COP, which oppose lymph removal *(Q)* of fluid. Intravascular fluid moves into the interstitial space when (1) Pc (capillary hydrostatic pressure) is increased over COPc (capillary colloid osmotic pressure); (2) capillary membrane pore size increases; or (3) COPc drops below COPi (capillary hydrostatic pressure).

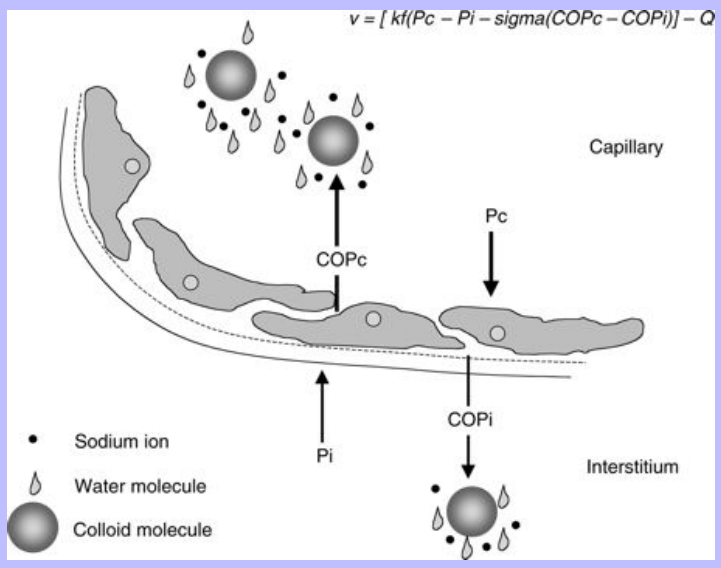

Figure 114-3

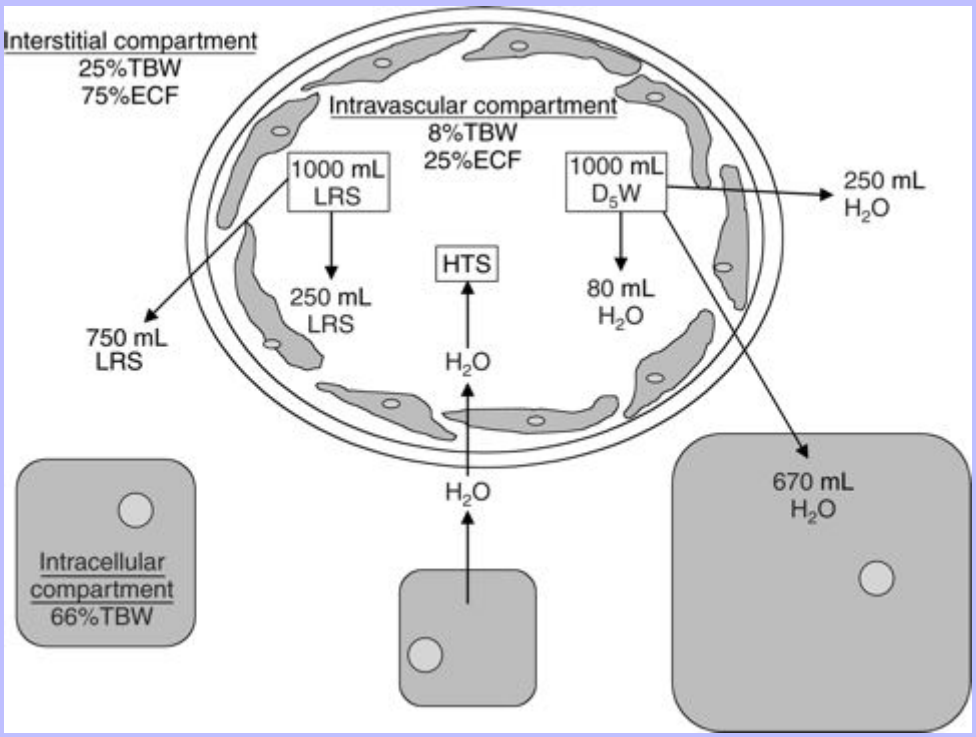


Tonicity and the distribution of various crystalloid fluids between body fluid compartments. Sixty percent of body weight is water. Of this water (total body water [TBW]), 66% is intracellular and 33% is extracellular fluid (ECF). Of the TBW that is extracellular, 25% is intravascular and 75% is interstitial. The membrane separating the intravascular and interstitial compartments is freely permeable to water and small ions, whereas the membrane surrounding the intracellular space is permeable only to water.

When solute-free water (e.g., D_5W), which has no osmotically active particles, is infused, it is distributed according to each body water compartment's percentage of TBW. Infusion of 1 L of solute-free water results in a net intravascular expansion of only 80 mL after 30 minutes of equilibration time.

When a hypertonic solution (HTS) is infused (e.g., 7% hypertonic saline or mannitol), the high concentration of osmotically active solutes draws water from the interstitial space into the intravascular space. The resulting increase in interstitial osmolality forces intracellular water to flow out into the interstitial space.

When a solution isotonic with plasma (e.g., LRS, Plasmalyte-A, Normosol-R) is infused, no alteration occurs in extracellular osmolality, and water remains in the extracellular space. Therefore, after infusion of 1 L of an isotonic solution, 250 mL remains in the intravascular space and 750 mL flows into the interstitial space after 45 minutes of equilibration time.

114.3 FLUID SELECTION

The two major types of fluid administered are crystalloids and colloids. A *crystalloid* fluid is a water-based solution with small molecules that are permeable to the capillary membrane. A *colloid* fluid is a crystalloid solution that contains large molecules that are not readily permeable at the capillary membrane. The most commonly used crystalloids, colloids, and hemoglobin-based oxygen carriers (HBOCs) and their specific characteristics are listed in Table 114-1.

114.3.1 Crystalloids

Crystalloid fluids replace and maintain extracellular volume. Because 75% to 80% of the isotonic crystalloids administered intravenously move to the extravascular space within 1 hour in a normal animal, crystalloids are necessary for interstitial rehydration (see Figure 114-3). The needs of the patient are weighed against the specific electrolyte concentration, osmolality, and pH of the fluid selected.

The sodium and glucose concentrations of crystalloids determine the osmolality and tonicity of the fluid and therefore the distribution between the fluid compartments. In most critical situations, an isotonic, balanced electrolyte *replacement* crystalloid solution, such as lactated Ringer's solution (LRS), Plasmalyte-A, or Normosol-R, is used to replace electrolytes and buffers in concentrations typical of the extracellular fluid. Normal saline (0.9% sodium chloride solution) is also an isotonic replacement fluid but is not “balanced” with electrolytes or buffers.

Hypotonic solutions, such as 5% dextrose in water (D_5W), contain water in excess of solutes. Once the dextrose has been rapidly metabolized, the remaining water is distributed among all fluid compartments (see Figure 114-3). The use of hypotonic fluids should be restricted to slow infusion to replace calculated free water deficits; slow administration of constant-rate infusion drugs; or combination with replacement fluids to create half strength *maintenance* fluids.

414

415

Crystalloid solutions are made hypertonic by the addition of sodium or glucose. Hypertonic crystalloids comprise 3%, 7%, and 7.5% saline and 5% glucose in replacement solutions. The concentrated solutes produce an osmotic gradient, drawing water into the vascular space after intravenous administration (see Figure 114-3 for more information). If ongoing loss of plasma water is a factor or if the interstitium is dehydrated, these fluids should be avoided. Hypertonic saline is often combined with colloids to prolong intravascular volume retention.

The basal need for solute-free water by the cells directs the sodium concentration in *maintenance* fluids to be approximately 50% of the plasma concentration. Potassium requirements for maintenance are up to three times the replacement fluid concentrations. Maintenance crystalloid solutions are made isotonic by the addition of glucose to make a 2.5% concentration.

114.3.2 Colloids

Colloid solutions are primarily intravascular volume-replacing fluids (see Table 114-1). Whole blood, plasma products, and concentrated albumin contain natural colloids in the form of proteins, primarily albumin. Dextran 70 and hydroxyethyl starches (hetastarch and pentastarch) are synthetically derived colloids. It is the difference in their macromolecular structure and weight that dictates their colloid osmotic effect, method of excretion, and solution half-life. The greater the number of small molecules per unit volume, the greater the initial colloid

osmotic effect and plasma volume expansion. Colloid solutions, in order of greatest plasma volume expansion, are 25% albumin, dextran 70, Oxyglobin, pentastarch, hetastarch, whole blood, and plasma. Often a combination of colloid solutions is the best therapeutic approach.

114.3.2.1 Natural Colloids

Natural colloid solutions are selected when the animal requires a colloid (albumin) as well as red blood cells, coagulation proteins, and/or antithrombin. A concentrated 25% albumin solution is available for rapid, low-volume resuscitation. In humans, 25% albumin is administered to the edematous patient who requires intravascular volume resuscitation. Although concentrated canine and feline albumin is not readily available, the human form has been used therapeutically in hypoalbuminemic dogs.

Dogs and cats receiving red blood cells in any solution should be blood typed and cross-matched. If time is a limiting factor, a dog erthrocyte antigen (DEA) 1.1-negative transfusion is preferred for the dog. Blood products should be warmed to normal body temperature prior to infusion and administered within 6 hours via an 18-μmicropore filter. The serum calcium should be monitored during multiple transfusions. Administration of large volumes of blood products can also cause a dilutional coagulopathy.

114.3.2.2 Synthetic Colloids

Synthetic colloid solutions were developed to provide timely and convenient fluid resuscitation while increasing the COP beyond that attainable with natural colloid solutions. They can be used in conjunction with whole blood or plasma but are not considered a substitute for blood products when albumin, red blood cells, antithrombin, or coagulation proteins are needed. Dextrans and hydroxyethyl starches (HES) are synthetic colloids, each with a pharmacology, specific qualities, and potential side effects that make it unique (see Table 114-1). The selection of a specific synthetic colloid is based on these individual characteristics.

114.3.3 Hemoglobin-Based Oxygen Carriers

Stroma-free hemoglobin solutions (e.g., Oxyglobin) are hemoglobin-based oxygen carriers (HBOCs) made of polymerized bovine hemoglobin suspended in LRS. These solutions have colloidal properties similar to those of heta-starch and exert a vasopressor effect. Administration of HBOCs improves oxygen saturation in the pulmonary capillary, with oxygen release at the tissue capillary at oxygen pressures of 40 mm Hg. Dosages up to 30 mL/kg/day have been approved for use in anemic dogs, with the rate of infusion equal to or less than 10 mL/kg/hour. When a HBOC is used in an animal with normal blood volume, slow administration and careful monitoring are necessary to prevent volume overload.

114.4 FLUID THERAPY PLAN

The fluid therapy plan must be adequate to replace fluid deficits in a timely manner, to replace continuing losses, and to meet the patient's ongoing requirements. Normal kidney and cardiovascular systems can correct most fluid therapy miscalculations, but these functions may be compromised in a critically ill animal. Often the clinician is challenged to promote organ perfusion while avoiding life-threatening interstitial edema. A fluid therapy plan should be formulated in a logical sequence, using end-point resuscitation techniques.

114.5 RESUSCITATION

During resuscitation, fluid therapy rapidly replaces a fluid deficit that is causing or has the potential to cause life-threatening organ compromise. A fluid deficit in the intravascular space manifests primarily as a *perfusion* problem. With a fluid deficit in the interstitial or intracellular space, the physical signs reflect a *hydration* problem.

114.5.1 Perfusion

Perfusion problems are manifested as changes in the heart rate, pulse intensity, mucous membrane color, capillary refill time, and rectal temperature. Resuscitation of perfusion deficits associated with hypovolemia requires rapid intravascular volume expansion by intravenous or intraosseous routes of administration. Fluid selection and doses are in part based on the animal's cardiovascular status and emergency data base (packed cell volume; total protein; serum glucose; sodium, calcium, potassium, and blood gas values; Table 114-2 and Box 114-1).

Crystalloids can be administered without colloids; however, perfusion end-points (Table 114-3) may be more difficult to reach without complications of edema. Large volumes of crystalloids rapidly administered intravenously cause an immediate increase in intravascular hydrostatic pressure and a reduction in COP, leading to extravasation into the interstitium. Extreme care must be taken when crystalloids alone are administered during resuscitation of animals with pathology of the brain, lungs, kidneys, or heart. The total amount of fluid required for resuscitation may be less or more than the estimated plasma volume (50 to 60 mL/kg in the dog; 40 to 50 mL/kg in the cat), requiring titration of volumes to effect.

Resuscitation using both colloids and crystalloids requires less volume and achieves faster resuscitation times. When colloid is added, crystalloid infusion rates can be reduced by 40% to 60% of that required if crystalloids were used alone. Synthetic colloids increase the COP effect, resulting in an increase in intravascular volume greater than the volume infused. Resuscitation of conditions with increased capillary permeability necessitates selection of a solution containing colloids larger than the pore size of the capillaries. This makes hetastarch, pentastarch, or stroma-free hemoglobin the preferred colloids. When the animal requires red blood cells, clotting factors, antithrombin, or albumin, natural colloids are the administered products. With natural colloids, the blood volume is increased by an amount equal to the amount infused. A combination of crystalloid, synthetic colloid, and natural colloids often is required to meet the patient's needs.

415

419

Table • 114-1 Characteristics of Crystalloids and Colloids

NAME	FLUID COMPARTMENT	OSMOLARITY (mOsm/L)	pH	Na^+ (mEq/L)	Cl^- (mEq/L)	K^+ (mEq/L)	Mg^{++} (mEq/L)	Ca^{++} (mEq/L)	DEXTROSE (g/L)	BUFFER	COP (mm Hg)	ADDITIONAL CHARACTERISTICS
CRYSTALLOID												
Replacement												
0.9% Saline	Extracellular	308 (isotonic)	5.0	154	154	0	0	0	0	None	0	Fluid of choice for treating hyperkalemia or hypochloremia associated with alkalosis.
Lactated Ringer's solution	Extracellular	275 (isotonic)	6.5	130	109	4	0	3	0	Lactate	0	Should not be administered in the same lines with citrate-containing transfusions.
Plasmalyte-A (pH 7.4)	Extracellular	294 (isotonic)	7.4	140	98	5	3	0	0	Acetate, gluconate	0	
Normosol-R	Extracellular	295 (isotonic)	5.5–7	140	98	5	3	0	0	Acetate, gluconate	0	
7% Saline	Extracellular	2396 (hypertonic)		1197	1197	0	0	0	0	None	0	Should not be used in a dehydrated patient or during hyperosmolar disease states.
5% Dextrose in water	Intracellular	252 (hypotonic)	4.0	0	0	0	0	0	50	None	0	Primarily used as a carrier for constant rate infusion drugs.
Maintenance												
2.5% Dextrose in ½ strength lactated Ringer's solution	Extracellular	264 (isotonic)	4.5–7.5	65.5	55	2	0	1.5	25	Lactate	0	
ProcalAmine	Extracellular	735 (hypertonic)	6–7	35	41	24	5	0	30	Acetate, phosphate	0	Contains 3% amino acid solution + 3% dextrose; beneficial during partial anorectic states.
3% FreAmine III	Extracellular	405 (hypertonic)	6–7	35	41	24	5	0	0	Acetate, phosphate	0	Contains 3% amino acid solution; beneficial during partial anorectic states.
COLLOID												
Natural												

Fresh whole blood	Intravascular	300 (isotonic)	Variable	140	100	4	0	0	0–4	None	20	Contains red blood cells, albumin, fibrinogen, globulins, alpha macroglobulins, coagulation proteins, and antithrombin. Factors V and VIII and platelets are absent in stored whole blood.
Stored whole blood												
Fresh frozen plasma, frozen plasma	Intravascular	300 (isotonic)	Variable	140	110	4	0	0	0–4	None	20	Contains albumin, fibrinogen, globulins, alpha macroglobulins, coagulation proteins, and antithrombin. Factors V and VIII are absent in frozen plasma.
25% Albumin	Intravascular	300 (isotonic)	Variable	130–160	0	1	0	0	0	None	100	Used during resuscitation of hypovolemic, edematous states. Slow infusion is used during hypoalbuminemic states.
Synthetic												
6% Hetastarch	Intravascular	310 (isotonic)	5.5	154	154	0	0	0	0	None	30	Molecular weight range is 10,000–3,400,000 daltons. Half-life is 25 hours. May increase plasma amylase and coagulation times.
10% Pentastarch	Intravascular	326 (isotonic)	5.0	154	154	0	0	0	0	None	25	Molecular weight range is 10,000–1,000,000 daltons. Half-life is 2.5 hours. May increase plasma amylase and coagulation times.

Dextran 70	Intravascular	310 (isotonic)	3–7	154	154	0	0	0	0	None	60	Molecular weight range is 15,000–160,000 daltons. Half-life is 25 hours. May increase coagulation times.
Hemoglobin-Based Oxygen Carriers												
Stroma-free hemoglobin (e.g., Oxyglobin)	Intravascular	300 (isotonic)	7.8	150	118	4	0	4	0	Lactate	40	Molecular weight range is 65,000–500,000 daltons. Half-life is 30–40 hours. Higher doses may result in darkening of plasma color, which may affect serum and urinalysis results.

Na^+, Sodium; Cl^-, Chloride; K^+, potassium; Mg^{++}, magnesium; Ca^{++}, calcium.

Table • 114-2 Emergency Data Base Information That Guides Formulation of a Fluid Therapy Plan

TEST	VALUE	COMMENTS
PCV (%)	≤20 or declining trend	Administer RBCs or HBOCs.
	>60	Causes hyperviscosity. Need rapid and aggressive hemodilution with crystalloids (+/– colloids).
Total protein (g/dL)	<5.0	Administer hetastarch during resuscitation and maintenance.
	>9.0	Need rapid and aggressive hemodilution with crystalloids (+/– colloids).
Glucose (mg/dL)	<60	May require 0.5 g/kg IV dextrose bolus.
	>400	Use slow rehydration to avoid rapid drop in plasma osmolality and cerebral edema. May require insulin therapy after resuscitation.
Sodium (mEq/L)	≥175 or ≤130 mEq/L	Give small volume resuscitation with 0.9% saline.
Potassium (mEq/L)	≥8.0	Use 0.9% saline if oliguric.
	≤2.0	Supplement resuscitation fluids if respiratory muscle fatigue is present.
	2.0–5.5	Supplement maintenance fluids.
Total calcium (mg/dL) (corrected value)	≥13.0	Use 0.9% saline for calciuresis.
pH and bicarbonate	Metabolic alkalosis	Use 0.9% saline if patient is hypochloremic.
	Metabolic acidosis	Aggressive fluid resuscitation usually corrects acidemia; recheck values after resuscitation.

RBC, Red blood cells; *HBOC*, hemoglobin based oxygen carrier; *PCV*, packed cell volume.

114.5.1.1

Box • 114-1 Steps for Formulating a Fluid Therapy Plan

1. Determine whether a fluid deficit exists based on the physical examination findings.

a. Poor perfusion (intravascular loss): Consider colloid and isotonic replacement crystalloid combination.

b. Dehydration (interstitial loss): Use isotonic replacement crystalloid.

2. Determine the resuscitation technique and end-points to be used.

a. Small volume resuscitation is used in the cat (Figure 114-5).

b. Most causes of hypovolemic shock in the dog warrant rapid intravascular resuscitation (Figure 114-4).

c. Complications such as heart disease, hemorrhage, lung or brain pathology, hyperglycemia, or hypernatremia warrant small volume resuscitation (Figure 114-4).

3. Assess the emergency data base (Table 114-2).

4. Determine which crystalloid to administer.

a. Each fluid therapy plan incorporates crystalloids.

b. A balanced isotonic crystalloid (e.g., Plasmalyte-A, Normosol-R, LRS) is usually selected for initial resuscitation.

c. 0.9% saline is used if hypernatremia, hyponatremia, hypercalcemia, hypochloremic metabolic alkalosis, or oliguric renal failure is a factor.

5. Determine which colloid to administer if poor perfusion is the result of hypovolemia.

a. Hetastarch is the colloid of choice if systemic inflammatory response syndrome is anticipated or if the patient is hypoalbuminemic.

b. Dextran 70 can be used for initial resuscitation if systemic inflammatory response syndrome is not suspected.

c. Anemia (PCV ≤20% or rapidly declining) may require administration of whole blood, packed red cells with a colloid, or stroma-free hemoglobin.

6. Evaluate for vascular leakage, vasodilatation, and third spacing of body fluids, which may require larger volumes of fluid to reach end-points of resuscitation.

7. If unable to reach or maintain end-points of resuscitation:

a. Evaluate for causes of nonresponsive shock (e.g., inadequate volume replacement, ongoing hemorrhage, ongoing fluid loss, heart failure, brain failure, hypoglycemia, hypoxia, hypokalemia, excessive vasodilatation/vasoconstriction).

b. Consider administering Oxyglobin in 5 mL/kg increments (dogs) for vasopressor and COP effects if not used previously.

c. Consider administering dopamine (5 to 15 µg/kg/min) as a constant-rate infusion.

8. After perfusion has been restored (Table 114-5), estimate the percentage of dehydration and calculate the fluid deficit.

    a. % Dehydration × Body weight (kg) = Fluid deficit (L)

    Example: 30 kg dog that is 10% dehydrated:

    0.10 × 30 = 3.0 L fluid deficit

9. Rehydration therapy may require a crystalloid different from that used to resuscitate the perfusion deficit.

114.5.1.1.1 Maintenance Fluid Plan

1. Estimate ongoing losses caused by vomiting, diarrhea, third spacing of body fluids, and polyuria.

    a. Use isotonic balanced replacement crystalloid fluids (e.g., Plasmalyte-A, Normosol-R, or LRS).

    b. Use 0.9% saline if hypernatremia, hyponatremia, hypercalcemia, hypochloremic metabolic alkalosis, or oliguric renal failure is a factor.

    c. Add crystalloid (2 mL/kg/h; see steps 2a and 2b below) to the volume of the estimated ongoing losses.

    d. Supplement potassium in fluids:

Serum Potassium (mEq/L)	Potassium Supplementation
4.0–5.5	5 mEq/250 ml fluids
3.0–3.9	7 mEq/250 ml fluids
2.5–2.9	8 mEq/250 ml fluids
≤2.5	10 mEq/250 ml fluids

2. Maintenance crystalloid fluids (see Table 114-1) are selected when no ongoing losses are present.

    a. Administer 2 mL/kg/h to replace free water and electrolytes consumed during metabolism and insensible losses.

    b. Dosage increases 1–2 mL/kg/h if fever or hyperpnea is present.

3. During anesthesia, replacement crystalloids (5–8 mL/kg/h) are used for maintenance.

    a. Adjust potassium supplementation according to the fluid rate; potassium-supplemented fluids are not used for rapid volume replacement.

    b. Keep warm bags of replacement crystalloids that do not contain potassium supplementation within easy reach, in the event rapid, large-volume boluses are required for resuscitation during the period of anesthesia.

4. For hypernatremia (Na^+ ≥170 mEq/L) with normal perfusion and hydration: Replace solute free water using maintenance crystalloids.
    a. [(Measured Na^+ – 140)/140] × Body weight (kg) × 0.3 = Free water deficit (L).
    b. Replace free water deficit over 24 to 48 hours: Lower 1 mOsm/kg/h.
    c. Add volume for metabolism and insensible losses (see steps 2a and 2b, above).

114.5.2 Rapid Intravascular Volume Resuscitation for Dogs

Dogs experiencing shock due to hypovolemia or maldistribution of blood flow from nontraumatic causes can benefit from rapid intravascular resuscitation techniques (Table 114-4). Whole blood products can be administered rapidly in catastrophic hemorrhagic situations, with input at least matching ongoing losses. Additional colloids can be administered using small volume intravascular resuscitation techniques if perfusion has not improved to the desired end-point after the initial bolus (see Figure 114-5). Rapid intravascular volume resuscitation techniques are not recommended in the cat in shock.

114.5.3 Small Volume Intravascular Resuscitation

Hypovolemic dogs with closed cavity hemorrhage, head trauma, pulmonary contusions, cardiogenic shock, oliguric renal failure, hypernatremia, or hyperglycemia can benefit from careful resuscitation using small volume intravascular resuscitation techniques (Figure 114-4). This also applies to all hypotensive cats (Figure 114-5). Hypothermia, especially in the cat, can significantly blunt cardiovascular responses to fluid resuscitation. Active external warming should occur once fluid resuscitation has been initiated. The goal is to reach a rectal temperature above 98°F within 30 minutes to maximize cat-echolamine receptor response. If no heart disease is present, small volume resuscitation efforts with crystalloids and synthetic colloid infusion is continued until the desired endpoints are obtained.

When the dose of hetastarch and dextran 70 exceeds 40 mL/kg/day in the dog and 20 mL/kg/day in the cat, plasma transfusions may be necessary to maintain adequate coagulation times. Stroma-free hemoglobin can be used in the dog, the total not exceeding 30 mL/kg/day. If the arterial blood pressure remains below 70 mm Hg after the maximum recommended doses have been administered, an investigation into causes of nonresponsive shock (e.g., severe vasodilatation/vasoconstriction, cardiac dysfunction) should be started, and administration of dopamine (5 to 15 µg/kg/min in a constant-rate infusion [CRI]) or stroma-free hemoglobin (if not yet used) should be considered for vasopressor effects.

114.5.4 Rehydration

Fluid deficit in the extravascular space (interstitial and intracellular) causes *dehydration*. Severe dehydration can lead to impaired perfusion due to fluid movement from the intravascular space to the dehydrated interstitium. To replenish the interstitial space, crystalloid fluids isotonic to plasma that contain specific electrolytes based on the patient's needs should be administered (see Table 114-1). The amount of crystalloid is determined by using physical parameters to estimate the percent dehydration (see Box 114-1 and Table 114-5). Intravenous or intraosseous administration of the fluid is preferred, although subcutaneous routes can be used.

The rate of administration should be determined by the urgency of the situation. Acute loss warrants acute replacement over 1 to 4 hours. Chronic losses or dysfunction of the lungs, heart, or brain usually require slower resuscitation rates, over 4 to 12 hours. The total amount given and the rate of administration should be determined by monitoring for specific endpoint parameters (see Table 114-3).

Table • 114-3 End-Point Parameters Monitored During Resuscitation

PARAMETER	NORMAL	COMPENSATORY STAGE	EARLY DECOMPENSATORY STAGE	LATE DECOMPENSATORY STAGE	RESUSCITATION END-POINT	TECHNICAL NOTES
Mentation	Alert	Excited and alert	Normal to decreased	Decreased to comatose	Alert	
Heart rate (beats/minute)	Dog: 60–120	Dog: >140	Dog: >140	Dog: <140	Dog: 80–140	Ensure pain relief.
	Cat: 170–200	Cat: Variable	Cat: Variable	Cat: <160	Cat: 180–220	Examine ECG with abnormal rate/rhythm and correct arrhythmia if contributing to perfusion deficit.
Mucous membrane color	Pink	Brick red	Pale	Grey/blue	Pink	Yellow color may also suggest icterus.
Capillary refill time (sec)	1–2	<1	>2	>2	1–2	Can be determined by examining gums, conjunctiva, vulvar/preputial membrane.
Mean arterial blood pressure (mm Hg)	80–100	>80	Variable	<80	80–100*	Renal blood flow is affected at MAP
					60–80**	<60 mm Hg; cerebral and coronary perfusion pressures are affected at MAP <70 mm Hg.
						Acute hypertension can occur with compensatory stages of shock.
Central venous pressure (cm H_2O)	0–2	Variable	<5	Variable	5–10*	Tip of catheter should be in the superior vena cava at the level of the right atrium.
					2–8**	Unexpected elevations can occur with right heart failure, loss of venous compliance, and increased intrathoracic pressure.
Urine output (mL/kg/h)	>1.67	Variable	<0.27	<0.08	>1	With decreased urine output, check for urine obstruction first (patent urine collection). MAP >60 mm Hg is required for adequate renal blood flow.

SpO_2	>97%	>97%	Falsely low levels can be caused by poor peripheral perfusion, dark pigmentation, bilirubinemia, and severe anemia. Falsely increased levels can be caused by carboxyhemoglobinemia or methemoglobinemia.
Packed cell volume	Dog: 40%–55% Cat: 30%–45%	25%–30%	Transfusion products containing red blood cells (whole blood, packed red cells) or a HBOC (in the dog) should be used; HBOCs do not change the PCV, therefore the hemoglobin level must be monitored. Ongoing hemorrhage must be controlled.
Hemoglobin (g/dL)	13.8–21.4	7–10	HBOC can be administered when the hemoglobin is <7 g/dL.
Albumin (g/dL)	2.6–3.9	>2.0	Plasma or albumin transfusion is required when the serum albumin is <2.0 g/dL.
Colloid osmotic pressure (mm Hg)	Dog: 21–25 Cat: 23–25	14–20	
Rectal temperature (°F)	100–102.5	98–102	

ECG, Electrocardiogram; *MAP*, mean arterial pressure; *SPO_2*, pulseoximeter hemoglobin saturation of oxygen; *HBOC*, hemoglobin based oxygen carrier; *PCV*, packed cell volume.

* Supranormal.

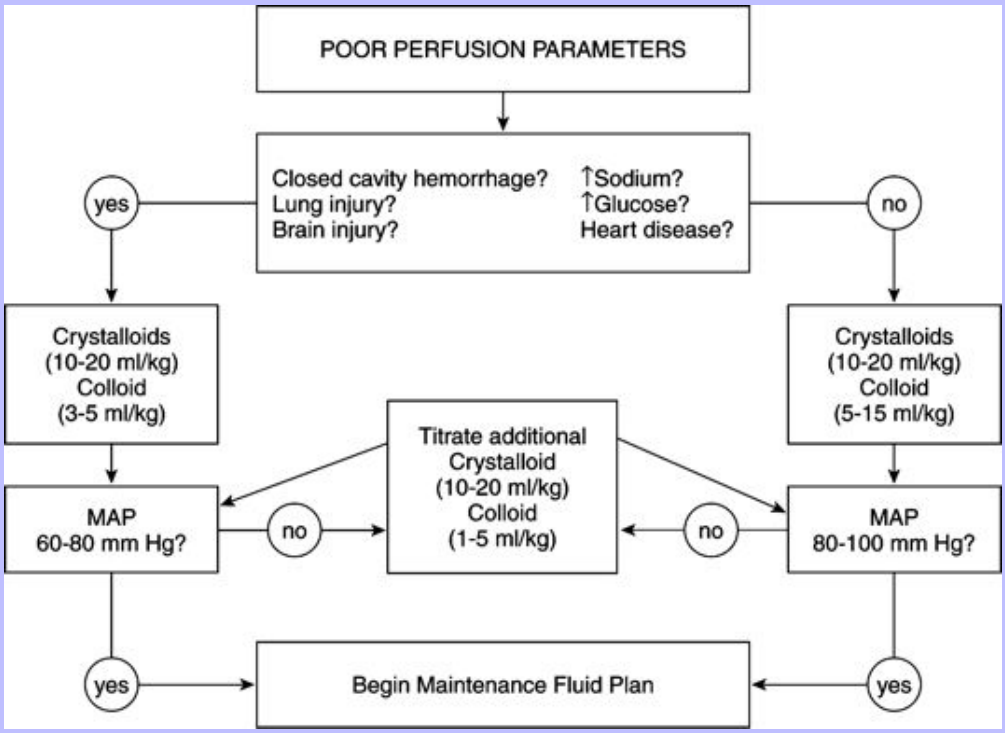
** Hypotensive.

Table • 114-4 Options for Fluid Types and Doses During Resuscitation

CARDIOVASCULAR STATUS	FLUID TYPE	COMMENTS
Compensatory shock	Isotonic crystalloid	If EP is not reached with several boluses, consider adding synthetic colloid.
	or	Treat for pain.
	Isotonic crystalloid + synthetic colloid	Not a condition typically seen in the hypovolemic cat.
Early decompensatory shock	Isotonic crystalloid	Rapidly correct hypothermia.
		Treat for pain.
	or	If EP is not reached with several boluses, consider adding synthetic colloid.
	Isotonic crystalloid + synthetic colloid	Rapidly correct hypothermia.
		Treat for pain.
		If EP is difficult to maintain, place patient on HES CRI, 0.8 mL/kg/h.
		Do not administer HTS to a dehydrated animal or one with pulmonary injury or cardiac disease.
Late decompensatory shock	Isotonic crystalloid + synthetic colloid	Rapidly correct hypothermia.
		Treat for pain.
	or	If EP is not reached with multiple boluses, consider administering vasopressors or oxyglobin boluses (5 mL/kg), up to 30 mL/kg/day (dog).
	Isotonic crystalloid + 7% HTS + synthetic colloid	If EP is difficult to maintain, place patient on HES CRI, 0.8 mL/kg/h.
	or	
Acute hemorrhage (PCV <25%; Hg <8 g/dL)	Whole blood	May require active hemostasis.
		Crossmatch and typing are preferred, time permitting.
	or	
	Packed red blood cells and/or	Can be reconstituted with isotonic saline, plasma, HES, or DEX.
	Oxyglobin	May require additional red cell transfusion.
Hypovolemia with pulmonary injury, head injury, or cardiac insufficiency	Isotonic crystalloid + HES	If EP is difficult to maintain, place patient on HES CRI, 0.8 mL/kg/h.
Low plasma albumin (<2.0 g/dL)	Plasma	Repeat as needed to increase albumin >2.0 g/dL and/or to normalize clotting times.
		Use fresh frozen plasma if factor V or VIII deficiency is present.
Coagulopathy (prolonged PT/PTT)		Consider heparin if DIC is suspected.
Low antithrombin		

HES, hydroxyethyl starch; *DEX,* dextran-70; *HTS,* hypertonic saline; *EP,* end-point; *CRI,* constant rate of infusion; *PCV,* packed cell volume; *Hg,* hemoglobin; *PT,* prothrombin time; *PTT,* partial thromboplastin time; *DTC,* disseminated intravascular coagulation.

Figure 114-4 Resuscitation technique for the dog with poor perfusion. Low-volume resuscitation (left arm of algorithm) is used when the consequences of fluid overload are life-threatening (e.g., lung, brain, or heart disease; closed cavity hemorrhage; or hyperosmolar condition). Low-volume bolus doses of crystalloid and colloid fluids are administered until the mean arterial pressure (MAP) is in the low-normal range. When the risk of fluid overload is not as likely, resuscitation fluid volumes are maximized (right arm of algorithm) to establish a high-normal MAP using larger volume boluses of crystalloid and colloid fluids. When the dose of colloid has reached 40 mL/kg without response, an investigation for causes of nonresponsive shock is begun, and use of vasopressors may be required.

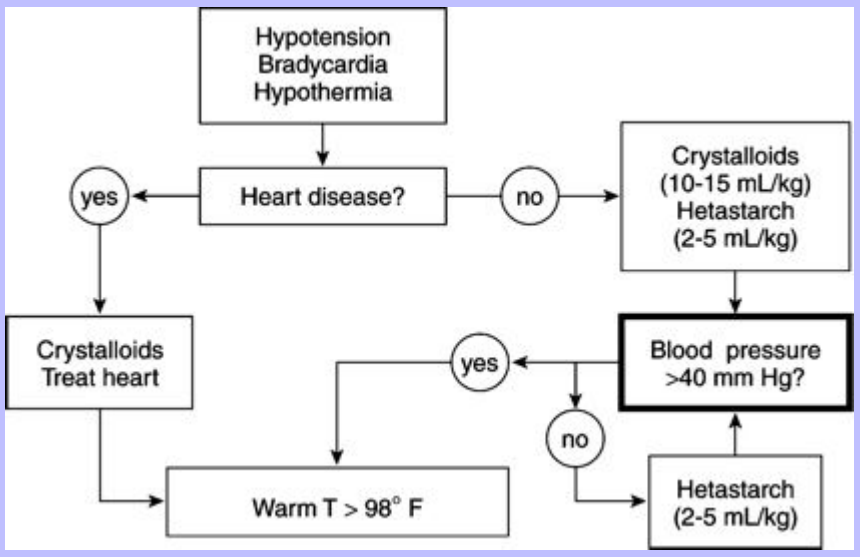


114.5.5 End-Point Resuscitation

Successful resuscitation therapy depends on the administration of quantities of fluids sufficient to reach specified endpoints. This process is termed *end-point resuscitation*. Prior to resuscitation, the clinician should determine the end-point values that will indicate successful resuscitation. Physical, hemodynamic, and blood

chemistry parameters are the mainstays of end-point monitoring (see Table 114-3). The inciting cause of the fluid deficit, as well as vital organ function, dictate the end-points selected and the end-point resuscitation techniques used.

Figure 114-5 Resuscitation technique for the cat with poor perfusion. When heart disease is suspected (auscultation of a murmur, arrhythmia, moist lung sounds, pleural effusion), isotonic replacement crystalloid fluids are administered at a maintenance rate; treatment of heart disease is instituted; and active external warming is provided. When poor perfusion is not attributed to heart disease, low volumes of crystalloid and colloid fluids are administered in bolus doses until the blood pressure registers above 40 mm Hg, and the cat is actively warmed. When the dose of colloid has reached 20 mL/kg without response, an investigation for causes of nonresponsive shock is begun, and use of vasopressors may be required.



For hypovolemic shock and systemic inflammatory response syndrome (SIRS), if brain or lung compromise is not a factor, resuscitation of perfusion to supranormal values to increase oxygen delivery is recommended. Restoration of physical perfusion parameters (lower heart rate, stronger pulses, normal capillary refill time, and pink mucous membranes) is used in conjunction with hemodynamic parameters (e.g., packed cell volume [PCV], COP, arterial blood pressure, urine output, and central venous pressure) as a measure of therapeutic success.

423

424

Table • 114-5 Parameters Used to Estimate Interstitial Fluid Deficit

ESTIMATED % DEHYDRATION	CLINICAL PARAMETERS
4–6	Sticky mucous membranes
	History of vomiting, diarrhea, lack of water intake
6–8	Loss of skin moisture
	Dry mucous membranes
8–10	Loss of skin moisture
	Dry mucous membranes
	Sunken eyes
>12	Loss of skin moisture
	Dry mucous membranes
	Dull mentation
	Dull corneas
	Perfusion deficit present

Traumatic shock with closed cavity hemorrhage and/or brain hemorrhage warrants hypotensive resuscitation. The animal is resuscitated to end-points of improved physical perfusion parameters, but the target blood pressure is in the low-normal range (see Figure 114-4). This method is used to avoid dislodging clots that may be providing life-saving hemostasis.

114.5.6 Maintenance

Crystalloids are the mainstay of fluid therapy, and the type of fluid chosen is based on the needs of the animal (see Table 114-2 and Box 114-1). Maintenance fluids can provide electrolytes, COP support, proteins, coagulation factors, glucose, or nutrients, depending on the fluid selected and the way it is supplemented (see Table 114-1). Increased capillary permeability and hypoproteinemic states can require ongoing maintenance of COP by a constant-rate infusion of hetastarch combined with maintenance crystalloid.

Normal maintenance fluid rates account for insensible, obligatory (urinary and fecal), and metabolic losses of water and electrolytes. The standard crystalloid fluid maintenance requirement is estimated to be 40 to 60 mL/kg/day. Ongoing losses through diuresis, fever, vomiting, diarrhea, or extravasation of fluid into third body spaces should be estimated and replaced with isotonic replacement crystalloids. This estimated volume is added to the total daily “maintenance” volume requirement, and oral intake volumes should be subtracted. The maintenance fluid therapy plan must be reassessed for the duration of therapy, with adjustments made accordingly.

115 CHAPTER • 115 Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar Syndrome

Michael Schaer

Dogs and cats afflicted with either diabetic ketoacidosis (DKA) or hyperglycemic hyperosmolar syndrome (HHS) can become acutely ill and benefit from prompt diagnosis and treatment. These disorders usually occur in middle-aged to old pets, often after a variable period of time characterized by polydipsia, polyuria, and weight loss. Alternatively, they can occur as acute metabolic complications of other conditions, such as acute pancreatitis or sepsis. The primary pathophysiology, clinical signs, and medical management of these interesting and challenging disorders are discussed in this chapter. Certain clinical findings shared by the two syndromes are discussed in the section on ketoacidosis.

115.1 PATHOPHYSIOLOGY OF KETOACIDOSIS

Hyperglycemia and accelerated ketogenesis occur when there is an absolute or relative deficiency of insulin and a relative excess of glucagon and other "counter regulatory hormones" such as cortisol, growth hormone, and epinephrine. Consequently, glucose and ketoacids are both overproduced and underutilized. Because the pathophysiologic details of DKA are discussed elsewhere in this text and throughout the medical literature, only those germane to the care of the critically ill patient are mentioned in this section.

The nitroprusside reaction is used to detect and semiquantitate plasma, serum, and urinary ketones. The test detects acetone and acetoacetate but does not react with beta hydroxybutyrate. This characteristic has clinical importance in situations in which shocklike states promote the production of beta hydroxybutyrate, thereby disabling clinical detection of ketoacidosis with the nitroprusside test.

After institution of insulin treatment, the beta hydroxybutyrate to acetoacetate (B:A) ratio decreases as a result of the metabolism of beta hydroxybutyrate to acetoacetate. Although acetoacetate concentrations eventually decrease, the shifting B:A ratio explains the clinical paradox occasionally encountered in which test results initially are negative for ketones but, with the same test given on the second and third days of treatment, are positive despite clinical improvement. A lingering ketonuria can also occur as a dog or cat improves because of the delayed clearance of acetone. Therefore it is not uncommon for ketones to persist well into the third or fourth hospital day while the pet shows signs of improvement.

115.2 DIAGNOSIS

115.2.1 History and Physical Examination

The history for either DKA or HHS often indicates that anorexia, depression, weakness, and vomiting have been observed for only 1 to 3 days. A complete physical examination is essential to detect any concurrent disorders that can significantly affect the outcome. It has been suggested that both conditions are invariably associated with concurrent disorders. The term *diabetic coma* is frequently used to describe the mental effects of the ketoacidotic and hyperosmolar conditions, but only a small percentage of dogs or cats actually have profound decreases in consciousness.

115.3 DIAGNOSTIC EVALUATION

Medical evaluation of a sick diabetic dog or cat should be thorough and should include thoracic radiographs, abdominal ultrasound scans, hematology, serum chemistry, and urinalysis. The acquired information creates an important data base for subsequent medical and sometimes surgical management.

Because hepatic production of glucose is increased in diabetic dogs or cats, the degree of hyperglycemia is determined by the severity of plasma volume depletion. Therefore extreme levels of hyperglycemia tend to occur only when extracellular fluid volume and blood pressure have decreased so much that urine flow is impaired. This is most obvious in dogs or cats that have extreme increases in blood glucose concentrations with minimal glucosuria. Marked hyperglycemia may also signify oliguria.

Metabolic acidosis is mainly attributed to ketoacid buildup, but acidosis can be enhanced by coexisting disease, such as renal failure and lactic acid production. The metabolic acidosis often is accompanied by a large anion gap (AG) (greater than 30 mEq/L) that can be calculated using the following formula:

$$AG = (Na^+ + K) - (HCO_3^- + Cl^-)$$

Hyponatremia in both syndromes can be factitious (attributable to hypertriglyceridemia) or real (due to urinary or gastrointestinal loss of sodium ions). Spurious hyponatremia can also occur when increases in the plasma glucose concentration draw water into the extracellular space, thereby diluting plasma constituents.

The serum potassium concentration in DKA and HHS can range from low to normal to increased. Hyperkalemia can result from a shift of potassium from the intracellular to the extracellular space as a consequence of acidemia, insulin deficiency, and plasma hyperosmolarity. It may also be associated with oliguric or anuric acute renal failure.

Hypokalemia is the most common and most serious electrolyte disturbance. This is usually a reflection of a substantial reduction in total body potassium stores. Even patients with normokalemia may have a considerable deficit of total body potassium; because 98% of total body potassium is intracellular, these concentrations are not easily assessed. Potassium losses occur with vomiting and osmotic diuresis and can be further complicated by therapy. Serum dilution from rehydration, continued urinary losses, correction of acidosis, and increased cellular uptake can “unmask” hypokalemia.

Phosphorus is an integral component of lean body mass. The enhanced catabolism of muscle and fat that invariably occurs in diabetes mellitus results in increased urinary phosphorus excretion and phosphorus wasting.

Increased serum liver transaminase (ALT) and alkaline phosphatase (SAP) activity is commonly attributable to the hepatic lipidosis that occurs in patients with DKA. Hypovolemia-induced central lobular necrosis can also increase liver enzyme values. These hepatic changes are completely reversible, and serum liver enzyme activity moves toward normal after successful treatment. Because diabetic dogs and cats almost always have abnormal liver enzyme values, it is not common for these test results to completely “normalize.”

Azotemia can be either prerenal or renal in origin. Extensive primary renal dysfunction is characterized by isosthenuria (fixed urine specific gravity of 1.008 to 1.012) in a dehydrated patient and an accompanying azotemia that does not readily resolve with rehydration. It should be remembered, however, that both glycosuria and hyperosmolarity can raise a urine specific gravity that remains “isosthenuric” (a specific gravity of 1.020 when the serum osmolality is 400 does not indicate good renal function). Urine sediment should be screened for any signs of infection such as pyuria and bacteriuria. Urine output should be monitored to detect oliguria or anuria.

A leukocytosis with a mature neutrophilia in the 20×10^3 range can be due to the stress associated with both disorders. Detection of bands and toxic cell changes should prompt a search for an inflammatory focus, which may or may not be accompanied by an infection.

115.4 TREATMENT

115.4.1 Fluid and Electrolytes

Disturbances in hydration and electrolyte balance are of great importance in DKA and HHS and require expedient correction (Figure 115-1). The calculated fluid requirements include the patient's dehydration deficits, the 24-hour maintenance needs, and extra losses that result from vomiting or diarrhea. The dehydration status is approximated on a scale ranging from mild (5%) to extreme (12%). The needed isotonic crystalloid fluid replacement volume can be calculated using either of the following equations:

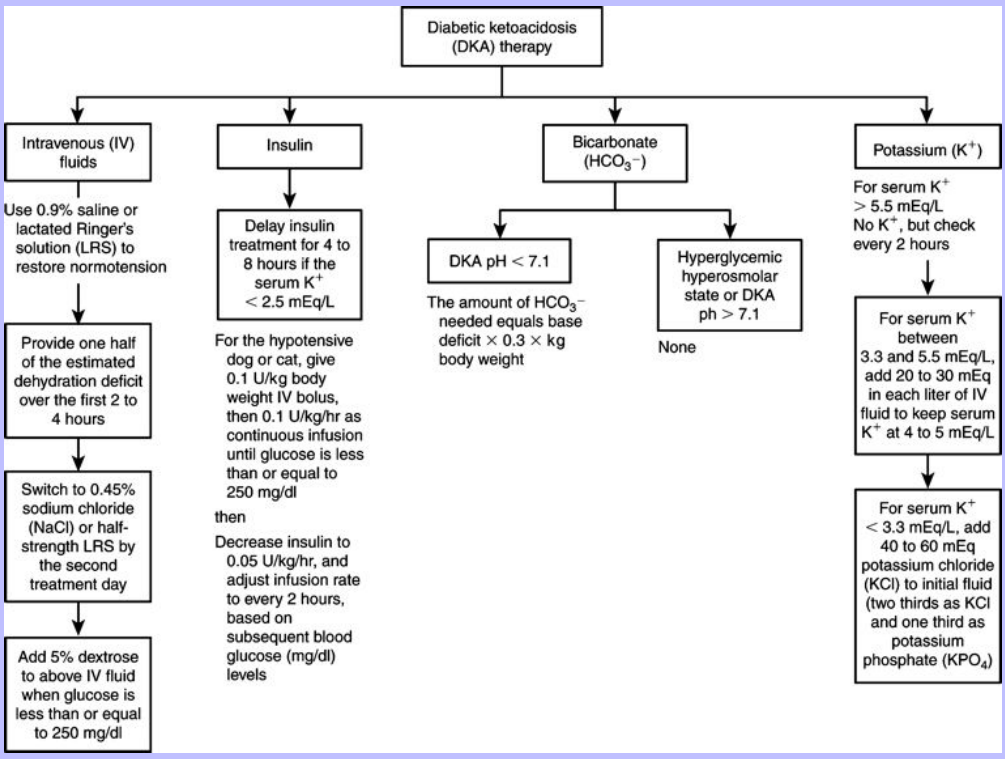
- Dehydration volume deficit (mL) = Dehydration (%) × Body weight (kg) × 1000
- Dehydration (%) × Body weight (lb) × 500

The 24-hour maintenance volume is roughly estimated (assuming adequate urine output) at 66 mL/kg (30 mL/lb). Therefore the first 24-hour total fluid volume is the sum of the dehydration and the maintenance volumes plus any ongoing losses from vomiting or diarrhea.

If the animal is 8% to 12% dehydrated, half of the estimated dehydration deficit should be administered intravenously over the first 2 to 4 hours of hospitalization; the remaining replacement and maintenance volumes, given over the following 20 to 22 hours, should be accompanied by any adjustments necessitated by changes in urine volume.

Hydration alone can substantially decrease the blood glucose level and hyperosmolarity. Hypovolemia in DKA and HHS is corrected with isotonic solutions, such as lactated Ringer's solution or 0.9% saline. Recommended maintenance solutions include 0.45% saline or half-strength lactated Ringer's solution. Dextrose solutions (2.5% to 5%) are used when the patient's blood glucose declines to 250 mg/dL or less in the setting of continued insulin administration.

Figure 115-1 Algorithm for the management of the critically ill dog and cat with diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar syndrome. (Modified from Umpierrez GE et al: Hyperglycemic crises in urban blacks. Arch Intern Med 157:669, 1997.)



425

426

Hyponatremia for both disorders is corrected with intravenous 0.9% saline solution to avoid any plasma hypo-osmolality that might occur when the hyperglycemia is reduced with insulin treatment. Plasma hypo-osmolality can cause a reversal of osmotic gradients and overexpansion of the intracellular compartment with resultant cerebral edema.

Potassium supplementation is best provided by adding potassium chloride solution to the parenteral fluids. If concurrent hypophosphatemia is present, one third of the potassium supplement can be in the form of potassium phosphate. Potassium supplementation is best begun after the first 2-hour period of fluid replacement, when hydration, blood pressure, and urine output are improved. If the patient is initially hypokalemic, potassium chloride (KCl) can be added to the hydrating solution; however, the infusion should be slowed so that half the dehydration replacement volume is delivered over an additional 1 to 3 hours. Although most texts list the maximum rate of potassium ion administration as 0.5 mEq per kilogram of body weight (BW) per hour, the author's experience has shown that this rate can be safely doubled when the patient is severely hypokalemic (serum potassium level less than 2.5 mEq/L) as long as electrocardiographic and urine output monitoring is done. The recommended amount of potassium that can be added to the parenteral fluids *over a 24-hour period* is shown, using two different but equally effective methods.

- *Mild hypokalemia* (serum K^+ of 3.0 to 3.5 mEq/L): administer 2 to 3 mEq/kg *or* add 20 to 30 mEq KCl per liter of replacement fluid
- *Moderate hypokalemia* (serum K^+ of 2.5 to 3.0 mEq/L): administer 3 to 5 mEq KCl/kg *or* add 40 to 60 mEq KCl per liter of replacement fluid
- *Severe hypokalemia* (serum K^+ below 2.5 mEq/L): administer 5 to 10 mEq KCl/kg *or* add 60 to 80 mEq KCl per liter of replacement fluid.

Daily serum electrolyte determinations and the necessary treatment adjustments are made until normal values are obtained. Intravenous fluids are discontinued when serum biochemistry values are normal, hydration is normal, and the patient is able to eat and drink without vomiting.

Any needed phosphate replacement can be given as potassium phosphate solution at the recommended dose of 0.01 to 0.03 mmol/kg BW/hour, with repeat serum phosphorus determinations every 6 hours. Attention should be given to avoiding iatrogenic hyperphosphatemia and hypocalcemia.

Hypomagnesemia has been shown to cause specific problems, especially cardiac arrhythmias, in diabetic humans; however, its association with any particular dysfunction in diabetic dogs and cats has not yet been demonstrated. The ionic and total bound forms of magnesium can be measured.

426

427

Sodium bicarbonate treatment for DKA is controversial. Advocates of this treatment cite concern that severe acidosis (blood pH less than 7.0) can adversely affect cardiovascular function; opponents base their concern on the treatment's causal relationship with paradoxical cerebrospinal fluid acidosis, hypokalemia, and worsened intracellular acidosis with overshoot alkalosis.

The use of sodium bicarbonate should be restricted to dogs or cats with a blood pH below 7.1 or those with a serum total carbon dioxide (CO_2) concentration less than 10 to 12 mEq/L. During most treatment courses, metabolic acidosis reverses without bicarbonate treatment because of the cessation of ketogenesis, the metabolic conversion of ketones to bicarbonate after initiation of insulin treatment, improved renal function, and conversion of the lactate in lactated Ringer's solution to bicarbonate. In severe cases of metabolic acidosis (i.e., an anion gap greater than 30 mEq/L and an arterial pH less than 7.1), sodium bicarbonate ($NaHCO_3$) can be given according to the following equation:

$$NaHCO_3\ (mEq) = \text{Base deficit (mEq)} \times 0.3 \times \text{Body weight (kg)}$$

Subsequent alkali treatment depends on the results of repeat plasma pH measurements; it should be discontinued when the blood pH has been restored to 7.2 or higher or until the serum total CO_2 concentration is greater than 10 to 12 mEq/L.

115.4.2 Insulin

The cornerstone of management of a sick DKA or HHS dog or cat is insulin administration. Regular crystalline insulin is used when the pet has signs of depression, dehydration, anorexia, and vomiting. Regular insulin has several advantages, including its various routes of administration (intravenous, intramuscular, and subcutaneous), rapid onset of action, and short duration of action. These properties allow adequate insulin titration throughout the day according to the animal's needs. The clinician must remember that the blood

glucose concentration declines much earlier than ketones, allowing for the persistence of ketonuria for the first 48 to 96 hours.

Regular insulin given intravenously by slow constant-rate infusion (CRI) is the preferred method of treatment for the critically ill hypotensive pet. The pet's hypovolemia should be partially corrected over the first 2 hours, before the insulin is administered.

A separate intravenous cannula is usually necessary for the insulin infusion. The CRI insulin solution is prepared by adding 5 U of regular insulin to a 500 mL bottle of 0.9% saline or lactated Ringer's solution to make up a solution that provides 0.01 U of insulin per milliliter. The infusion is delivered by an automatic injection syringe, an intravenous infusion pump, or a pediatric intravenous infusion set to deliver a therapeutic insulin dose of 0.1 U/kg BW/hour. To prevent binding of insulin to the intravenous lines, some clinicians prefer to run some of the diluted insulin infusion through the line before attaching it to the patient. Before this slow infusion is begun, the patient can receive an initial intravenous insulin bolus at a dosage of 0.1 U/kg. To avoid any complicating osmotic disequilibrium effects on the brain, the rate of decline in the blood glucose level should not exceed 75 to 100 mg/dL/hour. When the blood glucose level has declined to 250 mg/dL, after several hours of the CRI insulin infusion, the rate should be decreased to half the initial amount (i.e., 0.05 U/kg/hour), and dextrose should be added to the intravenous fluid to achieve a 2.5% to 5% dextrose concentration. The blood glucose level subsequently should be determined every 2 hours, using glucose oxidase reagent strips or a reflectance meter. Thereafter the rate of insulin infusion should be adjusted to maintain a blood glucose range of 150 to 250 mg/dL to avert hypoglycemia.

The disadvantages of the CRI insulin administration technique are the frequent need for a separate intravenous cannula, intensive care monitoring, and frequent monitoring of the blood glucose and serum potassium concentrations. If the patient initially is hypokalemic, the clinician can begin treatment with isotonic fluids containing added potassium chloride and delay insulin treatment for the first 4 to 8 hours.

Low doses of regular insulin also can be given intramuscularly. Initially, 2 U are injected into the thigh muscles of cats and dogs weighing less than 10 kg. For dogs weighing more than 10 kg, the initial dose is 0.25 U/kg BW. Subsequent hourly injections of 1 U for cats and small dogs and 0.1 U/kg BW for larger dogs are given until the blood glucose level is less than 250 mg/dL, at which time the subcutaneous route can be used to administer the insulin every 6 hours or as needed. The low doses used in this technique can be accurately measured with a special low-dose calibrated syringe.

Subcutaneous administration of regular insulin is a suitable alternative to the intravenous and intramuscular methods when intensive care monitoring is unavailable and when the patient is alert and normotensive. The initial dose is 0.5 U/kg BW, with subsequent doses given every 6 to 10 hours, depending on the need.

The patient is regarded as stable when normal hydration has been restored, blood glucose levels are below 250 mg/dL, serum and urine ketones are minimal to absent, and eating resumes. Subsequent insulin treatment can be changed to the intermediate-acting or the ultra-long-acting type.

115.5 COMPLICATIONS

The main complications of insulin treatment include hypo-glycemia, hypokalemia, cerebral edema, metabolic alkalosis, and paradoxical cerebrospinal fluid acidosis. Most of these problems are avoidable with meticulous medical management geared toward avoiding overtreatment of the patient.

115.6 HYPERGLYCEMIC HYPEROSMOLAR SYNDROME

The hyperglycemic hyperosmolar syndrome (HHS) is characterized by extreme dehydration, renal dysfunction, abnormal brain function, marked hyperglycemia, and the lack of significant ketoacidosis. The incidence of this disorder in the dog and cat has not been reported; however, isolated case reports can be found in the veterinary literature spanning the past 25 to 30 years. Underlying renal disease and a precipitating condition, such as an infection or pancreatitis, can often be found.

115.7 PATHOPHYSIOLOGY

Only the main pathophysiologic mechanisms are covered in this section. The development of HHS is attributed to three main factors: (1) decreased insulin utilization and glucose transport, (2) increased hepatic gluconeogenesis and glycogenolysis, and (3) impaired renal excretion of glucose.

Two concepts have been advanced to reasonably explain the pathophysiology of HHS. The first suggests that an insulinized liver (reflecting residual beta cell secretory activity) coexists with a diabetic periphery, resulting in inactivation of intrahepatic oxidation of incoming free fatty acids, which are directed largely along nonketogenic metabolic pathways, such as triglyceride synthesis. This could account for the absence of hyperketonemia. The second proposal suggests that enhanced gluconeogenesis occurs in the liver due to the prevailing elevated portal vein ratio of glucagon to insulin. This effect, accompanied by severe dehydration (greater than 8%), is mainly responsible for the development of marked hyperglycemia.

427

428

The decrease in consciousness and the onset of the associated neurologic abnormalities that characterize HHS result from the direct effects of hyperosmolarity-induced dehydration on the brain parenchyma.

115.8 DIAGNOSTIC EVALUATION

Several clinicopathologic abnormalities characterize the HHS. The blood glucose levels are often elevated above 800 mg/dL. Serum osmolality is elevated (normal serum osmolality is 290 to 310 mOsm/kg body water) and can be determined by the freezing point depression method with an osmometer, or it can be calculated using the following formula:

$$sOsm = 2\left(Na^{+} + K^{+}\right) + \frac{Glu}{18} + \frac{BUN}{2.8}$$

where Na^{+} is serum sodium, K^{+} is serum potassium, Glu is serum glucose, and BUN is blood urea nitrogen.

Most patients are azotemic, a condition that may be renal or prerenal in origin. The disturbances in serum electrolyte concentrations were described in the DKA section, above. It should be noted that an elevated serum sodium level during severe hyperglycemia can be explained only by significant plasma volume contraction caused by large water losses associated with hypotonic urine excretion.

115.9 TREATMENT

The main treatment objectives with HHS include reestablishment of normal hydration and adequate urine output; judicious use of insulin to avoid a precipitous decline in blood glucose levels; and ample potassium supplementation to make up the total body potassium deficit. Treatment techniques were described in the previous

section. The regular insulin dosage requirements for the hyperglycemic hyperosmolar diabetic are oftentimes less than those needed to treat diabetic ketoacidosis, but the technique for delivery is the same.

The diabetic ketoacidotic and hyperglycemic hyperosmolar syndromes pose noteworthy challenges to the practicing clinician. A sound understanding of the underlying pathophysiology, along with logical and timely therapeutic intervention, can usually lead to a remarkably optimistic outcome.

116 CHAPTER • 116 Gastrointestinal Emergencies

Elke Rudloff

Rebecca Kirby

Shock, dehydration, collapse, acute pain, electrolyte imbalances, respiratory distress, and cardiac arrhythmias are potential life-threatening consequences of gastrointestinal (GI) emergencies. The history, physical examination findings, and clinical signs attributed to the GI tract (e.g., vomiting, diarrhea, abdominal pain or distention) direct the investigation for either primary GI disease or pathology in other organs that manifests with GI signs.

Primary pathology involving the GI tract (i.e., the esophagus, stomach, small intestines, large intestines, cecum, rectum, and/or anus) can be a result of distention, inflammation, obstruction, hypoxia, and/or ischemia of affected GI tissues (Table 116-1).

Inflammatory mediators are released locally, causing local arteriolar and venous dilatation and increased capillary permeability. Severe inflammation results in loss of blood, fluids, electrolytes, and proteins from the capillaries into the GI tract (third body fluid spacing). Distension or inflammation of the GI tract can cause peripheral receptor stimulation of the vomiting center in the brain stem (Figure 116-1). Alterations in GI motility, secretory function, or permeability can result in diarrhea. Further increased vagal tone, aspiration pneumonia, bacterial translocation, and malnutrition are life-threatening consequences of vomiting and diarrhea.

Gastrointestinal signs can occur secondary to disease of other organs or to systemic diseases (see Table 116-1). Stimulation of receptors associated with the vomiting center and chemoreceptor trigger zone, as well as stimulation of peripheral GI receptors, can be caused by other organ inflammation or distention, circulating and ingested drugs or toxins, and central nervous system pathology (see Figure 116-1). Alterations in nerve conduction and smooth muscle action as a result of toxins and electrolyte or acid-base imbalances may also affect GI function.

The systemic consequences of vomiting and diarrhea are similar whether the cause is a primary or a secondary GI emergency. The animal must be rapidly assessed for life-threatening complications (primary survey) and rapidly resuscitated. Once the patient has been stabilized, diagnostic tests are performed to determine the underlying cause. One of the key immediate diagnostic goals is to determine whether the underlying pathology requires emergency surgical intervention. Careful monitoring is required during treatment and recovery.

116.1 PRIMARY SURVEY

The primary survey is a rapid evaluation of the patient's history and physical parameters to detect life-threatening complications that require immediate attention. The history may reveal evidence of vomiting, diarrhea, abdominal pain or distension, collapse, or respiratory distress. Airway, breathing, and circulation are rapidly assessed. Upper airway obstruction from aspiration of gastric contents can manifest with labored, loud breathing, heard without the aid of a stethoscope, and cyanosis. When aspiration pneumonia causes lung parenchymal pathology, physical evidence of a labored, synchronous breathing pattern with moist or harsh lung sounds may be heard on lung auscultation.

Figure 116-1 Vomiting Reflex and Antiemetics. Receptors located in the vomiting center and chemoreceptor-trigger zone (CRTZ) in the brain stem can be triggered by sensory and chemical input from multiple sources. Targeting the different neurotransmitters is the basis of anti-emetic therapy. Specific anti-emetic therapy should be selected based on the most likely mechanism initiating the stimulus to vomit. a-D_2 Dopaminergic antagonist Metoclopromide (0.2-0.4 mg/kg SQ q6-8h or followed by a 1.0-2.0 mg/kg/day IV by constant rate infusion) b-5-HT_3 Serotoninergic antagonists Ondansetron (0.1-0.2 SQ q8h, or 0.5 mg IV load then 0.5 mg/kg/hr constant rate infusion) Anzemet (0.6 mg/kg q8-12h) Metoclopramide (0.2-0.4 mg/kg SQ q6-8h or followed by a 1.0-2.0 mg/kg/day IV by constant rate infusion) c-M_1 muscarinic cholinergic antagonists Chlorpromazine (0.01-0.025 mg/kg IV (cats) q4-6h in cardiovascularly stable) Ranitidine (2 mg/kg IV q12h) d-H1/2 Histaminergic antagonist Meclizine (25 mg/kg q24h) e-Opioids Butorphanol (0.2-0.4 mg/kg IV load then 0.05-0.1 mg/kg/h by constant rate infusion) f-α_2-adrenergic antagonists Chlorpromazine (0.05 mg/kg IV (dogs) and 0.01-0.025 mg/kg IV (cats) q4-6h in cardiovascularly stable) Prochlorperazine (0.05-0.25 IV mg/kg q6-8h) g-5-HT_{1A} Serotoninergic antagonist Ondansetron (0.1-0.2 SQ q8h, or 0.5 mg IV load then 0.5 mg/kg/hr constant rate infusion) Anzemet (0.6 mg/kg q8-212h) Metoclopramide (0.2-0.4 mg/kg SQ q6-8h or followed by a 1.0-2.0 mg/kg/day IV by constant rate infusion) h-Gastrointestinal motility enhancers: 5-HT_4 serotoninergic agonists Metoclopramide (0.2-0.4 mg/kg SQ q6-8h or followed by a 1.0-2.0 mg/kg/day IV by constant rate infusion) Cisapride (0.1-0.5 mg/kg PO q8-12h (dog) 0.5-1 mg/kg PO q8h (cat)) i-Motilin agonists Erythromycin (0.5-1 mg/kg PO/IV q8h (dog)) j-Nasogastric or gastrostomy tube suctioning

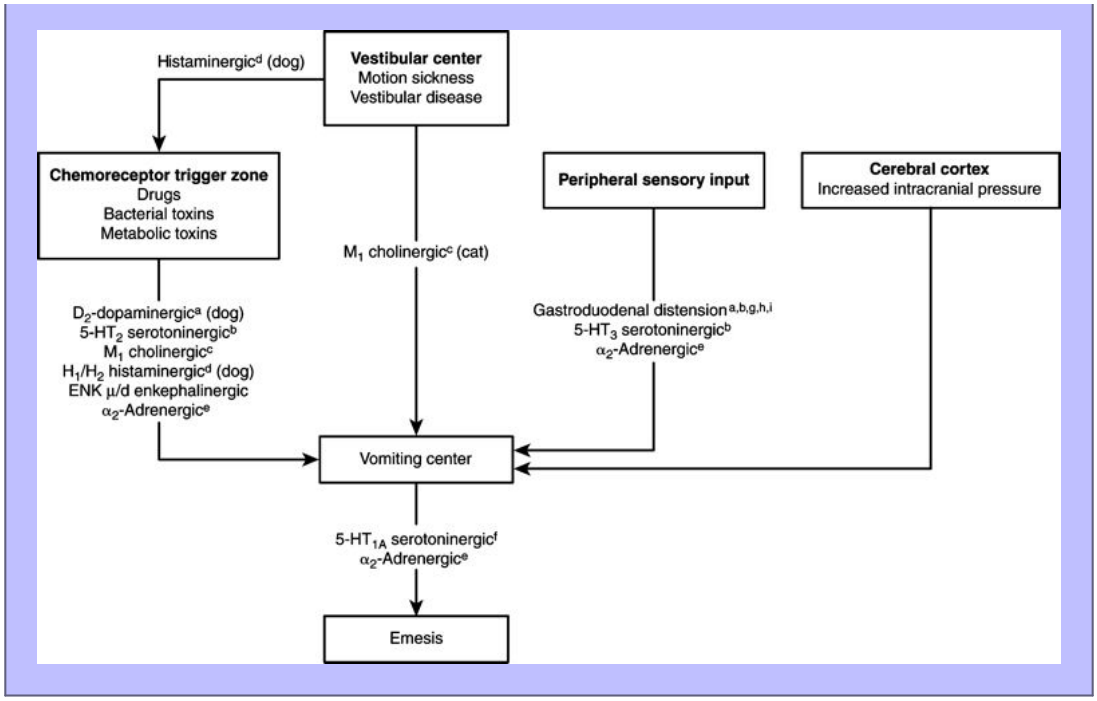

Table • 116-1 Causes of Gastrointestinal Emergencies

PRIMARY	SECONDARY
Gastrointestinal Obstruction	Organ dysfunction
Foreign body*	Pancreatic disease
Neoplasia*	Urinary tract disease
Pyloric hypertrophy	Hepatobiliary disease
Intestinal stricture*	Pyometra/metritis
Functional ileus	Adrenocortical insufficiency
Gastrointestinal inflammation	Diabetic ketoacidosis
Infection (bacterial, fungal, viral, protozoal)	Central nervous system disorder
Trauma	Increased intracranial pressure
Diffuse neoplasia	Meningoencephalitis
Adverse reaction to food	Vestibular disease
Inflammatory bowel disease	
Hemorrhagic gastroenteritis	**Systemic Disorders**
Drugs/toxins	Electrolyte disorders
Ulcerative disease*	Acid-base disorders
Lymphangiectasia	Peritonitis
	Toxemia/sepsis
Gastrointestinal Hypoxia/Ischemia	
Gastric dilatation-volvulus*	**Toxin/Drug Reaction**
Mesenteric torsion*	
Intestinal volvulus*	
Intussusception*	
Mesenteric thromboembolic disease*	

* May require requires emergency surgical intervention for correction.

Poor perfusion can result from rapid fluid loss, organ hypoxia, and endotoxemia; it is evidenced by pale mucous membranes, a prolonged capillary refill time, poor pulse quality, and tachycardia (in the dog). Dehydration is detected by dry mucous membranes, increased skin tenting and, when severe, dry corneas. An altered level of consciousness or the presence of an arrhythmia can suggest electrolyte and/or acid-base imbalances, hypoglycemia, circulating toxins, or hypoxia. Bradycardia may be a result of excessive vagal stimulation or late-stage decompensatory shock. Abdominal pain or distension or a fluid wave alerts the clinician to shock, dehydration, and serious primary GI pathology.

116.2 RESUSCITATION

Life-threatening problems are immediately resuscitated prior to further diagnostics. Any breathing abnormalities warrant flow-by oxygen administration. An intravenous catheter is placed, and analgesia is provided if pain is present. If upper airway obstruction is evident, the oropharynx is suctioned, an airway is established and oxygenation and ventilation are provided. Poor perfusion and dehydration are treated with fluid therapy, specifically crystalloid (balanced isotonic type, 10 to 20 mL/kg given intravenously) and colloid (hetastarch, 5 mL/kg given intravenously) in increments to effect. If a gastric dilatation-volvulus is suspected, careful percutaneous decompression of the stomach is recommended during fluid resuscitation to relieve pain and reduce pressure on the diaphragm and vena cava. Depressed consciousness due to hypoglycemia is treated with dextrose (0.5 g/kg given intravenously). Life-threatening bradycardia is treated with atropine (0.02 mg/kg given intravenously) and warrants rapid assessment of the serum potassium level.

116.3 SECONDARY SURVEY

Once the patient's condition has been stabilized, information is obtained from a more thorough history and physical examination to determine the origin of the GI signs. Historical information should be obtained regarding the vaccination and internal parasite history, recent or chronic administration of medications (e.g., nonsteroidal or steroidal anti-inflammatory agents); changes in appetite; sudden changes or excessive fat content in the diet; access to garbage, bones, or moldy food; and the availability of string, foreign bodies, toys and balls, corncobs, socks, and other small items or toxins. Vomiting is differentiated from regurgitation. Nonproductive vomiting or retching may indicate the presence of a gastric dilatation-volvulus. Vomiting and/or diarrhea should be characterized with respect to color, consistency, and frequency (Table 116-2).

The rectal temperature can reveal fever associated with inflammation or hypothermia from poor perfusion. Digital examination demonstrates the consistency of the stool. Careful abdominal palpation can detect abdominal pathology associated with organ distension, thickening, masses, foreign body (FB), free fluid, or fluid in the bowel. Physical signs that increase the possibility of emergency surgical intervention include: gas distention of the stomach or bowel; nonresponsive shock with evidence of intra-abdominal pathology; progressive abdominal distension; palpation of intestinal plication or a painful mass or FB; and persistent, severe vomiting unresponsive to therapeutic intervention.

116.4 TESTS

Blood, urine, and fecal samples are collected and evaluated. An immediate data base (packed cell volume, total protein, blood glucose, electrolyte panel, acid-base panel, blood urea nitrogen, platelet estimate, and activated clotting time) may be useful in detecting the presence of hemorrhage, a coagulopathy, protein depletion, hypoglycemia (supporting sepsis), hypoxemia, or a gastric outflow obstruction (hypochloremia with a metabolic alkalosis). In addition, a complete blood count, serum biochemistry profile (including amylase and lipase),

microscopic fecal examination, parvoviral fecal antigen test (when indicated), fecal cultures, urinalysis, and coagulation profile may aid in the determination of the underlying cause and whether secondary complications or additional organ dysfunction exists. Hyperphosphatemia is not unexpected with intestinal ischemia or severe inflammation. Specific diagnostic tests to identify secondary GI disease are performed as indicated (e.g., adrenocorticotropic hormone [ACTH] stimulation, preprandial and postprandial bile acids).

Two-view abdominal radiography (Table 116-3), as well as abdominal ultrasonography, may help identify the cause of the GI signs. A lateral thoracic radiograph may show a gas-dilated esophagus indicative of megaesophagus. When the pathology is likely intra-abdominal and the definitive cause cannot be determined by radiographs or ultrasound, abdominal paracentesis and/or diagnostic peritoneal lavage are indicated (see Chapter 72). Emergency surgical intervention becomes part of the diagnostic and therapeutic plan when primary GI pathology is suspected to be associated with ischemia, severe ongoing hemorrhage, or sepsis or when a diagnosis is lacking in a dog or cat whose condition is deteriorating.

116.5 MEDICAL INTERVENTION

Fluid therapy is adjusted to meet ongoing fluid, electrolyte, and acid-base abnormalities. Definitive treatment of the underlying pathology is initiated as soon as possible. When GI integrity is compromised, injectable antibiotics are administered against gram-positive, gram-negative, and anaerobic bacteria that translocate from the bowel into the bloodstream. Cefazolin (20 mg/kg given intravenously [IV] every 8 hours), in addition to metronidazole (10 mg/kg given via slow IV every 8 hours), can provide broad-spectrum coverage. Signs of pain are treated with opioid drugs (for mild pain: butorphanol, 0.4 mg/kg given intravenously, followed by a constantrate infusion of 0.1 mg/kg/hour; for moderate pain: hydromorphone, 0.1 to 0.2 mg/kg given intravenously every 4 to 6 hours). Analgesia can be augmented with concurrent administration of antianxiolytic and sedative medication (e.g., diazepam, 0.5 mg/kg given intravenously).

The selection of antiemetic agents is based on the likely mechanisms of vomiting (see Figure 116-1). Motility inhibitors (e.g., centrine) are not used as antiemetics/antidiarrheals because they reduce GI motility, which allows toxins to accumulate, and they affect nutrient delivery and absorption. A nasogastric tube allows for continued gastric decompression, cold water lavage for severe intragastric hemorrhage, and trickle flow feeding of the gastric mucosa. Promotility agents are administered only after GI obstruction has been ruled out.

430

When esophageal or gastric ulceration is suspected, H_2-blockers (cimetidine, 4 mg/kg given intravenously every 6 to 8 hours, or ranitidine, 2 to 2.5 mg/kg given every 12 hours IV) or H-pump inhibitors (omeprazole, 0.7 mg/kg up to 20 mg given orally every 24 hours) are administered to reduce acid secretion and reflux and promote mucosal healing. Liquid sucralfate (0.5 to 1 g given orally every 4 to 8 hours) is administered to protect the area of ulceration once vomiting has been controlled.

432

Table • 116-2 Character and Origin of Vomiting and Diarrhea

CHARACTER OF VOMIT OR VOMITING EPISODE	LESION	DIFFERENTIAL CAUSES
Occurs shortly after eating	Gastric inflammation	Gastric ulceration
	Gastric obstruction	Foreign body (FB)
		Toxin ingestion
		Infection
Large amounts of undigested food up to 6 hours postprandial	True vomiting: Pyloric outflow obstruction	Pyloric hypertrophy
		Pyloric mass
	Gastric atony	Foreign body
		Electrolyte imbalance
		Megaesophagus
	Regurgitation: Esophageal outflow obstruction	Esophagitis
		Esophageal FB/mass/stricture
		Persistent right aortic arch
		Hiatal hernia
Projectile vomiting	Pyloric or upper duodenal outflow obstruction	Pyloric hypertrophy
	Upper duodenal ileus	Mass
		Foreign body
		Pancreatitis
		Infiltrative bowel disease
Blood in vomit in the absence of nasal or oral disease	Esophageal hemorrhage	Ulceration
	Gastric hemorrhage	Coagulopathy
Streaks of blood	Duodenal hemorrhage	Severe inflammation
	Gastric mucosal damage	Persistent vomiting
White or mucoid fluid	Gastric fluid	Gastritis
	Swallowed saliva from true regurgitation	Megaesophagus
		Esophagitis
		Gastric dilatation-volvulus
		Gastric outflow obstruction
Yellow	Gastric fluid	Gastritis
		Foreign body
Green	Upper duodenum	Duodenal ileus/obstruction
Fetid brown fluid	Lower duodenum	Pancreatitis
	Jejunum	Intestinal obstruction
CHARACTER OF DIARRHEA	**LESIONS**	**DIFFERENTIAL CAUSES**
Watery	Small bowel inflammation	Infectious disease
		Partial small intestinal obstruction
		Pancreatitis
		Toxin/drug reaction
Mucoid	Large bowel inflammation	Infectious disease
		Partial large intestinal obstruction
		Toxin/drug reaction
Presence of digested blood (black stool) in the absence of nasal or oral disease	Esophageal hemorrhage	Ulceration
	Gastric hemorrhage	Coagulopathy
	Small bowel hemorrhage	Severe inflammation
		Ischemia

Presence of frank (bright red) blood	Large bowel hemorrhage	Ulceration Coagulopathy Severe inflammation Ischemia

Table • 116-3 Radiographic Changes Noted During Gastrointestinal Emergencies

RADIOGRAPHIC CHANGE	INDICATION	CAUSE
Generalized loss of radiographic detail	Intra-abdominal fluid	Ascites Peritonitis Hemorrhage
Diffuse gas dilatation of the small and large intestines	Ileus	Enteritis Mesenteric volvulus
Severe segmental gas dilatation of the small intestine	Obstruction	Foreign body Mass Mesenteric volvulus
Intestinal bunching, plication, “string of pearls”		Intussusception Linear foreign body
Severe segmental gas dilatation of the large intestine +/−colonic displacement	Colonic obstruction	Colonic torsion
Severe gas dilatation of the stomach without pyloric displacement	Gastric outflow obstruction	Foreign body Pyloric mass Pyloric hypertrophy Motility disorder
with pyloric displacement		Gastric dilatation-volvulus
Free intra-abdominal gas	Gastrointestinal (GI) rupture	Rupture of GI tract
	Infection	Growth of gas-forming bacteria Abdominal wall perforation
Radio-opacities involving the GI tract	Foreign body Mass lesion	Foreign body Neoplasia
Duodenal loop sign or loss of contrast in right upper abdominal quadrant	Duodenal ileus Focal inflammation	Pancreatitis

116.6 SURGICAL INTERVENTION

When emergency surgery is indicated, rapid stabilization of perfusion and hydration is optimal prior to anesthetic induction. However, stabilization may be difficult to achieve with significant ongoing large-volume fluid loss, organ ischemia (gastric or intestinal volvulus/torsion, intussusception, necrosis), or uncontrollable hemorrhage. Rapid induction of anesthesia using injectable anesthetics is recommended, because ventilation capabilities may be impaired with significant abdominal distension, aspiration pneumonia, or analgesic medication. Oropharyngeal and esophageal suctioning may be required if gastric fluid has refluxed.

Surgical intervention for acute GI emergencies may require the use of specific equipment and access to a GI stapling device to reduce the surgical time. Clinicians are referred to surgical texts for detailed surgical techniques for specific GI problems.

Gastric dilatation-volvulus requires decompression, derotation, and gastropexy. Gastric necrosis requires resection of compromised tissue. If a gastric FB is palpated or gastric ulcers are present, a gastrotomy is performed.

Ulcerative mucosal lesions are resected and submitted for histopathologic evaluation. When a GI foreign body is present, an attempt can be made to gently pull it from the intestines and out through the gastrotomy site. If resistance is felt, the FB is transected at the level of the pylorus and an attempt is made to massage the remaining FB through the intestines to the distal colon, where it can be removed by means of a digital rectal examination. When a linear FB is present, the gastric portion is cut and the remaining portion is sutured to a red rubber feeding tube, which can be massaged out through the colon. If the FB cannot be milked through the intestines into the distal colon, one or more enterotomies may be required to remove the object.

Ischemic or perforated bowel requires debridement or resection prior to closure. The most difficult regions requiring resection are the descending duodenal flexure (where the duodenum is fixed to the parietal peritoneum) and the ileocecal region (where various vascular supplies feed the region). When multiple ischemic sites in proximity are discovered, en bloc resection may prove more efficient and pose less risk of complications. Either simple interrupted or continuous closure can be performed, provided there is good apposition and minimal restriction of blood flow. GI stapling can also be used for rapid anastomosis.

Placement of a nasogastric, nasoesophageal, esophagostomy, gastric, or jejunal feeding tube is considered if injury to the GI tract is significant or if a prolonged time to voluntary oral nutrition (longer than 2 days) is expected. A gastrostomy tube can help maintain gastric decompression when motility disorders are present. When gastric or proximal intestinal tract dysfunction or procedures are a factor (e.g., pancreatitis, peritonitis, Billroth procedures), placement of a jejunostomy tube allows immediate initiation of enteral feeding. The intra-abdominal tubes are placed prior to closure. 432 433

When bowel or peritoneal perforation has occurred, a decision must be made regarding open abdominal drainage or the placement of drains. If the peritoneal wall and serosal surfaces appear only mildly hyperemic and the repair is considered curative, copious saline lavage and suctioning may be all that is required. If inflammation of the peritoneal wall or serosal surfaces is localized to the surgical site, placement of an abdominal suction drain in the affected area may be of benefit. Open abdominal drainage is indicated with generalized abdominal contamination or inflammation or when re-examination of the surgical sites is desired.

If there is no nonresectable pathology of any organ, multiple biopsies are obtained. Tissue samples should be obtained from the liver, stomach, duodenum, jejunum, and mesenteric lymph nodes. Fluid from the duodenum is evaluated for *Giardia* organisms. Samples of the spleen, pancreas, and kidney, as well as fluid from the gallbladder and urinary bladder, are taken for histopathologic evaluation and are cultured at the discretion of the surgeon. Intensive care and monitoring are required during medical and postoperative treatment of GI emergencies.

116.7 RECOVERY

An organized, systemic approach is required during the recovery phase of the GI emergency. The *Rule of 20* provides a check list of critical parameters that must be monitored and treated for an optimal outcome (Box 116-1).

116.7.1 Box • 116-1 Rule of 20

Monitoring and treatment of the following critical parameters help ensure the best outcome for the recovery phase of a gastrointestinal emergency.

Fluid balance

Colloid osmotic pressure

Serum albumin

Blood pressure

Heart rate and rhythm

Electrolytes and acid/base balance

Oxygenation and ventilation

White blood cell count, immunity and antibiotic therapy

Red blood cell and hemoglobin concentration

Mentation

Drug dosages and interactions

Liver function and drug metabolism

GI motility and integrity

Nutrition

Renal function

Coagulation

Wound care

Nursing care

Body temperature

Pain control

117 CHAPTER • 117 Global Approach to the Trauma Patient

Kenneth J. Drobatz

***T**rauma* is defined as a "wound or injury" caused by numerous "accidents." The severity may range from mild to fatal. Trauma may affect only one organ system or multiple organ systems, either directly or indirectly. Therefore a global and thorough approach is required to improve survival and decrease morbidity in traumatized dogs and cats. The initial approach to the critically ill trauma patient often makes the difference in the eventual outcome. The veterinary staff should be well versed in the evaluation and therapy of a traumatized pet. The initial trauma assessment involves a primary survey that includes assessment of tissue oxygen delivery (respiratory and cardiovascular systems), the central nervous system, and the urinary system. The primary survey is followed by a secondary survey that involves a complete examination of all other systems.

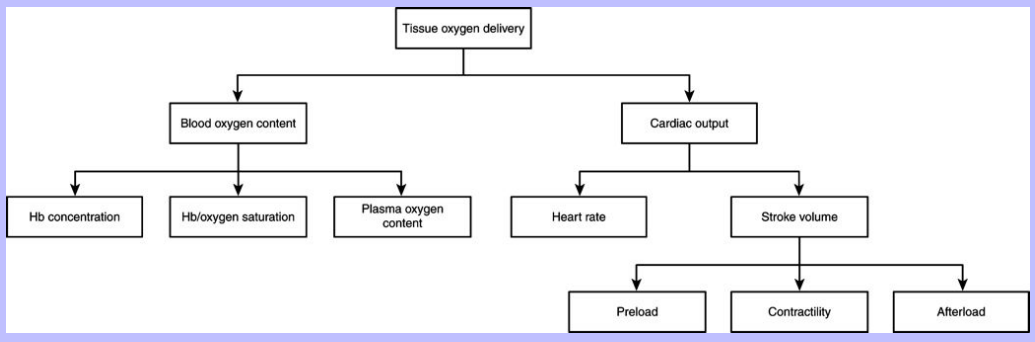
117.1 PRIMARY SURVEY

The first goal with a critically injured trauma patient is to optimize oxygen delivery to the tissues. All assessments and therapeutics are oriented toward this goal in the initial approach and resuscitation. Emphasis on early detection and aggressive reversal of impaired tissue perfusion or oxygen delivery improves survival and minimizes multiorgan dysfunction. Oxygen delivery depends on the blood oxygen content and tissue perfusion (Figure 117-1).

117.2 BLOOD OXYGEN CONTENT

Maintaining oxygen saturation of hemoglobin through assessment and treatment of respiratory abnormalities is one of the first goals of the critical care team in maintaining oxygen delivery. Pale, cyanotic, or gray mucous membranes; signs of respiratory distress, such as increased respiratory rate and effort, extended head and neck, and open mouth breathing; and loud upper airway sounds and abnormal or diminished breath sounds on auscultation are all potential indicators of inadequate oxygen saturation of hemoglobin. More objective assessments of the oxygenation of blood include pulse oximetry and arterial blood gas analysis. Initially, supplemental oxygen should be provided to any critically ill traumatized animal until it is proved that oxygen supplementation is not necessary.

Figure 117-1 Determinants of tissue oxygen delivery.

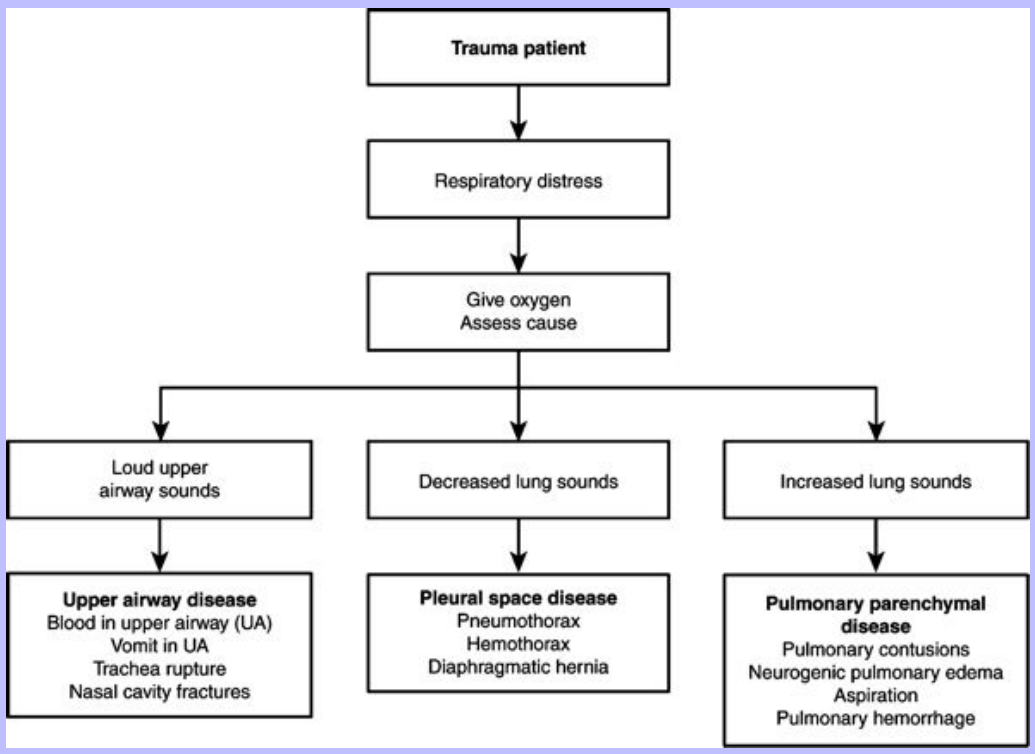


A variety of conditions associated with trauma can result in respiratory distress and decreased oxygenation of hemoglobin (Figure 117-2; also see Thoracic Trauma; Chapter 126), but the most common are pneumothorax and pulmonary contusions. In animals suspected of having pleural space disease (decreased lung sounds with signs of respiratory distress), thoracocentesis should be performed even before thoracic radiographs are taken. If done correctly, the benefits far outweigh the risks (see Thoracic and Pericardial Taps and Drains). Tension pneumothorax is rare but is an acute, life-threatening pleural space abnormality. It is characterized by extreme respiratory distress, poor tissue perfusion and, rarely, a "barrel chest" appearance. Rapid thoracocentesis is immediately indicated. A small incision in the intercostal space may release the air more quickly in animals in whom death or collapse is imminent.

Increased bronchovesicular sounds in a traumatized animal are commonly a result of pulmonary contusions. Pulmonary contusions often worsen before they improve. Intravenous fluid therapy for other conditions should be given with caution in these dogs and cats. There is no specific therapy for pulmonary contusions. Supportive care, with oxygen supplementation and pain relief, is the mainstay of treatment. Most dogs and cats with pulmonary contusions begin to improve 24 to 36 hours after the initial insult (see Thoracic Trauma; Chapter 126).

Other respiratory conditions include open chest wounds, flail chest, and rib fractures. The open chest wound should be covered and sealed as soon as possible. Once that has been done, the closed pneumothorax should be resolved by thoracocentesis. Treatment of an animal with a flail chest or rib fractures primarily involves oxygen supplementation and pain management. Surgical repair is rarely necessary.

Figure 117-2 Causes of respiratory distress in a trauma patient.



Neurogenic pulmonary edema occurs rarely but is most often associated with severe head trauma. The pulmonary edema can range from mild to severe enough to require mechanical ventilation. Most of these cases are managed successfully with supportive care, such as oxygen supplementation and judicious diuretic therapy. Generally, respiratory problems in animals with neurogenic pulmonary edema caused by head trauma improve substantially within 48 hours, or the animal dies of severe respiratory compromise.

An adequate amount of hemoglobin in the vascular space is essential to maintenance of tissue oxygen delivery. A decreased hemoglobin content severely limits the oxygen-carrying capacity of the blood and can contribute to decreased tissue oxygen delivery. The packed cell volume (PCV) provides the most rapid estimate of the hemoglobin concentration in a traumatized dog or cat, but it should be interpreted in conjunction with assessment of the vascular volume status (see Tissue Perfusion, below) to get a complete assessment of the total hemoglobin content of the vascular space. Acute blood loss often is not reflected by the initial PCV measurement because of splenic contraction in the dog and the length of time it takes for interstitial fluid to shift into the vascular space to dilute the PCV. Initial total solids (TS) and serial measurements of the PCV and TS as intravenous fluid is administered are more sensitive indicators of acute blood loss. There is no specific PCV at or below which transfusion is required. Transfusion therapy should be based on whether the animal is affected by the decreased hemoglobin content, which is indicated by clinical signs such as pale mucous membranes, tachycardia, tachypnea, bounding or weak pulses, depressed mentation, or cardiac arrhythmias. As with any animal in critical condition, it is best to anticipate and treat problems before they cause physiologic compromise. For example, if the PCV is dropping rapidly, it is best to start a blood transfusion or administer hemoglobin solutions before the hemoglobin content drops to a life-threatening level.

435

436

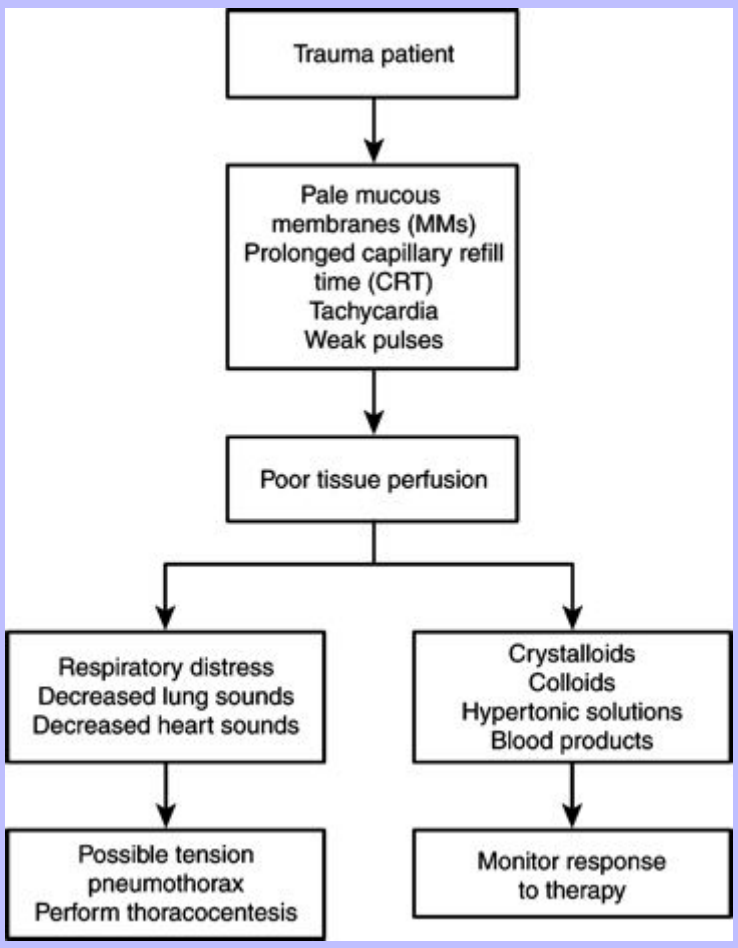
117.3 TISSUE PERFUSION

Physical assessments of tissue perfusion on the first examination include mucous membrane color, capillary refill time, and pulse rate and quality (Figure 117-3). The arterial blood pressure should be measured directly or indirectly by Doppler or oscillometric techniques when possible. The most common clinical signs indicative of poor tissue perfusion are pale or gray mucous membranes, a prolonged capillary refill time, a rapid heart rate, and weak pulses. The most common cause of poor tissue perfusion after a traumatic event is hypovolemia secondary to hemorrhage.

Administration of a balanced electrolyte solution at a rate of 90 mL/kg body weight/hour in the dog (40 to 60 mL/kg body weight/hour in the cat) is indicated with physical evidence of poor tissue perfusion. Two separate, large-bore, intravenous catheters may be required in large dogs (i.e., body weight exceeding 20 to 30 kg). Mucous membrane color, capillary refill time, pulse quality, heart rate, and blood pressure (if available) should be assessed continuously and the intravenous fluid rate adjusted as perfusion parameters improve or worsen. In most uncomplicated situations, improvement in tissue perfusion often is seen by the time one half of a vascular volume of fluid (45 mL/kg in the dog, 20 to 30 mL/kg in the cat) has been administered.

If clinical perfusion parameters or the blood pressure has not significantly improved after this volume of fluid has been administered, an investigation into causes of nonresponsive cardiovascular shock should be pursued. Such causes include ongoing intravascular volume loss (most commonly due to ongoing hemorrhage) or, less commonly, cardiogenic causes, such as arrhythmias, pericardial effusion, myocardial depression or failure, electrolyte abnormalities, decreased venous return (e.g., tension pneumothorax), or ischemic organs. The most common location of substantial hemorrhage that can lead to hypovolemia is the peritoneal space. Less common locations are the pleural space and retroperitoneal space, external hemorrhage, and hemorrhage into the muscles surrounding the femur.

Figure 117-3 Assessment of tissue perfusion.



Abdominal binding may help control ongoing intra-abdominal hemorrhage (see Abdominal Trauma). However, this is no substitute for adequate intravascular volume supplementation. In human beings, some physicians advocate delayed resuscitation (see Abdominal Trauma). In animals with severe hemorrhage, the fluid of choice is whole blood, packed red blood cells and plasma, hemoglobin substitutes (e.g., Oxyglobin), and/or colloid supplementation, such as hydroxyethyl starch or dextran 70 (see Crystalloid and Colloid Therapy; Chapter 114). Hypertonic solutions can be considered after head trauma if the dog or cat is hypovolemic (see Traumatic Brain Injury; Chapter 113) or if the animal is in severe hypovolemic shock and may die before an adequate amount of balanced electrolyte solution can be administered (see Chapter 124).

Traumatized animals are physiologically dynamic and should be continuously monitored until physiologic parameters are stable. Close monitoring of cardiovascular and respiratory trends allows early detection of problems, before they become life-threatening.

117.4 CENTRAL NERVOUS SYSTEM AND URINARY TRACT

The central nervous system (CNS) (brain and spinal cord) and the renal system are two other organ systems that should be assessed and supported as priorities. Compromise of either of these systems can result in irreversible damage. After the initial assessment and treatment of the cardiovascular and respiratory systems, it is important that the clinician do a thorough neurologic examination, including assessment of mentation and of cranial nerve and spinal cord function, to establish a baseline for further monitoring and potential therapy. Brain dysfunction may be a result of poor oxygen delivery to the brain, direct brain tissue damage, intracranial hemorrhage, cerebral edema, ischemia, and/or increased intracranial pressure. Therapeutic considerations with head trauma and brain dysfunction include optimization of tissue perfusion, administration of mannitol (0.5 g/kg given intravenously), mild elevation of the head (avoiding flexion of the neck and occlusion of the jugular veins), hyperventilation, and maintenance of oxygenation (see Traumatic Brain Injury; Chapter 113).

Spinal cord assessment should include thorough palpation of the spine and assessment of spinal function, including voluntary motor movement, conscious proprioception, ambulation, spinal reflexes, and pain sensation.

Assessment of neurologic function should always be evaluated in light of how well the central nervous system is perfused. In most animals, head trauma is obvious. However, those with severely compromised perfusion may have severely depressed mentation, as well as diminished pain sensation. The mentation and sensation abnormalities may normalize with correction of the poor tissue perfusion.

Manifestations of urinary tract injury or dysfunction may not be immediately evident and may not be detected until after several hours of continuous monitoring. Potential renal system abnormalities include direct kidney damage (e.g., contusions, hematomas, avulsion), ureteral rupture, bladder rupture, and urethral trauma. Any animal that has been traumatized may have experienced renal system trauma. Therefore serial assessment of the blood urea nitrogen, creatinine, and serum potassium levels, as well as of urine output, should be considered. It should be remembered that animals with a ruptured urinary bladder might still urinate. Ureteral rupture may result in urine accumulation in the retroperitoneal space, a situation in which abdominocentesis fails to obtain fluid. Abdominal radiographs, abdominal ultrasound scans, and intravenous contrast studies may be necessary to diagnose ureteral rupture. If free abdominal fluid is present, it should be analyzed for the creatinine and potassium concentrations, which should be compared to the concentrations in peripheral blood. If the fluid is urine, the creatinine and potassium concentrations are higher.

436
437

117.5 SECONDARY SURVEY

After assessment of tissue oxygen delivery, CNS function, and renal function, a full physical examination should be performed. Limb function should be evaluated and should include palpation of the entire appendicular and axial skeletal system. The eyes and oropharyngeal area should be examined for evidence of trauma. The mouth should be manually opened and closed to assess for malocclusion, pain, or crepitus. A rectal examination should be performed, and attention should be paid to palpation of the pelvic canal for fractures or instability and evidence of blood in the rectum. The skin should be thoroughly examined for lacerations, abrasions, and bruising.

117.6 MONITORING

After the initial assessment, all the above systems should be monitored for at least 24 to 48 hours, despite how well the animal looks when first examined. In general, if problems are going to occur, they usually occur within this time frame. The intensity and duration of the monitoring should be proportional to the degree of compromise.

The owner should also be warned that rarely, complications may arise several days later. For example, clinical signs of a ruptured gallbladder are not often manifested until several days after the traumatic injury.

In summary, assessment of tissue oxygen delivery should be performed at presentation and treated appropriately. Assessment should also include the CNS and renal systems, as well as the musculoskeletal, cutaneous, and peripheral nervous systems. A global approach, with emphasis on the most life-threatening conditions first, optimizes the outcome.

CHAPTER • 118 Heatstroke

Roger Gfeller

Heatstroke is a syndrome of cellular damage caused by a marked increase in body temperature with loss of thermoregulatory control. This potentially fatal syndrome occurs when heat production (high ambient temperature, metabolism) overwhelms normal heat dissipation mechanisms (conduction, convection, evaporation, and radiation). Heatstroke can result in damage to nearly every body system. The degree of injury is determined by the magnitude and duration of core temperature elevation. Direct thermal injury occurs at approximately 109°F (42.8°C), resulting in enzymatic alterations and denaturation of proteins. Systemic damage has been reported in patients with *sustained* temperatures as low as 105°F (40.6°C). On the other hand, literature reports at least one case of full recovery in a patient that had a core temperature of 115.7°F (46.5°C).

Most cases of heatstroke are reported during the time of year when ambient temperatures are high and pets are not acclimated. Predisposition to heatstroke may arise from environmental factors (high temperature, high humidity, lack of water, poor ventilation), medical factors (obesity, laryngeal paralysis, upper airway obstruction, concurrent heart disease, concurrent central nervous system disease, hyperthyroidism, seizures, lack of conditioning), and variable other factors (previous episodes of heatstroke, toxins, drugs, exertion). The most common cause of heatstroke in dogs is confinement in a closed automobile, in which ambient temperatures can reach dangerously high levels in minutes. Cats are commonly affected when they get trapped in clothes dryers.

Heatstroke affects almost all systems of the body. Acute renal failure is common; it can manifest as oliguric or polyuric renal failure and can be fatal. Oliguric renal failure causes acidemia, hypokalemia, inactivation of heparin, and possibly cerebral edema. These patients are prone to volume overload and electrolyte imbalances. Polyuric renal failure causes fluid and electrolyte loss. Protein loss accompanies polyuric renal failure if the glomerulus is damaged.

Disseminated intravascular coagulation (DIC) is very common in heatstroke and may appear early or late. Activation of coagulation and fibrinolysis occurs early and is profound and sustained in heatstroke. Liver dysfunction related to heatstroke results in loss of production of active coagulation proteins.

The cardiovascular system may be in a compensatory or hyperdynamic state (high cardiac output, low systemic vascular resistance) early in the course of heatstroke. With continued hyperthermia this state progresses to the hypodynamic state, in which signs of hypotension, hypoxemia, hypoperfusion, and hypovolemic shock are manifest. Cardiac myocyte necrosis rarely causes overt heart failure, but rather initiates arrhythmias up to 36 hours after the initial insult.

Central nervous system (CNS) injury can occur as a result of: direct thermal injury, respiratory alkalosis, thrombosis, or hypoperfusion from shock. DIC and hyperthermia lead to intraparenchymal hemorrhage that can result in seizures, thus sustaining hyperthermia. Complications of CNS injury include seizures, hypoventilation, coma, respiratory arrest, and cardiac arrest. CNS dysfunction and future episodes of heat stroke may be sequelae.

The gastrointestinal tract (GIT) is exquisitely sensitive to heatstroke. Direct thermal injury damages the gastrointestinal barrier. Hypoperfusion and hypoxemia result in necrosis, death, and sloughing of the mucosa, leading to bacterial translocation. Bacterial translocation can cause sepsis and systemic inflammatory response syndrome (SIRS). Mucosal ulceration and loss of the gastrointestinal barrier leads to hemorrhage into the GIT, fluid and protein losses, and electrolyte imbalances.

Direct thermal injury and hypoxemia from hypoperfusion also damage the liver. Liver dysfunction results in loss of protein synthesis, including albumin and several coagulation factors. Complications associated with liver failure can include hypoalbuminemia, hyperammonemia, coagulopathies, icterus, and hypoglycemia. Persistent hypoglycemia or hypoalbuminemia is associated with increased mortality. Damage to the monocyte-macrophage system of the liver may result in endotoxemia and sepsis, leading to SIRS.

Heatstroke damages the muscles of the body, especially if it is the result of excessive exertion (seizures, excessive exercise without adequate training). Widespread necrosis of muscle cells results in hyperkalemia, hypocalcemia, lactic acidosis, and rhabdomyolysis. Rhabdomyolysis results in systemic release of myoglobin, which is toxic to kidney cells. Fibrinolysis is initiated by release of thromboplastin from injured myocytes. Conditions associated with muscle damage include acute renal failure, cardiac arrhythmias, DIC, pain, and hypocalcemic tetany.

Acid-base and electrolyte balances are affected by heat-stroke. Initially animals pant, which does not increase alveolar ventilation and does not affect the acid-base balance. As the core temperature increases, panting gives way to hyperventilation, resulting in respiratory alkalemia. Respiratory alkalemia is associated with hypokalemia and hypophosphatemia. Later, respiratory alkalemia gives way to metabolic acidemia as shock induces lactic acidosis. Metabolic acidemia is associated with hyperkalemia, heparin inactivation, cardiac arrhythmias, loss of peripheral vascular tone and ongoing hypotension, and decreased myocardial contractility.

Clinical signs of heatstroke are related to the systems affected and the degree of injury to those systems. Early signs include panting, hypersalivation, tachycardia, hyperemic mucous membranes with shortened capillary refill time (CRT), bounding pulses, and increased blood pressure. The patient is often excited and hyperactive. The rectal temperature is often elevated.

Signs of shock become more pronounced as the syndrome progresses. The rectal temperature may be high, normal, or low. Tachycardia is common. The mucous membranes are pale and have a prolonged CRT. Blood pressure is often low. Tachypnea and hyperventilation are noted. Dehydration (often severe) is common. Hematemesis, hematochezia, and melena accompany injury to the GIT. The pupils are commonly dilated but may be miotic if the syndrome has caused CNS damage. Altered mentation and cortical blindness have been reported. Respiratory distress with or without cyanosis may be noted later in the syndrome. Generalized petechiation, evidence of thromboembolism, and/or hemorrhage can be seen as DIC progresses. Muscle tremors, seizures, collapse, and coma often precede cardiopulmonary arrest.
